During the first year of the third strand, Christina developed independently a large number of activities to support children to understand specific mathematical concepts. In that period the exploratory plane was more a resource for ideas in the planning of her teaching. She realised her instruction through the use of multiple representations and a variety of contexts for the embodiment of the mathematical concepts. The following game that she organised in her attempt to lead the children to discover addition and subtraction as opposite operations demonstrates this approach:

"From this moment the dumb king starts. Nobody speaks. Not even me. We are going to play a game. You need to be very careful. Your eyes open! When I hit somebody's back, she speaks. Now, we start the game. I want you to tell me, using a lot of words, what I am doing."

Using the abacus, she shows ten balls, adds five and then takes away five again. This was quickly repeated several times. She then asked the children to identify the mathematical model, which described this action. Her teaching approach can be seen as "discovery" learning where she expects children to work towards her aims. Talking about her teaching in that year she believed that, "I am better this year than last year in the classroom". She justified this claim by arguing that her children had obtained better results that year although she believed that she was asking them more difficult questions. An explanation for this was that, "The children in this year worked more on written tasks so they were prepared for the tests".

It seems that Christina does not exploit children's thinking in the same way that she used to in the previous strands. Her teaching aims are more result-oriented and the activities she developed were closely related to those aims. Christina's teaching priorities were possibly driven by her feelings of success and the acceptance that she experienced in the broader school environment. However, her view about children's active involvement in the learning process was still apparent.
Reconsidering existed teaching practices

Through her engagement in the group meetings and the individual discussions with the researchers, she started to challenge the effectiveness of her approach. To illustrate this, we present below an extract from a discussion with one of the researchers towards the middle of the second year of the third strand. In this discussion, Christina asked for help to resolve a conflict she faced when her children could not reply to the following sentences:

\[ \square + 1 = 5 \text{ and } 6 = 1 + \square ; \text{ although they could solve the sentences } 1 + 5 = \square \text{ and } 1 + \{5\} = 6. \]

In the dialogue below, Ch stands for Christina and R stands for the researcher.

1. Ch: What is happening? And why?
2. R: What are we doing in cases like these? We probably try smaller numbers, change the problem...
3. Ch: You will laugh. I was thinking again of a visual solution, visual representation, you know, as usual.
4. R: Why didn't you try?
5. Ch: Because I wanted to try something different.

Line 3 indicates that Christina is aware of her tendency to use a variety of representations in her teaching. In line 5 she probably wanted to change her approach because it was inadequate for resolving the conflict. This point is further supported later on in the discussion, when she admitted that the following year she would teach that specific content differently. Four days later she came up with three different approaches to the problem. In the first she started with the equality \(6=6\), and she planned to ask the children to substitute the numbers with appropriate sums. Another idea was to use two bags, each containing 6 items. Then the children had to choose from a pile of cards with numbers and symbols, and construct sentences to represent the equality of the number of items in each bag. The third idea was to ask children to create a story about \(5 + 1 = 6\) but she rejected this immediately because she was worried that the children would give a trivial word problem from the textbook. In this proposed planning she again acknowledged the role of different representations but it seems that she allowed more space for the children to act. Christina had probably arrived at a certain point where she conceptualised the activity not merely as a means for discovery but as a starting point for mathematical constructions.

Promoting the continuing development of a teacher’s practice

The above analysis reveals that Christina formed certain views about teaching and learning mathematics during her university studies. She started building a vision of mathematics teaching different from that which she had experienced as a school student. The latter context supported her in viewing teaching as a process for exploring children’s thinking, and provided her with the opportunity to experiment with this perspective. Normal classroom constraints that a schoolteacher faces were not Christina’s main concern. So, her desire for “the children to learn” could be fulfilled in this “ideal” situation.
By becoming a school teacher she started to experience the disparity between vision and daily classroom reality (Goldsmith and Schifter, 1997). In this new context she felt responsible for children’s learning; she wanted to be approved by the head of the school, the parents and her colleagues. At the same time she wanted to develop further her university experience, although this experience was in contrast to the culture of the broader school environment. A way to satisfy all these expectations was to derive elements from both contexts and move in parallel directions. On the one side, she adapted to “established” school teaching practices but, on the other, she was choosing open activities from time to time, just to get children involved and explore their thinking. However, we did not discern many moments in her teaching behaviour where she could integrate these two practices. It is possible that Christina could have found her own way to modify her teaching behaviour in order to reach an acceptable level of harmony with her view about teaching, which was developed at the university. This assumption has been supported in a way by the work of Chapman (2001) who demonstrated that teachers’ primary beliefs about mathematics remained unchanged while teaching behaviour was adjusted to those beliefs. However, Cooney (1985) found that a beginning teacher lost his belief that he could try a problem-solving approach in his teaching.

It is difficult to foresee what Christina would have done if she had been operating in the same school context without any further connection to her pre-service mathematics education. In the second and third year of teaching, Christina experienced situations similar to those she had had at the university such as group meetings, reading of research papers, and discussions on the use of materials and about classroom incidents, with her colleagues and with one of the researchers. In these situations the issues discussed emerged from the actual mathematics teaching classroom, yet in some cases, Christina recalled events from the university course that she found to be relevant to those issues. In that period, it seems that Christina reformulated her teaching practice by viewing learning as a process whereby the children discover certain mathematical relations. In this way, she managed to associate the exploratory teaching approach with the instructive but she limited the opportunities for the children to develop their mathematical thinking. The mutual rapport that was developed between her and one of the researchers possibly helped her to reflect on her action and to identify the limitations of her teaching approach.

Concluding Remarks

The seeds for change can and should be planted early in teachers’ professional lives, taking advantage of the social contexts in which teachers learn to teach (Cooney and Shealy, 1997, p.92).

The above quotation implies that, especially for the beginning teacher, there is a need for support and feedback in order to foster the continuing development of teaching practices. In Greece, the school context does not promote approaches other than those characterised as “traditional”. So, there is a big gap between what the teacher has experienced at University and what he/she faces in the school environment (Potari, 2001). The school environment constrains rather than supports the beginning
teacher to act in accordance with his/her views. The first findings of this study indicate how long and strenuous the process of a teacher’s development is and, more specifically, how her view of children’s learning was expressed in her teaching behaviour while working in different contexts. Further analysis of the data could reveal other aspects of this process of adaptation.

It is clear to every high school student that the mean of two values is half their sum. Is it also clear that the mean is their point of balance? Not quite. In the course of studying pattern exploration disciplines of high school computer science majors, we noticed that a non-negligible number of students lack a clear view of the mean as the point of balance. The students were asked to design a computer program that inputs \( N \), a positive integer, and outputs all the positive integer pairs \( \langle x, y \rangle \) which average \( N/2 \). The majority of the students demonstrated limited orientation with patterns of the mean. In particular, a considerable number of them designed programs that “search for each \( x \) the \( y \)'s which average \( N/2 \) with \( x \)”. The student solutions, together with representative interviews, reflect diverse levels of mathematical insight and pattern recognition.

INTRODUCTION

One of the fundamental concepts in basic statistics, as well as everyday life, is that of the mean (average). The mean is introduced in primary school and invoked in numerous occasions thereafter, in mathematics, science, and other domains. The computation procedure of the mean is almost as fluent as the fundamental arithmetic operations of addition and division. However, the conceptual understanding of the mean is far less assimilated. In this paper we display a study on the limited conceptual understanding of the mean with respect to its notion as the center point of balance.

The lack of conceptual understanding of the mean was studied during the last two decades in several respects and for different group ages. Pollatsek, Lima, and Well (1981) reported on difficulties in conceptual understanding of the weighted mean among college students. Mevarech (1983) expanded their study and showed that non-mathematically oriented students “misconceive a set of given means under simple mean computation as … satisfying the four properties of closure, associativity, identity, and inverse” (1983, p. 425).

Strauss and Bichler (1988) studied development aspects of understanding seven mean properties among young students of the ages 8-14. They found that the property of ‘average as representative’ was difficult for students to see. Mokros and Russell (1995) focused in mathematical representativeness of the mean, and identified five basic approaches among 4th, 6th, and 8th graders, and named them from the less
insightful to the more insightful - average as ‘mode’, ‘algorithm’, ‘reasonable’, ‘midpoint’, and ‘mathematical point of balance’. Cai (1998) noticed that a significant number of 6th graders were unable to correctly solve a contextualized average problem. Those who used algebraic representations performed better than others.

These studies demonstrated the gap between procedural and conceptual knowledge of the mean. While students are easily able to calculate the mean by straightforward sum-and-divide, many lack understanding of its meaning and have difficulties in performing insightful mean-related tasks. The gap between procedural and conceptual knowledge is apparent in a variety of mathematical domains, as discussed by Hiebert and Lefevre (1986), Bin-Ali and Tall (1996), and others. The lack of conceptual knowledge is strongly related to indications of the need for elaborating pattern exploration in mathematics (e.g., Schoenfeld 1992).

This paper extends the view on conceptual understanding of the mean, together with the formulation of arithmetic expressions. In addition, it illustrates the important role of pattern exploration and exploitation. Different from previous studies, in which students where questioned on particular values of elements, our study focuses on general formulation of tuples (pairs) of elements with the same mean. Its core emphasis is on conceptual understanding and arithmetic expression of the mean as the center point of balance. The participants were high school students, rather than college or elementary school students in the earlier studies.

The study was part of a broader inquiry into mathematical pattern exploration of high school computer science majors in solving algorithmic tasks. The broader study involved a series of short algorithmic tasks with emphasis on efficient algorithmic solutions. Although we expected some inefficient student solutions, we were surprised to see the extent of inefficiency and the lack of pattern recognition regarding the concept of the mean. As a result, we decided to carefully examine, analyze, and display the solutions.

In the next section we present the methodology used, involving both qualitative and quantitative evaluations. In the section that follows we display the results and focus on several solution categories that reflect gradual levels of mathematical insight. In the last section we discuss the results, relate them to previous work, and note on tying statistical concepts to pattern exploration and exploitation.

METHODOLOGY

Participants

The study involved 82 computer science majors (36 10th graders and 46 11th graders), with sound mathematical background. The students were selected from four different schools in different geographic locations in the country. All students had basic programming background, and were particularly aware of the fundamental concepts of correctness and efficiency of algorithms.
Task

In the broad study, the students were asked to design algorithmic solutions to four algorithmic tasks aimed at examining their mathematical pattern exploration. The students were explicitly told that they should write efficient solutions based on mathematical patterns they identify. We let each student write the solutions in his/her most convenient language – either algorithmic pseudo-code, or one of the programming languages Pascal or C. The mean-related algorithmic task was:

**Same-Average-Pairs:**

*Design* an algorithm/computer-program which inputs a positive integer N and outputs all the pairs \(<x,y>\) of positive integers which average N/2.

*Write* a short explanation of your underlying idea.

*Note:* As our focus was on mathematical pattern exploration, we told students that each of them can choose, according to his/her programming convenience, whether to consider pairs of the form \(<i,j>\) and \(<j,i>\) distinct. They could choose to output either both pairs or only one of them.

Our purpose in posing this task was to examine whether students view the mean as the center of balance of all pairs with the same average, and whether they can express it arithmetically.

Procedure

The students were given up to 25 minutes to solve the above task (as part of 90 minutes provided for all four tasks). One source of our data was the 82 solution sheets we obtained from the students, with algorithms and descriptions of their underlying ideas. In addition, nine of the students were asked to elaborate on their solutions in individual interviews.

RESULTS

The solutions to the task varied considerably. Only one third of the students demonstrated a clear view of the mean as the center point of balance. The rest of the students showed limited degrees of insight. We refer to the different degrees of insight through five patterns that characterize the task output:

- **element range** – the range of the output elements is 0..N.
- **unique pairing** – no range element has more than one pairing element.
- **pair symmetry** – the two elements of an output pair are located on two different ‘sides’ of the mean, at the same distance from it.
- **pair arithmetic** – one way of arithmetically expressing pair values in the task is: \(<N/2-d,N/2+d>\). Another way is: \(<d,N-d>\). Since we are interested in integer values, the second expression is more convenient to utilize.
pair adjacency – adjacency in the sequence of ‘same-mean pairs’ corresponds to adjacency on the line of natural numbers.

We divided the student solutions to four different categories based on their insight of the above patterns.

- **Clear-View**: Solutions that reflect clear view of the five patterns.
- **Incomplete-View**: Solutions that reflect incomplete view of the pair arithmetic and the pair adjacency patterns.
- **Search-View**: Solutions that reflect no clear view of the unique pairing, pair symmetry, pair arithmetic, and pair adjacency patterns. These solutions are based on inefficient search “for the y’s that match each x”.
- **Dim-View**: Solutions that do not reflect any clear pattern. Some of these solutions only include a search for pairs of the form <x,x> or <x,x+1>.

In what follows we describe each of the above solution categories.

### Clear-View Solutions

34% of the students (28 of the 82) provided algorithmic solutions that reflect clear view of the mean as the center point of balance of the output pairs. The code typical for these solutions was:

```plaintext
for i from 0 to N do
    write (i, N-i)
```

Those students who chose not to output both <x,y> and <y,x> bounded the “for” loop by \( \lceil N/2 \rceil \) (rather than N). This loop outputs the pairs starting from the range ends towards the mean. A couple of students output the pairs in the opposite order – from the mean towards the ends. Below are two student explanations.

**Omer:** The mean of two numbers is exactly their middle, thus if we increase the smaller by 1 and decrease the bigger by 1 we will preserve the same middle point, which is the mean.

**Nimrod:** Every two numbers have the same mean as the mean of the lowest number (of the range) plus a constant and the highest number (of the range) minus that constant; and that constant may be from one of the (range) ends until half the difference between them.

Both students explicitly expressed the patterns of pair symmetry and pair adjacency. Their algorithmic solutions expressed the additional patterns.

### Incomplete-View Solutions

18% of the students (15 of the 82) provided algorithmic solutions that reflect partial view of the mean as the center point of balance. They all noticed the element range and the unique pairing patterns. Many also had ‘a picture’ of pair symmetry. But their notions of pair arithmetic and pair adjacency were incomplete. They noticed
that each element within the range 0..N may be in at most one output pair, but they were not clearly convinced that each element will indeed be in the output. Their programs generated the relevant symmetric pairs, but checked for each pair whether its mean indeed equals N/2. One representative solution was:

```plaintext
for i from 0 to N do
    if (i+(N-i))/2=N/2 then write (i, N-i)
```

We wondered how it is that the students who provided this solution did not see that the condition in the if statement is completely unnecessary. The interview below sheds some light on that:

Interviewer: Amit, what is the idea underlying your solution?
Amit: When you take a number from the beginning and a number from the end, 0 and N, and then add and reduce 1, you get the potential pairs.

Interviewer: What do you mean by ‘potential pairs’?
Amit: 0 and N have the mean N/2, also 1 and N-1, ... as i grows you get more pairs ...

...<some additional interaction>...

Interviewer: Can you explain the condition (i+(N-i))/2=N/2 in your code?
Amit: For example, for i=0 it will be true ... then, for 1 also ... then ...???

Amit did not immediately notice the algebraic equality in the condition that he himself wrote. While he did have some notion of symmetry (<0,N>, <1,N-1>), he had a difficulty in expressing it with an arithmetic expression. He also had a vague view of the complete sequence of output pairs.

Search-View Solutions

32% of the students (26 of the 82) provided solutions which reflect a view that does not adhere to any of the patterns: unique pairing, pair symmetry, pair arithmetic, or pair adjacency. Many simply generated all the <x,y> pairs in the range 0..N (a total of (N+1)^2 pairs). Some let x be in the range 0..N/2 and y in the range N/2..N. The only pattern to which these student solutions clearly referred was element range. A common solution in this category was:

```plaintext
for i from 0 to N do
    for j from 0 to N do
        if (i+j)/2=N/2 then write (i,j)
```

From interviews with some of the students we learned that they did not have a clear picture of the output pairs, and quite a few were not sure of the unique pairing pattern. The following interviews with Kfir and Anat illustrate that.

In his solution, Kfir enumerated both i and j from 0 to N.

Interviewer: Kfir, why did you write the nested loops with i and j?
Kfir: I needed to find for each element the elements that can be paired with it.

Interviewer: Can you say something about the number of elements that may pair with a particular element?

Kfir: Well ... I has only one match, but 2 may have more ...

Interviewer: How many? For example let's say that N=100.

Kfir: Then, 1 has one match – 99; but 2 may have many ...?

Interviewer: ???

Kfir: Eh, ... 98 is one match ...<trying further>... maybe only 98? ... Yes ...

He gradually started realizing unique pairing, pair symmetry, and pair adjacency.

In a different class we interviewed Anat. Her solution included the enumeration of: i for 0 up to N/2 and j from N down to N/2+1.

Interviewer: Anat, what is the rational underlying your solution?

Anat: I divided the numbers into two groups – those from 0 to N/2 and those from N/2 to N; for each number in the first group there is a search for a match in the second group.

Interviewer: Why did you do that?

Anat: When we deal with average you cannot immediately tell both numbers; I need to loop through the 'upper' group in the order to search for corresponding matching ...

Later in the interview Mat conjectured the unique pairing and pair symmetry patterns, but she had a difficulty to formulate a proper arithmetic expression.

Dim-View Solutions

16% of the students (13 of the 82) provided solutions that reflect no clear recognition of any of the five patterns. From their solutions it was even unclear whether they noticed that the range of element pairs is 0..N. Some designed solutions that output a single pair: <N/2,N/2>, or <N/2-1,N/2+1>. The latter case shows some 'picture' of symmetry, but only with respect to one output pair. Some provided solutions in which all the pairs of the form <i,i+1> were generated and checked for the possibility of having the mean N/2.

Interviews with two students who provided solutions in this category revealed that they searched for some time to find pair examples. They mentioned rather quickly the output pair <N/2,N/2>, for the case that N is even. The case of odd N was more subtle. We posed the task of generating the pairs which to N. This assisted one of them, who noticed the similarity to the original task. Shortly after, she managed to write down relevant pairs, mentioning that "the sum question is much easier". We got this response from students of other categories as well (see next section).
DISCUSSION

The results of this study showed diverse levels of recognition and exploitation of patterns of the mean. The task posed to the students involved the formulation of a general scheme, based on the patterns common for all pairs that have the same mean. As in all the previous studies of conceptual understanding of the mean, here too, the task focused on a perspective more involved than the simple computation of sum-and-divide. The new contribution of this study stems from examining the formulation of a general expression rather than calculation of values for particular examples. In addition, the participants were high school students (rather than 4th to 8th graders or college students).

In order to properly answer the task, students had to identify and utilize the five patterns element range, unique pairing, pair symmetry, pair arithmetic, and pair adjacency. The pattern of element range is related to the property of extreme points examined by Strauss and Bichler (1988). The pattern of pair symmetry corresponds to Mokros and Russell's midpoint representation. The pattern of pair arithmetic is correlated with Cai's (1998) observation of algebraic representation.

Our division of the diverse solutions into different categories characterizes four different levels of mathematical insight with respect to conceiving the mean as the center of balance. The first, Clear-View category, includes the students who realized and efficiently exploited all the five patterns. Only one third of the students were in this category. The second, Incomplete-View category, includes about a fifth of the students, who realized the first three patterns but did not clearly see the latter two. Their solutions were still rather efficient. The third, Search-View category, includes almost a third of the students, who exploited the first pattern, but not any of the other four. Their solutions were correct, but very inefficient. The fourth, Dim-View category, includes the students with very vague insight.

We posed to the interviewed students the task of calculating all the pairs of elements which sum to N (rather than average N/2). The first, Clear-View category students instantly noticed the identity between the two tasks. Students from the other categories noticed it more gradually, and indicated that the sum task is easier (to some - "much easier") than the average task. One explanation of this phenomenon is the gap in familiarity between the notions of the sum and the mean. Apparently, conceptual understanding of the sum is more developed, even for high school students, than conceptual understanding of the mean.

Shaughenessy (1992) indicated, in his review on reflections in probability and statistics, the limited perspectives presented to students. One study that elaborates perspective diversity and conceptual understanding of the mean is that by Meyer, Browning, and Channell (1995). Their study introduces four activities for elementary and middle school students, involving concrete values. Our study suggests the need for further insight elaboration of the mean, for more mature students. General formulation, based on recognition and exploitation of patterns of the mean, as in the
task presented here, should enhance conceptual understanding as well as competence in arithmetic and algebraic representation.

The results in this study add not only to the study of statistical conceptions but also to the research on limited pattern exploration. In particular, it illuminates the need for elaborating mathematical insight in algorithmic problem solving. It is our hope that this study will encourage further elaboration of students’ pattern exploration both in statistics and algorithmics.

COMPARING REPRESENTATIONS AND REASONING IN YOUNG CHILDREN WITH TWO-YEAR COLLEGE STUDENTS

Barbara Glass  Carolyn Maher
Rutgers University  Rutgers University

Problem solving and justification of a diversified group of two-year college students was compared with approaches of younger pre-college students working on the same task. The students in this study were engaged in thoughtful mathematics. Both groups found patterns, justified that their patterns were reasonable and, utilized similar strategies for their solution and methods of justification. The findings support the importance of introducing rich problems to pre-college and college students, under particular conditions.

Students enrolled in college level mathematics are expected to have developed effective reasoning skills. Unfortunately this is often not the case. This may be explained, in part, by a history of mathematics instruction in settings that devalue thinking and focus on procedural learning. From a perspective of conceptualizing reasoning in terms of solving open-ended problems, it was of interest to learn whether two-year college students enrolled in a liberal-arts college mathematics course could be successful in providing arguments to support their reasoning in a problem-solving based curriculum.

Considerable data have been collected showing pre-college students' success in solving open ended problems, over time, under conditions that encouraged critical thinking and building arguments to support their solutions (Maher & Martino, 1996, 1997, 1998; Muter, 1999; Maher, 1998; Maher & Speiser, 1997; Kiczek & Maher, 1998; Muter & Maher, 1998). These studies with younger students raise the question if similar reasoning and justifications are achievable by liberal-arts college students within a well-implemented curriculum that includes a strand of connected problems to be solved over the course of the semester. Specifically, this paper reports on one aspect of a larger study of two-year college students enrolled in liberal arts mathematics. It will describe, in the context of combinatorics, (1) how college students solve non-routine mathematical investigations and (2) how college students’ representations and level of reasoning contrast with those of younger children from a longitudinal study engaged in the same investigations.

THEORETICAL FRAMEWORK

The growth of mathematical knowledge is the process whereby a student constructs internal representations and connects these representations to each other. Understanding is the process of making connections between different pieces of knowledge that are already internally represented or between existing internal connections and new knowledge. (Hiebert and Carpenter, 1992) Students build their understanding of
concepts by building upon previous experience, not by imitating the actions of a teacher or being told what to do. (Maher, Davis & Alston, 1991) Learners who first learn procedures without attaching meaning to them are less likely to develop well connected conceptual knowledge. When students encounter new problems they are more likely to retrieve prior knowledge that is well connected than to retrieve loosely connected information. (Hiebert and Carpenter, 1992). The students in this study were encouraged to think about their solutions to the problems that they were given, develop understanding of the mathematics and justify their answers.

BACKGROUND FOR PRE-COLLEGE STUDENT RESULTS

Researchers have documented children’s thinking as they investigate problems in the area of combinatorics to determine how they think about the problems and justify their solutions (Maher & Martino, 1996, 1998, 2000; Muter, 1999; Maher, 1998; Maher & Speiser, 1997; Kiczek & Maher, 1998; Muter & Maher, 1998; Martino, 1992). One of these problems is the Towers Problem, which invites a student to determine how many different towers of a specified height can be built when selecting from two different color cubes, and to justify that all possibilities have been found. In a Rutgers University longitudinal study, students first encountered the Towers Problem in the third grade when they worked on towers that were four tall. Researchers found that these pre-college students were able to invent strategies that they used to solve the problems. Most of the pre-college students started the Towers Problem by using guess and check methods to create towers, and check for duplicates. They then became more organized and created local organization strategies This resulted in the use of patterns such as “opposites”, two towers with the colors reversed, “cousins”, two towers that were vertical inversions, staircase patterns, and elevator patterns. They later developed global organization strategies as they realized that their local organization strategies created duplicates and could not be used to account for all possibilities (Maher & Martino, 1999, 2000; Muter, 1999; Martino, 1992). These students were also able to create convincing arguments that they had accounted for all possible combinations (Maher & Martino, 1996, 1998, 1999, 2000; Muter, 1999; Muter & Maher, 1998; Martino, 1992). The initial method of justification of many of the third and fourth grade pre-college students was to state that they could not find any more towers (Martino, 1992; Maher & Martino, 1996). For example, fourth grade Milin justified that he and his partner had found all possibilities because they had gone a long period of time without finding another one (Alston & Maher, 1993). Some of the children developed a proof by cases and others developed an inductive argument. For example, Milin started to build a proof by cases, but then developed an inductive argument when he looked at simpler cases of the Towers Problem (one-tall, two-tall and three-tall) and noticed the doubling pattern. He was able to explain how he could build up the larger towers from the smaller towers by placing either one or the other of the available colors on the top of the smaller towers
Within this same time period, fourth grade Stephanie was able to present a proof by cases for the towers that were five tall. During a small group assessment, Stephanie presented a proof by cases for towers that were three tall and Milin presented his argument by induction (Maher & Martino, 1996; Alston & Maher, 1993). About a year later, in grade five, Stephanie also developed an inductive argument (Maher & Martino, 1996).

COLLEGE STUDENTS

Data Collection and Analysis

Nine classes ranging in size from 6 to 25 students were studied from 1998 – 2000. Two groups from each class were videotaped as they worked on the Towers Problem. Following the class sessions each student was required to submit a write-up of the problem. In addition, videotaped, task based, interviews were conducted.

Eleven students, representative of the larger population were selected for a case study analysis. The criteria included student willingness to be videotaped, fully participate in regular class problem investigation sessions and participate in follow-up interviews. Videotapes from class sessions and interviews were transcribed, coded, and analyzed for methods of problem solving and justification. The written work of students was coded and analyzed. The coding schemes for problem solving strategies and methods of justification are in table 1 and table 2.

<tr>
<td>The study was conducted at a small community college in a mathematics course for liberal arts majors. Sections of the course met for two seventy-five minute classes each week or three fifty minute classes each week for fifteen weeks. The students spent approximately half of all class time working on various non-routine problems in a small group setting. The Towers Problem was given during the ninth week of the semester. Two groups from each class were videotaped as they worked on the problem. The students began by working on towers that were four cubes tall. They then were asked to consider towers that were five cubes tall. Some groups also worked with towers where three different color cubes were available.</td>

<tbody>
<tr>
<td>Most of the college students used patterns or some other form of local organization immediately and some immediately imposed a global organization scheme. One group started the problem by randomly generating towers using a build and check method. A student in the group, Jeff, soon suggested, however, that they should organize the towers that they had built by cases so that they could check more easily for missing combinations. After another pair of students, Stephanie and Tracy, built all sixteen towers using opposite pairs, they stated that they had to impose some type of organization to convince themselves that they had found all combinations. They first used staircase patterns, but rejected this because it did not account for all towers. They then arranged the towers by cases (Glass, 2001). While working on the five-tall Towers problem one student, Wesley, built his towers five tall by adding a red cube to the top of each of his towers of four and then building the opposites of these towers to find all towers with a yellow cube on top. Another student, Errol used an inductive argument that he had developed while working with towers four tall to predict that there would be</td>

</tbody>
</table>
thirty-two towers of five. He produced a list of all towers five tall on his written assignment using an inductive method (Glass, 2001).

Six of the profiled college students justified that they had found all possible towers four tall by using a cases approach. Each of these students used an elevator pattern to justify the towers with three cubes of one color and one cube of the other color. The students used a variety of methods to justify that they had found all towers with two cubes of each color (Glass, 2001). Two groups, Melinda’s group and Donna’s group justified that they had found all towers because they couldn’t find anymore. As these groups spoke to the instructor they began to organize their towers and moved toward a proof by cases. Both groups still justified that they had all towers with two of each color because they could not find anymore.

Five of the profiled college students did a proof by cases for the five-tall towers. Each of these proofs by cases referred to opposites. They also all used an elevator pattern to account for the towers with one cube of one color and four cubes of the other color. They used a variety of methods to justify that they had all towers with two cubes of one color and three cubes of the other color (Glass, 2001). One student, Wesley built his towers five tall by adding a red cube to the top of each of his towers of four. He then built the opposites of these towers to find all towers with a yellow cube on top. He justified that he had found all towers five tall with an inductive argument. He was unable at this time to extend this reasoning to predict how many towers that he would get six tall. During an interview seven weeks later, Wesley correctly extended the doubling pattern beyond the case that went from four tall to five tall. Another student, Jeff applied the fundamental counting principle to predict that there would be thirty-two towers that were five tall. After Jeff’s group had produced the thirty-two towers he used an inductive argument to show that they had found all possible towers by pairing each of the five-tall towers with the corresponding towers that were four tall. Errol, who did not wish to build the five-tall towers in class, used an inductive argument on his written assignment to justify that he had listed all the possibilities. Penny, a student in Errol’s group who was absent the day that the class worked on the Towers Problem, completed the problem at home. She invented a tree diagram strategy to produce an inductive argument for the towers four and five tall. Tim used a binary coding system to justify that he had found all possible combinations. This is the same method that tenth grade Michael from the Rutgers longitudinal study used to justify that there were thirty-two different pizzas with five available toppings (Muter, 1999).

Several groups also had time to work on the Towers Problem with three available colors. Mike’s group and Rob’s group worked on four-tall towers, while Jeff’s group worked on three-tall towers. Rob and his partners applied the inductive method that they had developed for towers with two colors to quickly solve the problem. Jeff used the fundamental counting principle to calculate the number of towers, but did not use an
inductive method to build the towers. Mike’s group divided the problem into the three problems of finding towers with two available colors and the problem of finding towers that contained all three colors. They then built all the towers in a systematic fashion.

CONCLUSIONS, IMPLICATIONS AND LIMITATIONS

The college students used many of the same strategies for solution that the pre-college students from the longitudinal study had used when they solved the same problems. However, unlike the third and fourth grade children they did not generally rely on random checking as a primary strategy when they began to solve the problems. In general, the college students were able to solve the problem more quickly than the third and fourth grade children working on the same tasks. All were able to solve the four-tall Towers Problem and start the five-tall Towers Problem within a fifty-minute or a seventy-five-minute period. Most also finished the five-tall problem within the same period. Several students also had time to work on extensions of the problem within the class period. The college students also showed less inclination to think about problems for extended periods of time. Many stopped thinking about the problem after they had arrived at an answer, even when the instructor asked them to think more about the problem in order to reveal their thinking.

The college students also demonstrated methods of justification that were similar to those of the pre-college students. The method used by one of the college students, Robert, to show that he had found all towers with two cubes of one color and three cubes of the other color was the same as that used by Michael and Ankur from the Rutgers longitudinal study in one of their tenth grade after school sessions (Muter, 1999). Two of the profiled college students, Stephanie and Lisa used a method in which they fixed one of the two cubes on the top of the tower and moved the second cube into all possible positions. They then fixed one cube on the bottom and moved the other cube into all possible positions. This is similar to what fourth grade Stephanie from the Rutgers longitudinal study had done with towers six tall. Lisa and Stephanie from this study accounted for towers that did not have one of the two cubes on either the top or on the bottom of the tower while fourth grade Stephanie did not pursue this idea (Máher & Martino, 1996; Glass, 2001).

After another student, Rob and his group had built their towers by organizing them by cases they noticed the doubling pattern and developed a proof by induction, which Rob used in his written assignment. This is similar to what fourth grade Milin had done. College-aged Mike also noticed that the number of towers was doubling, but was unable to think of a reason for the doubling pattern (Glass, 2001). It is interesting to note that both Stephanie and Milin from the Rutgers longitudinal study had noticed the doubling pattern in the Towers Problem as fourth graders. Stephanie’s progression from pattern recognition to development of an inductive argument took about eight months while
Milin’s understanding developed more quickly (Alston & Maher, 1993; Maher & Martino, 2000). Perhaps college-aged Mike would also have recognized the reason for the doubling pattern if, like fourth grade Stephanie, he had been given an extended time frame in which to develop his ideas. Mike, however, was limited to about eight weeks to develop his ideas about the problem.

Although some of the conditions of the Rutgers University longitudinal study such as extended classroom sessions and revisiting the same problem several times within an extended time frame, could not be replicated because of time constraints within a college classroom, many of the conditions that enabled the pre-college students to become thoughtful problem solvers were duplicated. Both groups were given rich mathematical tasks and were encouraged to explain their reasoning and methods of solution and justify their solutions to the problems. Both groups of students were engaged in thoughtful mathematics. They found patterns, justified that their patterns were reasonable, and developed methods of proof. While it cannot be disputed that the students in the Rutgers longitudinal study benefited from exposure to rich mathematical experiences over an extended period of time, the students in this study, who had previously experienced a variety of traditional mathematics instruction, demonstrated that it is not too late to introduce rich mathematical experiences in a collegiate level mathematics class. The level of reasoning that these students demonstrated provides evidence that it is possible to experience thoughtful mathematics within a traditional fifteen-week semester. The findings support the importance of introducing rich problems to college students and giving them opportunities to work together toward a solution.

REFERENCES

The purpose of this study was to understand how participants in a professional development program initiated, developed, and supported a learning community focused on students' understanding. The analysis focuses on teachers' activity as they participated in a community of practice and how that participation promoted (or restricted) their learning and therefore theirs students' learning. The components that characterize a community of practice are 1) mutual engagement, 2) a joint enterprise, and 3) a shared repertoire. The study took place in a bilingual (English-Spanish) high school in a large district in the Midwest, with a high percentage of Latino/a students, and situated in an urban setting. The study shows how the community was transformed by the practices and resources available to the members.

INTRODUCTION

Mathematics teachers' participation in communities of practice has been identified as a promising strategy for professional development. Studies focused on school organization have found strong relationships among teachers' participation in professional communities, innovative practices, and student learning (Adajian, 1995; Lee, Smith, & Croninger, 1997; Louis, Marks & Kruse, 1996). Mathematics teachers who participate in communities of practice are more willing to change their practices and their learning becomes generative (Franke, Carpenter, Levi, & Fennema, 1988; Stein & Brown, 1997).

While studies have found that teacher's participation in communities of practice is one significant element for supporting teacher change, we do not know how those communities are constructed and supported. In many studies, the communities were already organized or, in some cases, the communities emerged from the reform process in ways that are not clear. Regardless, communities are important in supporting both mathematics teachers' and their students' learning.

OVERVIEW OF THE STUDY

This study was part of a larger study that took place during a two-year period. The goal of the larger study was to examine how the focus on student understanding affects different systems at school. The hypothesis was that when teachers have knowledge about how students reason, they are able to interpret patterns in students' thinking and they are responsive to student understanding in the classroom (Carpenter, Fennema, Perlterson, & Carey, 1998). This knowledge would also help teachers to select and construct meaningful tasks that highlight the development of student's algebraic thinking. At the same time, this knowledge would give teachers tools to promote discourse in which students are allowed to express their opinions, defend their solutions, question other's ideas, and reorganize their own thinking.
The purpose of this study was to understand how participants in a professional development program initiate, develop, and support a learning community focused on students' understanding. The analysis focuses on teachers' activities as they participate in a community of practice (Wenger, 1998) and how that participation promotes (or restricts) their learning and therefore their students' learning. The three dimensions characterizing a community of practice are 1) mutual engagement, 2) negotiation of a joint enterprise, and 3) development of a shared repertoire. This study seeks to describe how a specific design for professional development serves the different requirements for learning defined on a framework in which communities of practice and participation in those communities are the fundamental unit of analysis. Such a conceptual framework emphasizes the negotiation of meaning and the building of identities, which take place during the development of practice (Wenger, 1998).

THE CONTEXT

The concern for minority students' achievement in schools in the United States is well known. Many Latino students attend overcrowded schools, live in economically distressed areas, and face prejudice and stereotypes in their daily lives (Secada, et al., 1998). The city where this study took place had been making efforts for improving minority student opportunities. The school, Urban High School, faced strong pressure from the school district to improve student achievement and to get more students to pass the graduation test required by the school district. The school district agreed five years before the beginning of the study, to require algebra for all ninth-graders.

Urban High School offers a bilingual program for its 57% of Latino and Latina students. Close to 66% of students received free lunch (1997-1998). The school had 1500 students, and it was considered the most diverse school in the district with 19% of African-American, 10% white, and 7% Asian. Like any other inner city high school in the United States, Urban High School had many problems to confront. Teen pregnancy, truancy, and gangs were the most prominent.

The mathematics department at Urban High School had twelve teachers where five of them were bilingual. Four bilingual teachers volunteered to participate in the program. They were looking for mechanisms to get subject-colleagues support and to get a common understanding of the challenges they faced due to the changes in the school structure. The school was in the process of reconstruction due to poor student achievement and failing performance. The idea of "schools within schools" (or families) was being utilized since 1996-1997 when the new principal was hired. The family structure encouraged teachers to change their academic organization. Instead of traditional departments, the school was organized into families by areas—business, art, geography, science, and computers. Students belonged to a family and took most of their classes together. The mathematics department still existed but its function was not clear. While many teachers belonged to families and shared experienced with these teachers, others did not belong to a family and did not have an opportunity to talk to other teachers. The department was mostly a remnant from the previous structure and its function was mainly informative.
Participants

The teachers are Femanda, Celina, Gustavo and Armando. They all identified themselves as Latino; three of them were Mexican-American and one Spanish-American. They lived in the neighborhood and participated in activities with the community. They were bilingual and received bachelor’s degrees in mathematics or mathematics education. Urban High is the only school they had taught. Armando and Celina belonged to the arts and science family respectively. Femanda and Gustavo did not belong to a family.

During the first year we observed five classrooms, two from Celina and one from each one of the other teachers. During the second year we observed two classrooms, one from Gustavo and one from Armando. One hundred and sixty students attended these classes during these two years. The demographic characteristics of these classes were very similar. In Celina’ and Armando’s classes, the students were mostly 9th and 10th graders. In Gustavo’s and Fernanda’s, they were mostly 11th and 12th graders. The age varied from 14 to 18 years old and the time living in the United States varied from one month to all their lives. Most of the students were bilingual. Ten percent of the students were born in the United States, 60% were born in Mexico, 27% were born in Puerto Rico and the remaining 3% of the students were born in other Central or South American countries. Sixty-two percent of the students in these classes were female and 38% male.

THE COMMUNITY OF PRACTICE

Different researchers have shown the importance of communities, usually in the form of academic departments, in secondary schools (Gutierrez, 1996; Adajain, 1995; Siskin, 1994). But, what happens when teachers do not find places and opportunities in the school for creating these communities? With efforts from different directions in changing school structure and improving students’ learning, it is difficult for teachers to come together and find the cohesiveness necessary to maintain groups together. At Urban High School neither the families nor the department had the structure for community. These teachers spent most of their time in their rooms, where they had lunch, tutored students, had parent conferences, and planned their classes. These teachers fit what Hargreaves (1993) described as “isolation, individualism, and privatism” as model of teachers’ work. Different from what Siskin (1994) said, at Urban High School the department structure had not given teachers opportunities for collaborative efforts, for creating a strong identity, or for having norms and shared values. The family structure had not given them that support either.

The community engaged in two kinds of practices—the general meetings and the reflection meetings—aligning efforts to understand students’ thinking and creating images to communicate and share knowledge. The next section describes how this community defined the three components of the framework during the two years.

Mutual engagement

Because engagement refers to the ability to take part on meaningful activities of the community, in interactions with other participants, in the production of tools and artifacts and in the whole process of community building, it is necessary to look at the planned
activities, the way those activities allowed different participants to be involved in, and the way the activities were structured to guarantee an uninterrupted succession of events in which the participants would be engaged. For this group of people the general meetings were opportunities to talk, interact, and engage in doing things together. Sharing their experiences in the classroom, designing a test, and critiquing the school curriculum gave every participant opportunity for mutual engagement. The reflection meetings provided the opportunity to reflect about specific aspects of each teacher’s practice. Using observations of students’ strategies and responses in class, the researchers focused the conversations around the meaning of those observations and the way this information could be used by the teachers to plan following classes. These conversations with critical friends were also opportunities to get to know the teachers in a more personal way.

One of the first activities the community engaged in was the sharing activity. It was proposed by the teachers during the second meeting as a way to maintain contact with others and keep some coherence between mathematics courses at Urban High School. During the fourth meeting three of the teachers presented some of the experiences they had designed for their classes. Another activity the group engaged in was the discussion about curriculum. Because the group of teachers had decided it was important to have some coherence in the curriculum at the school, the teachers decided to discuss what the purpose of algebra would be and what would be the best way to organize the courses at school to reach the goals they had defined. Fernanda expressed her concerns about coherence in the curriculum at school and the effect of this lack of consistency in students’ achievement. She promoted the idea of discussing the coherence of the curriculum at Urban High School in order to help her understand what content was important for her courses and how much emphasis was adequate on certain topics for getting students ready for the next course.

The design of the test was an opportunity for the teachers to participate in the research process. The researchers used the classroom observations as a way to get some knowledge about what the teachers considered important for the content of the algebra course and using these ideas to design a first draft for the test that was shared and discussed with the teachers. Engaging in looking at student work and analyzing possible student responses in different situations proved to be a successful task for this group. Teachers’ knowledge of their students and researchers’ knowledge about theories of learning provided opportunities for complementary contributions. The results from the test gave teachers information about what their students knew. The gap between teachers’ expectations and test results created an opportunity to reflect about the main ideas of the algebra class. The teachers saw the need to make changes in their practices and give students more opportunities to explain their thinking. Having the possibility of talking about students’ different strategies and levels of development of understanding gave teachers a new insight into students’ learning. Teachers began to focus on the big ideas of algebra and on developing strategies to help students understand those ideas.

One the one hand, the activities the community was engaged in during the study offered to all participants opportunities for using their knowledge about their students, for making decisions about curricular issues, for evaluating the situation of bilingual students at Urban
igh, and for creating tools, specifically the test, to get a better understanding of student’s
inking. On the other hand, the teachers took responsibility for selecting the activities they
considered worthwhile. Even though the researchers were interested in carrying out
activities more related with looking into student understanding, the teachers were concerned
about other issues they needed to deal with before, e.g. the discussion about curriculum.

tegotiation of a joint enterprise

he negotiation of a joint enterprise refers to the ability to coordinate perspectives and
actions to a common goal. It is necessary to understand the enterprise of the community, to
ake responsibility, and to contribute to the process of pursuing it. The practice of this group
of teachers and researchers reflected an attempt to create a context in which to advance in
their understanding of student thinking. The teachers struggled to satisfy the restrictions
on the school and the district, and they worried about their students’ future. The teachers
egotiated the enterprise with the other member of the community. The members were
engaged together in the joint enterprise of understanding student’s thinking. This does not
mean all participants agreed on everything, had the same dilemmas, or found the same
swers. But they found a way of working together, negotiating the goals, and recognizing
the effects of it in their practice.

his process of negotiation also entailed the development of relations of mutual
accountability. In this case, accountability included not only trying things out in the
classrooms, but also sharing experiences, expressing concerns, and making sense of their
practices. The need for coordinating a perspective on what all participants meant by
udent understanding, for example, made the processes of coordination and
communication dynamic, open-ended, and generative. This community developed in a
larger context, which shaped and influenced its practice. The practice of this community
as part of an historical development and it was influenced by the institutions to which the
embers were part of. Resources and constraints, from the school as well as from the
iversity, were negotiated by the community in the process of defining its enterprise.

ther aspects related to coordination include the research methods used by the group and
the ways for communicating that were followed during the study. Most of the processes for
athering data were defined by the researchers and agreed to by the teachers. Some of those
 processes included giving tests to students, participating in interviews, and collecting
mission forms. Some other issues were negotiated with the teachers. Setting the
erviews with the students is one example of how the teachers helped the researchers to
ake use of the resources available and even proposed alternative solutions.

ne of the conflicts the group had from the beginning was the lack of time for the teachers
to meet and do things together. Other than time during the general meetings, there were very
few opportunities for teachers to even see each other during the day at school. This fact
stricted opportunities to engage in discussions or even in planning activities for their
urses and to reach their goal of getting some coherence in the curriculum. This conflict
dould not be resolved during the first year. Even though the group found different
alternatives like meeting on Saturdays, using the banking days, and meeting after school,
there were always other issues that conflicted with the schedule and made difficult to find time to meet.

Development of a shared repertoire

The development of a shared repertoire refers to the creative process of generating new ways of looking at the activities the community is engaged in. In order to belong to a community of practice, participants must be engaged in activities and have aligned processes. Participants must interpret events, locate themselves in the world, and explore other possibilities. The process of pursuing the enterprise creates resources for negotiating meaning. In this case, the use of specific terms such as “students understanding” or “informal assessment”, routines such as discussing scheduling issues, tools such as the test, stories such as those shared by the teachers, and actions such as discussing the school curriculum were examples of the repertoire of the community. This repertoire was developed during the process of mutual engagement. Each one had its own history, its well-established interpretation, and it could be re-used in new situations.

Another important piece of the repertoire was the shared positive beliefs and high expectations about Latino students. All participants expressed an honest concern for their students. They believed their students’ Latino heritage was worthy of respect, and they believed all students were capable of success. This set of beliefs was critical for getting the group together and, even when other meanings were negotiated, they were almost “underlying principles” for the community.

During the joint process of pursuing the enterprise the community creates resources for negotiating meaning. In this community, certain terms, routines, stories, and concepts took on specific usage. Two clear examples were the concept of “student understanding” and the “rate of change test” as an artifact. During the first year, the ambiguity of the term “student understanding” made the process of communication difficult. The teachers were confident their students had complete understanding of the algebraic concepts. For them, being able to complete homework or not asking questions during the class were evidence of understanding. At the same time, they believed covering all the topics from the book would give students an understanding of all the concepts necessary to understand future topics. During the general meetings the concept of understanding as being able to see things related or connected to other things was brought by the researchers and adopted by the community after a process of negotiation.

The rate of change test was one of the artifacts that emerged as part of the engagement of the participants and allowed the convergence and stabilization of meanings. The test was developed based on researchers observation of teachers’ classrooms and using teachers’ insights about its relevance to their practice. Looking at strategies students used to solve these problems, instead of looking at performance, served as a resource to talk about understanding. Based on the test results from the first year, the teachers wanted to talk about the big ideas and ways to promote student participation in the classroom during the second year. The gap between teachers’ expectations and the evidence from the test created a conflict the teachers struggled to resolve.
The community focused its attention and efforts to the development of meanings that mattered to the participants. For the researchers it was important to understand the impact of talking about students’ understanding with these teachers. For the teachers it was important to look at their practice from a new perspective and pay attention to students thinking.

**IMPLICATIONS**

Membership in the community benefited the participant teachers in different and personal ways. From a social perspective, learning is fundamentally experiential and social. It depends on the opportunities to contribute to the practices of the community (engagement), on the connection to the frameworks that determine the social effectiveness of the actions (alignment), and on the processes of orientation, reflection, and exploration of identities and practices (imagination). In this way, the learning in the community presented here took place because of the practices, norms, and images the teachers and researchers constructed together over the two years.

In this group Isabel could be considered as an experienced teacher, while Fernanda and Armando were just passing the critical initial stage of their professional lives, and Gustavo was a new teacher with just one and one-half year of experience at the beginning of the study. On one hand, the two teachers in the extremes, Isabel and Gustavo, were the most engaged participants and benefited the most from the community by taking into their classroom what they learned within the community. On the other hand, the other two teachers, Fernanda and Armando, represent the larger group of traditional teachers who find the ideas of reform difficult and even threatening. Many teachers will listen and participate marginally in the activities with some attempting some changes despite finding the experiences intimidating and risky while others neglect to translate the experiences to their classrooms entirely.

The study contributes to research in professional development in two ways, (1) understanding how a community of practice emerges and (2) validating the relevance of the content on professional development programs. The framework used helped to describe the different stages of the community and the way the group matured over time. Looking at the facilities available for each component during the process of community formation has given a detail description of what activities the participants were engaged in, what goals they negotiated, and what tools they produced during these activities for reaching the goals. The description brings to the front the importance of the content in the development of the community.

The second contribution to the research literature is the relevance of the content in professional development programs. The changes observed from the first year to the second year, show how important is the content of the conversation in a professional development program. Only when student understanding was the real focus of conversations and the community had tools to talk about it, did the teachers engage in more meaningful activities. The focus of the discussion was always highly related with the mathematical content, specifically with student development of algebraic reasoning.

Learning Mathematics for Teaching: Developing Content Knowledge and Pedagogy in a Mathematics Course for Intending Teachers

Cynthia Nicol, Zahra Gooya, Janet Martin

University of British Columbia, Vancouver, Canada, Shahid Beheshty University, Tehran, Iran, University of British Columbia, Vancouver, Canada

Abstract. This study is situated within the context of a mathematics course for undergraduate students intending to apply to the teacher education program. The course is problem-based and designed to develop students' mathematical knowledge and address students' fears and apprehensions in studying mathematics. Analysis of data collected through student autobiographies, journals, and written feedback indicate that: 1) students developed attitudes toward learning that included an inclination to seek conceptual understanding and alternative ways of understanding and solving problems, and 2) students reflected not only on their understanding of math but also on their roles as future teachers. This study builds on our understanding of mathematics for teaching and how a mathematics content course can provide opportunities for learning content and pedagogy.

Introduction.

Over the past decade much has been written about the mathematical preparation of teachers. There are many studies that document teachers' adequate or more often inadequate knowledge of mathematics (Ball, 1990; Borko et. al, 1992; Leinhardt & Smith, 1985; Koirala, 1998; Ma, 1999; Heaton, 2000). Moving beyond a counting of the number or type of mathematics course taken or the kind of degrees obtained as a way of defining mathematical preparation for teaching, current research attempts to understand more about the kind of mathematical knowledge teachers need in order to teach well. Questions of what mathematics content teachers need to know, how they should develop that knowledge, and how their understandings of mathematics relate to teaching practices are not easily answered. Research on professional development provided to practicing teachers which includes opportunities for teachers to examine students' thinking (Franke, Carpenter, Fennema, 2001; Vacc, Bowman, & Bright, 2000), reflect on teaching practices (Schifter, 1996), develop or discuss teaching cases (Barnett & Tyson, 1999), or participate in teacher study groups (Stigler and Heibert, 1999), indicates promise toward enhancing teacher content and pedagogical knowledge. However, we know far less about how we might support beginning or intending teachers' understandings of mathematics for teaching. This paper examines issues around the kind of mathematical content and pedagogical structures needed to help pre-service teachers' develop their knowledge of mathematics. Our study is situated within the context of an undergraduate mathematics content course.
and we ask how such a course might provide opportunities for learning mathematics for teaching.

THEORETICAL FRAMEWORK

Researchers have developed various frameworks for describing the mathematics needed for teaching well. Ball (1991) suggests that teachers need not only knowledge of mathematical concepts, topics, and procedures but also about the nature and discourse of mathematical inquiry. Using her own teaching practice as a site for research, Ball concludes that teachers’ subject-matter knowledge needs to be correct, connected, and meaningful. Ma (1999) extends Ball’s work in her analysis of Chinese teachers’ development of profound understanding of fundamental mathematics. A “Profound understanding of fundamental mathematics,” suggests Ma, “goes beyond being able to compute correctly and to give a rationale for computational algorithms” (p. xxiv). With a profound understanding of mathematics, a teacher, according to Ma, “is not only aware of the conceptual structure and basic attitudes of mathematics inherent in elementary mathematics, but is able to teach them to students” (p. xxiv). Ma explains that a profound understanding of mathematics is an understanding that is deep, broad, and thorough. Deep understanding is evident when teachers make connections to topics that have further conceptual power. A broad understanding, states Ma, involves teachers in connecting topics that have similar conceptual power. Thoroughness, as an aspect of profound understanding, involves interweaving both deep and vast understandings into a coherent whole. For example, a teacher who is able to connect the topic of subtraction with regrouping to rates of composing and decomposing (depth), can connect this topic to addition or to subtraction without regrouping (breadth), and can interweave these into a coherent whole (thoroughness) would have profound understanding of fundamental mathematics and be in a position to connect student understanding to the curriculum.

Ma found that Chinese teachers, even with less post-secondary education than American teachers, developed their profound understanding of fundamental mathematics during their years of teaching. Comparing this to American teachers and using data collected in Ball’s (1990) research, Ma found that neither experienced nor beginning American teachers tended to develop such profound understanding. The Chinese teachers in Ma’s study also displayed various mathematical attitudes. Chinese teachers sought to “know how to carry out an algorithm and to know why it makes sense mathematically” (Ma, 1999, p. 108). Unlike American teachers they shared a disposition to ask why and to explore the mathematical reasoning underlying mathematical procedures. Other basic attitudes of Chinese teachers include the expectation that claims be justified with mathematical arguments and that problems be approached in multiple ways. These basic attitudes play an important role in teaching. A teacher may have conceptual and procedural understanding of mathematics but may not see the importance of conveying that understanding to
students. On the other hand, a teacher may come to teaching with an expectation that learning mathematics involves a focus on proficiency with mathematical procedures over a focus on why they work. As a result teachers may not be in a position to hear or attend to the possibilities for learning or teaching displayed in student responses, problems, or solutions. Teachers’ attitude, as an aspect of their understanding of the discipline, influences what mathematics they know, how they know it, and how they share their understanding with students.

An important aspect of Ma’s research is the intertwining of content and pedagogy. The Chinese teachers in Ma’s study developed their profound understanding of mathematics over time during their teaching careers. Teachers learn mathematics through multiple sources: examining curriculum materials while teaching, working with colleagues, learning mathematics from students, and doing mathematics themselves. Learning mathematics for teaching involves an interplay of learning mathematics content and pedagogy. One does not necessarily precede the other. Teaching practices provide opportunities for learning mathematics. Likewise undergraduate and teacher education programs are contexts for learning both content and pedagogy. However, what teachers take from their undergraduate mathematics coursework is not often of use to them in classroom practice. How we might offer mathematics courses to intending teachers, so that teachers are in a better position to develop the kind of understanding and attitudes Ma speaks of, is an important question.

RESEARCH CONTEXT AND DESIGN

The Course

The context for this study is an undergraduate mathematics course taught through the University of British Columbia’s mathematics department. A condition for admittance into the university’s elementary teacher education program is the successful completion of any undergraduate mathematics course. One particular course was designed by the math department to meet the unique needs of intending elementary teachers. Taught differently from most undergraduate math courses in the department, this course focuses on developing students’ skill and confidence in doing mathematics and engaging in mathematical inquiry. The course is problem based; lecturing is replaced by cooperative work in small groups and whole class discussions, and reflective math journal writing is expected. The content is connected to the school curriculum and is composed of three sections: geometry, arithmetic, and combinatorics (with probability). These sections are organized around themes or conceptual anchors such as the Pythagorean theorem and scaling, exponential growth, and binomial probabilities. Moving within the themes and sections the historical development of mathematical ideas can be addressed.
Participants
Forty-six of 54 students enrolled in the mathematics content course during the summer of 2001 participated in this study. The class met every day for two hours over a six-week period. All students enrolled in the course did so as a requirement for entry into the elementary teacher education program. Students were either nearing the completion of their undergraduate degrees or had extensive work experience and were considering a career change. Thus, the demographic blend of the students varied; the youngest were in their early 20's and the oldest in their mid 50's. Participants therefore came with varied educational backgrounds and work experiences, as well as different expectations and visions about the teaching profession. There were 11 males and 43 females in the class.

Data Collection and Analysis
For the purposes of this paper, we draw upon data collected through the teaching of this mathematics course. Zahra Gooya was the instructor for the course. Data sources include: participants' autobiographies collected during the first day of the class; participants' math journal entries written throughout the course; students' written evaluations of the course collected at the end of the course; participants' responses to a course reflective feedback survey collected at the end of the course; and the instructors' reflective field notes. Student autobiographies, student daily journal entries, and their responses to the course were analyzed for common issues and themes that were raised by students in terms of their mathematical backgrounds, their initial attitudes toward mathematics, learning and teaching mathematics, and how these attitudes developed or changed by the end of the course. Using Ma's (1999) description and framing of basic attitudes for teaching mathematics, our analysis involved both direct interpretation of individual student responses across the course and the aggregation of particular instances (Case, 1995).

RESULTS AND DISCUSSION
Changes in Attitudes
Student autobiographies and journal entries written at the beginning of the course indicate that most students were apprehensive about taking a mathematics course and successfully completing the course as a requirement for application to the teacher education program. More than three-quarters of the students in the class expressed negative feelings toward mathematics, writing that they were "terrified", "intimidated", "anxious" and/or "stressed" about studying it. They described their previous experiences learning mathematics as "difficult", "overwhelming" and "frustrating." Although a few students mentioned they liked the predictable and sequenced nature of solving problems, many wrote about their loss of interest in mathematics as it began to make less sense or became less meaningful to them over their years of school study. This student's comments are representative of others: "I actually liked math as a kid. It was always challenging and I liked that challenge. But
I gradually liked it less as I was not able to apply the higher level math to practical life”. With apprehension in successfully completing a university level mathematics course many students expressed a desire for the course to be taught in a familiar and traditional manner. As one student wrote, “we need lecturing, solving examples, doing lots of drill and practice, and telling us what and how to do it.”

The course, however, was not taught in this traditional manner. Students worked in small groups on rich problems [1]. The instructor emphasized conceptual understanding through problem solving and encouraged students to communicate their thinking orally to their peers in whole class discussion and in writing in their journals. As the course progressed, the content of students’ journal entries and reflections of their work with mathematics changed. Students’ journal entries and their course evaluations written toward the end of the course indicate that many students not only developed a conceptual understanding of the math content taught but also some basic attitudes they felt necessary for learning math. Many students wrote that “the course encouraged me to be more curious about math and greatly diminished my anxiety towards the subject.” In addition to changes in feelings toward mathematics, students wrote about the importance of explaining mathematical ideas, about seeking understanding rather than memorizing, and about searching for different ways of solving problems. For example, this student’s comments are representative of others: “I feel this course did an excellent job of easing me back into math. It made me realize that it is not sufficient just to get the answer, it is necessary to know where and how it came to be, and how the formulas are created.” Other students wrote expressions similar to this student’s: “I’ve developed not only a clearer understanding of the basic concepts of mathematics, but also an appreciation for the many different methods there are to explain one concept.” Still others, such as this student, wrote about their participation in creating mathematics, “I really enjoyed learning how to make formulas and proofs, instead of being given them.”

These comments indicate how students’ attitudes developed throughout the course. However, such a change did not occur for all students. Eight students of the 54 in the class wrote about how the course did not meet their needs. Throughout the course during class discussions and through journal writing, these students expressed a preference for a more traditional teacher-centred approach to teaching and were angry when this approach was not adopted. Although the course instructor offered opportunities for individual instruction outside of class time to these and all students, few of these dissatisfied students accepted this as an opportunity to meet their needs.

**Learning Teaching While Learning Mathematics**

Although this course was a content course taught to students who were intending to but not yet enrolled in a teacher education program, students made explicit connections between their learning mathematics and their roles as future teachers. Analysis of students’ journal entries and reflective course feedback indicate that...
students were learning about pedagogy while they were learning about content. Many, such as this student, wrote about the importance of developing conceptual understanding of mathematics, "It isn't sufficient just to get the answer, it is necessary to know where and how it came to be, ... and how the formulas are created." They reflected on how they might engage students in learning mathematics. This student’s comments are representative of others when she wrote, "I've learned to work from where students are in terms of their level of learning, learned to ask what they know and how they understand what they know." A focus on teaching strategies was not an explicit focus of the course, yet students in this course drew upon their experiences as students in the class and upon their analysis of the instruction to inform their ideas about teaching. Their comments focus on both themselves as teachers (e.g. "I understand now that we as future teachers need to understand the underlying principles of math and also how and why, ... this course is preparing us"), and on their future students (e.g. "Children will ask 'why, why is math important, why do we do that, why is it important to learn math?' and we have to be prepared to respond to that"). Using their own experiences in the course as a place of reflection, the course provided beginning opportunities for students to learn content and pedagogy.

CONCLUSION

The results of this study point to the possibilities offered in mathematics content courses for developing productive attitudes and dispositions toward learning and teaching and for developing understandings of content and pedagogy. Studies of experienced and prospective teachers’ subject-matter knowledge indicate that teachers require a rich and connected understanding of the mathematics they will be teaching in order to teach well. Ma’s (1999) research indicates that teachers can develop their knowledge of mathematics for teaching over their careers of teaching and that these teachers display attitudes which include an inclination to pursue a conceptual understanding of a concept, to seek alternative solutions to problems, and require mathematical reasoning to justify claims. Most students in our study, as a result of their experiences in the course, developed the desire to pursue an understanding of mathematical concepts. They also wrote about the excitement of seeing and the challenge of understanding alternative solutions to problems. Although students wrote about these attitudes and their own changes in attitudes, how students use these in their roles as beginning teachers is a question for further research.

It must be stated that not all students wrote about a desire to learn and understand the conceptual underpinnings of various mathematical principles. These students sought a more traditional form of instruction, one that provided sample problems, clear steps to follow, and problems that allowed students to practice the application of the procedures. These students, eight in total, did not feel as if the course were designed
around their learning needs. This raises questions around how we might provide instruction that meets the needs of all our students.

For a mathematics course to offer opportunities for students to learn mathematics and pedagogy it requires a structure and content unlike typical mathematics courses offered to undergraduate students. Two issues need to be considered, one issue focuses on the mathematics content and the other on the nature of teaching a mathematics course. Students in the course spoke about the need for the content they were learning to be connected to the content they will be teaching. Students who wrote and reflected on the course content, mentioned how they felt they could now engage their own students in a similar investigation of mathematics. Yet, the content for this course was only loosely structured around the elementary school math topics of arithmetic, geometry, and probability, and more closely fit the secondary school curriculum. Interestingly, those students who were dissatisfied with the course spoke of the need for the content to the same as that which elementary students would be learning. This raises an important point as to what mathematics intending teachers should study. Our study indicates that content which is aligned with school mathematics, is familiar to students, but is not necessarily the same as it can be a context for learning mathematics and engaging mathematical inquiry. A second issue focuses on pedagogy. Students need opportunities to learn mathematics with their peers, they need a chance to communicate their thinking to each other and to the instructor, they need to experience mathematical inquiry around rich problems, and their fears about studying mathematics need to be addressed. It is the modelling of good teaching that provides students with possibilities for how students might experience mathematics and how they might consider teaching it. Developing mathematics courses where students can develop their subject-matter knowledge and pedagogical knowledge requires the co-operative efforts of university mathematics and education departments, of mathematicians and mathematics educators.

This study shows that a mathematics content course can have a profound influence on students’ learning in general, on their attitudes toward mathematics, in particular, and on their developing ideas for teaching. The study challenges the traditional separation of content and pedagogy, in which content is typically taught through a mathematics course and pedagogy through a methods course. Current studies suggest that methods courses can be places to learn mathematics (e.g. Tirosh, 2000), our study suggests that a content course can also be a place for learning about teaching. This study emphasizes the interconnectedness of content and pedagogy and points to the possibilities well-designed content courses can offer in helping develop teachers’ mathematical knowledge, attitudes, and beginning ideas about pedagogy.

NOTES

1. An example of a problem posed to students early in the course involved squares and their roots. Moving historically from Meno to Pythagoras and one of the first recorded math lessons where Socrates helps a boy
discover how to double a square geometrically, students in the class are asked to generalize this method to find ways of producing squares equal (in area) to 5, 10, 13, 17 times a given original. In terms of side-length, this means geometrically constructing certain square roots. For example, re-arranging the area left over when four (equal) corner triangles are cut from big square. This area can form a single mid-size square or two smaller ones. This leads to the theorem of Pythagoras – merging two squares area-wise into a single one.

DEVELOPING CONCEPTUAL UNDERSTANDING: THE ROLE OF THE TASK IN COMMUNITIES OF MATHEMATICAL INQUIRY

Susie Groves
Deakin University

Brian Doig
Australian Council for Educational Research

As part of a study of mathematics classrooms functioning as communities of inquiry, video and other data were collected in ten randomly selected Victorian grade 3 and 4 classrooms and two classes at the Japanese School of Melbourne. In this paper, two lessons — one Victorian and one Japanese — are analysed in terms of the conceptual focus and cognitive demands of the instructional tasks and the opportunities these afford for advancing students' conceptual understanding. The stark contrast between the two lessons suggests that, in Australia at least, insufficient attention is being paid to the critical role of the development of conceptually focussed, robust tasks which can be used to support the development of sophisticated mathematical thinking.

INTRODUCTION

A community of inquiry is not just ... a certain kind of social, interpersonal or ethical environment. It is an environment in which inquiry occurs, by which is meant, among other things, a focus on key concepts and complex thinking. (Splitter, 2000, p. 14)

The Mathematics classrooms functioning as communities of inquiry: Models of primary practice project was based on the notion of communities of inquiry, which underpins the Philosophy for Children movement (see, for example, Splitter & Sharp, 1995; Splitter, 2000). One of Splitter and Sharp's (1995) conditions for dialogue, which is the cornerstone of a community of inquiry, is that “conversation is structured by being focused on a topic or question which is problematic or contestable” (p. 34). Thus, in a community of inquiry, participants are engaged in confronting problematic situations and participating in dialogue and argumentation (in the sense of Krummheuer, 1995).

Classroom discourse and the sociomathematical norms associated with achieving quality dialogue have received considerable attention (see, for example, Yackel & Cobb, 1996; Kazemi, 1998; Groves & Doig, 1998). However, frameworks for effective teaching to support children’s conceptual understanding also emphasise the need for tasks which are mathematically challenging and significant (Askew, Brown, Denvir & Rhodes, 2000; Fraivillig, 2001). In particular, the critical role of the design and enactment of instructional tasks in the development of students’ increasingly
sophisticated mathematical reasoning and understanding is a key component of much of work related to mathematical communities of inquiry (see, for example, Cobb, Yackel & Wood, 1995; Gravemeijer, McClain & Stephan, 1998).

The purpose of our project was to examine current models of Australian mathematics practice in order to investigate the extent to which these support or hinder mathematics classrooms functioning as communities of inquiry, and to determine the extent to which the wider local education community endorse the goal of mathematics classrooms functioning as communities of inquiry. Analysis of focus group responses from principals, teachers and mathematics educators showed a high level of support for mathematics classrooms functioning as communities of inquiry, together with a realisation that current Australian practice falls far short of this goal (Groves, Doig & Splitter, 2000). Principals and mathematics educators rated the cognitive demands of typical lessons as low to very low and not challenging children, while teachers saw the cognitive demand as being determined by the tasks (Doig, Groves & Splitter, 2001).

This paper compares two videotaped lessons from the project in terms of the conceptual focus and cognitive demands of the instructional tasks and the opportunities afforded for advancing students’ conceptual understanding.

METHODOLOGY

One mathematics lesson of approximately one hour’s duration was videotaped in a stratified random sample of ten year 3 and 4 classrooms in the state of Victoria. A lesson observation schedule was also used to record detailed field-notes of each lesson. Teachers’ lesson plans, as well as copies of any work-sheets used by the children, were also collected. In addition, each teacher was asked to complete a written questionnaire providing background information, information related to the specific lesson (e.g. the main topic of the lesson, the aims, resources used, the purpose of any group work and whole class discussion, and the most important part for children’s learning), together with information on their mathematics teaching in general. In keeping with Hiebert and Stigler’s (2000) view that one way to imagine alternative models is to “step outside the ... culture and look at how others handle similar issues” and that “Japan provides an eye-opening contrast” (p. 10), similar data were collected from the year 3 and the year 4 classes at the Japanese School of Melbourne.

An analysis of the videotapes was carried out, using a framework based on that developed by Schmidt et al (1996), who use the term “characteristic pedagogical flow” to describe recurrent patterns of observable characteristics in a set of lessons. Each lesson was analysed in terms of its structure, organisation, interactions, cognitive demand, and teacher actions. Based on this analysis and the written questionnaires, data from two lessons — one Victorian and one Japanese — were selected for a more detailed re-analysis in terms of the conceptual focus and demands of the tasks and the
opportunities afforded for advancing students’ conceptual understanding. These lessons are described and discussed below.

THE CHANCE AND DATA LESSON

This lesson, which occurred in a grade 4 class of 30 children, in a middle class suburb of Melbourne, focussed on aspects of Chance and Data and lasted for about one hour. Children were involved in three different tasks: using sales catalogue prices to spend $1 million while satisfying certain constraints; tossing three coins to investigate the outcomes; and estimating the amount of money in a jar of coins.

In her responses to the written questionnaire and the lesson plan provided, the teacher, Ms E, identified the main mathematics topic of the lesson as being “The chance of winning one million dollars” and listed the above three tasks.

During the lesson, children worked in two groups — one for each of the first two tasks — with the money estimation happening simultaneously as children took the jar of coins around the room and collected estimates. Ms E stated that the two groups would swap tasks in the following lesson.

For reasons of space and the emphasis in this paper on conceptual focus, only the coin tossing task will be discussed here. Ms E said that the aims of the lesson were stated in her lesson plan, where she described the coin tossing task as follows:

Three coins to be tossed in the air at the same time. What are the possible outcomes? (These are to be listed.) Look at the pattern after 5 throws. BEFORE the 6th throw predict. RECORD what you think the outcome will be. Toss. Record. Repeat activity — compare results. What do you conclude?

This outline closely follows an activity from the Mathematics: Course advice (Directorate of School Education, 1996) on which Ms E based her lesson. The Course Advice version includes questions such as: “Did anyone predict the correct answer for any of the throws?” and “Is it possible that all coins could land on the same side?” It also suggests that results should be combined with those of another class leading to “Which results were most common?” and “How do these compare with predictions?”

Ms E identified the outcomes from this activity as being ones related to Level 3 of the Curriculum and Standards Framework (CSF) (Board of Studies, 1995), namely that children will be able to record and identify all possible outcomes arising from simple chance experiments; identify outcomes as being equally likely; and make predictions. (In fact, the Level 3 CSF learning outcomes state “identify some outcomes as being equally likely” [emphasis added] and the only mention of predictions is at Level 4 “make simple predictive statements about everyday events ...”, which suggests a quite different context from the one in this lesson.)

In the lesson, children were told to use any three plastic coins from a collection of coins of different denominations and devise their own method of recording. Some
children used three coins of the same denomination and others two or three different denominations. Children recorded their throws typically as either HTH or 2H 1T, but it was never clear whether or not HTH was considered different from HHT and there was no discussion of this at any stage.

While the children worked on their tasks, Ms E moved from group to group, discussing progress and generally praising children’s efforts. Typical comments from Ms E include:

*What do you think the next [toss] will be? Have a guess. ... Have you got your estimate?*

*Compare your results with those of ... same or totally different? [Two girls carefully compare their results line by line, with obvious enjoyment but without any comment or follow-up.]*

After 17 minutes of coin tossing, Ms E called the group together to ask what they had found out. Children’s comments included: “More heads than tails”, “Tails, heads, tails the most — five times”, “Three heads most”, “Normally get two tails and a head”. The discussion lasted a total of five minutes and continued as follows:

Ms E: Can you tell me how many different combinations you can have and what they are?
John: Five.
Ms E: Who agrees? [Three children raise hands.] What are they?
John: TTH, THH, TTT, HHH, [inaudible].
Ms E: Oh right. Has anybody got something to say about that?
Mary: I had tails.
Ms E: What is your most common combination? ... And how many did you have altogether Neil?
Neil: Two.
Ms E: Two! ... You just had two for all those throws!
Sally: I got the same.
Jim: I had five.
Ms E: And John had five. Did anyone else have five? [No hands.] Who had four combinations? How many did you have Helen?
Helen: Two.
Ms E: Two! Oh goodness! ... [You had] quite a few throws and still had only two different combinations every time, Goodness gracious! I think you can put these in your maths folders now.

According to Ms E’s questionnaire responses, the most important part of the lesson from the perspective of children’s learning was:

*Being aware of the price of homes, cars and holidays. The exchange of views between individuals. Thinking it would be easy to spend one million and finding the opposite.*
A number of things are clear from this lesson. Firstly, the coin tossing task is severely flawed — both as recommended and as implemented. Is it intended that there are eight possible (equally likely) outcomes (i.e. are the coins intended to be treated as different) or only four? Secondly, what concepts are intended to be developed and what possible place does the prediction (far less “estimation”) of outcomes have in such a development? Thirdly, there clearly needs to be some agreement about the possible outcomes and how these are recorded before any comparison can be made of the results of the experiment. But perhaps most importantly, the discussion at the end of the lesson segment proceeded no further than eliciting results, with questions all being of the form “Who got this?”, “Who agrees?” or “Who got something different?”.

Unfortunately in our experience this type of discussion is not uncommon. What is clearly lacking in this lesson is any serious consideration of the mathematical concepts that might be developed through the use of the activity, the types of responses which children might give and how the discussion could be used to focus on the conceptual aspects of the task.

THE CIRCLE LESSON

This lesson occurred in a grade 3 class of 8 children at the Japanese School of Melbourne. The school teaches the Japanese curriculum, in Japanese, to children whose parents are in Australia for periods of one or two years, with teachers usually coming to Australia for three years. An interpreter was present throughout the lesson and assisted with completion of the written questionnaire. According to the teacher, Mr J, the main mathematics topic for the lesson was “the concept of a circle”.

The lesson began with Mr J producing a pole for a game of quoits. Mr J placed the pole in the centre of an open space in the classroom and asked three children (referred to here as B1, G1 and B2) to stand at three marked places on a red line along one side of the room (see Figure 1). Children expressed concern that the game would be unfair, but mainly focussed on the distance between children on the red line. After a discussion on how to measure distances and children using a metre ruler to measure children’s distances from the pole, Mr J put out pre-cut coloured strips of paper, as shown in Figure 1, and held them up to show that the distances were different. He then defined the problem as being: “How can we make the game fair?” It is only after five more minutes, during which children continued to try to find points to stand on the red line, that B2 came up with a way that two people can be the same distance from the pole — he moved the yellow strip so that it went from the pole to the point B2* on Figure 1. Mr J then gave all the
children a yellow strip and asked them to “think for themselves” and find somewhere to stand so that everyone was the same distance from the pole. Children were excited that now would be at a disadvantage. This segment took 20 minutes in the 45 minute lesson.

Mr J then reproduced the situation on a large sheet of paper on the board. He stuck a miniature pole on the paper and asks children to use sticky yellow paper strips and dots to represent their positions (see Figure 2).

Mr J: Look at the different positions — what do you notice?
G2: It’s like a round circle [makes circle shape with hands].
G3: No — it’s like a flower.
G1: If you follow the end of each yellow strip it will become a circle [traces large circle on the desk with her finger].
Mr J: What if every student in the school took part? [adds more strips] …
B3: If there are many students standing round, maybe it’s a circle.

Mr J removed the pole and put another sheet of paper over the first with a circle drawn where the dots were and asked “How many yellow points would we need? 100? 1 000 000?” He then put the word circle on the paper and elicited names for the centre, radius and diameter from the children.

The remaining 15 minutes of the lesson were taken up with the children working in pairs drawing circles. Initially many children chose to use a compass, even though Mr J told them that they had not yet learnt how to use one and encouraged one girl, who said that she could use a yellow strip of paper or a plastic circle to trace round, to show him how. After about 7 minutes, Mr J asked children to find a way to draw a circle without a compass. A few minutes later Mr J said “Now everyone is tracing — is there another way?” Children tried various ways, while Mr J pivoted one of the yellow strips of paper around an end held by his finger. B2 excitedly cried out that he could do it and demonstrated drawing a circle by holding the middle of one end of his pencil case and tracing a circle with his finger in the hole at the other end. Children applauded and Mr J demonstrated B2’s method at the front of the class. The lesson finished with a few minutes of suggestions from children how to fix one end, culminating in the use of a drawing pin. Mr J summed up by saying: “As you suggested, there are other ways of drawing a circle than just using a compass”.

In contrast to Ms E in the chance and data lesson, Mr J highlighted the conceptual aspects, both in the lesson and in his responses to the questionnaire. He stated that his
aims were that “children have the concept of a circle and find real circular objects” [emphasis in original]. According to Mr J, the most important aspect of the lesson in terms of children’s learning was that children understand that the circle is a locus. The purpose of working in groups (in this case pairs) was “to facilitate discussions while working”, while the purpose of the whole class discussion was for children to “share ideas and strategies for solutions [demonstrating that] there are many different ways of thinking which reach the same conclusions”. Mr J further described his mathematics lessons as follows:

Introductory lessons [to a topic] use materials. So this was typical. The introduction is very important and takes a lot of time. After that there is much practice, then we go to calculations — a series of 3 or 4 lessons [per topic].

Mr J concluded his questionnaire with the comment that “Mathematics should be part of children’s daily lives”. In the 20 minute quoit activity, Mr J embedded the concept of a circle in a rich, intriguing, intrinsically motivating, problematic framework, by asking: “How can we make the game fair?”

CONCLUSION
The two lessons above provide a stark contrast in terms of the potential offered by the tasks on which they were based to advance children’s conceptual understanding.

Kazemi (1998) argues that in his two classroom examples, where teachers use the same tasks and establish similar social norms, high press for conceptual thinking was created by the establishment of appropriate sociomathematical norms. While we would not wish to disagree with this, we contend that, in general, insufficient attention is being paid to the critical role of the development of conceptually focussed, robust tasks which can be used to support the development of sophisticated mathematical thinking. Moreover, teachers themselves need to engage in the detailed planning of how such tasks can be implemented in their lessons and this requires a deep engagement with the concepts involved, as well as an anticipation of likely student responses. The focus for teachers needs to be on all three of the key components of communities of inquiry: the social norms, the sociomathematical norms, and the conceptually complex, intriguing and problematic tasks.

While Mr J attributed the source for his lesson as being himself and the textbook, we believe it is no accident that while at ICME9 in Japan, we saw photos and descriptions of a number of similar lessons on the concept of a circle at a display by a local teachers’ association. We concur with Hiebert and Stigler’s (2000) view that the Japanese process of lesson study, where groups of teachers engage in an iterative process of refining a small number of lessons, warrants consideration as a procedure for reform of teaching. As they argue (p. 16), “Improving teaching does not depend on eventually perfecting 182 lessons but rather on engaging intensively with the issues involved in teaching any lesson”.

EXPLORATION OF AN ART VENUE FOR THE LEARNING OF MATHEMATICS: THE CASE OF SYMMETRY

Despina A. Stylianou & Ivona Grzegorczyk

University of Massachusetts Dartmouth, California State University Channel Islands

This study examines an art venue for abstract mathematics thinking, specifically, students' understanding of symmetry groups in the context of a course for art students. The findings suggest that when working with repetitious geometric art designs students' approach of various symmetries often go beyond the one-to-one correspondence between specific pieces of art and particular transformations, but they also develop a correspondence between types of art designs and abstract types of symmetries. Further, familiarity with symmetry groups allows students to use abstract mathematical thinking as a tool in their artistic creations.

The idea of viewing mathematics through an art lens can be appealing at many levels. People who find joy in doing mathematics advocate the natural connections between mathematics and art (e.g., Huntley, 1970; Kappraff, 1991; Linn, 1974). Convincing examples are provided by the complexity of Islamic mosaics in the Alhambra, the Greek canons of harmony and beauty, and the magnificence of many architectural designs. Renaissance artists like Leonardo da Vinci, Michaelangelo, Durer, and Piero della Francesca were not only master painters, but skilled geometers as well. In later years, mathematicians such as Kepler, Euler, Gauss and Fermat, studied problems related to art, including tilings, and 3-D solids. More contemporary designs, for example, the works of M C. Escher and A. Fomenco, are coming from the perspective of artists drawing inspiration from complex mathematics rules, and mathematicians who use art as a means to express certain mathematical abstractions, respectively, and they illustrate the strong bond between mathematics and art. An exploration of the natural connection of math and art is now being proposed in the service of education. The idea of “learning mathematics by making art” comes to advance our thinking on mathematics and on pedagogy. Mathematics educators suggest that the integration of arts with mathematics may liven our classes and may also be motivating to some students for whom the “traditional” curriculum and pedagogy has not proven fruitful. This vision is also presented by the National Council of Teachers of Mathematics (2000) who calls for the introduction of extended projects, group work, and discussions among students, as well as the integration of mathematics across the curriculum – elements of a learning environment that seems more similar to a studio art course rather than to a traditional mathematics class.

In recent years, there have been a few examples of interventions that demonstrate the power of the vision that integrates art and mathematics. Yet, little of this work has been done at advanced levels; the bulk of the research in this area has been conducted in elementary and secondary school classrooms. For example, in a quantitative study at the elementary school level, Willett (1992) demonstrated that mathematics learning can be very effective in the context of arts-based lessons. Similarly, Loeb’s visual
mathematics curriculum (Loeb, 1993), though it has not been studied formally, provides substantial anecdotal evidence which supports the study of the formal mathematics of symmetry through a design studio as an effective learning environment for undergraduate students. The “Escher World” project (Shaffer, 1997) explored successfully an open learning environment created by combining mathematics and design activities.

Here, we explore one more example of a learning environment created by combining mathematics and art activities in an art studio-like environment. We designed a course for students interested in arts and design, with the emphasis on understanding mathematical concepts by self-explorations in art (Grzegorczyk, 2000). Instead of introducing theoretical concepts, the course created a vast reservoir of art-related examples and hands-on experiences. The course contained a wide variety of accessible yet challenging problems, and served as an introduction to systematic and complex mathematical thinking, experiences and discovery used in contemporary and classic arts. One of the main themes in the course was symmetry in mathematics.

The focus of this article is to examine one specific aspect of this art venue for mathematics learning, specifically to document students’ understanding of symmetry groups. While our broader goal is to study the process by which mathematics learning takes place in environments where it is approached through art, and to further develop a model for this type of teaching, here we focus on the learning of symmetry and the implications that this may have on the overall mathematics learning and attitudes of students towards mathematics. Specifically, our goal was to examine the ways, strategies, and approaches college students use art as a gateway in their attempts to develop an understanding of design classification and symmetry (through crystallographic groups).

METHOD

Participants and course activities: Twenty-five undergraduate students who major in art studies participated in a one-semester mathematics course. Students were asked to work on short problem investigations, or extended projects with increasing sophistication and complexity. These included either the study of existing artwork to develop mathematical insights, or the use of mathematical ideas to develop original art and design works. Students worked on these projects and then presented their work to their peers for discussion, questions, comments. The class was equipped with commercial and shareware drawing and image-manipulation programs as well as geometry and symmetry software.

Mathematics of the course: Central to this course was the development of the concept of various types of two and three-dimensional symmetries, a topic that is significant both in art and in nature. This was motivated by discussions on designs produced by individual artists and traditional designs from various cultures around the world. Students entered the course with a vague understanding of the concept of
symmetry, one that was often disconnected from mathematics. As their discussions on works of art and the complexity of their designs progressed, they were encouraged to use precise language and to clarify the term “symmetric.” It became apparent that the class would benefit from a systematic and deeper study of this broad topic. Students were invited to study symmetries as rigid motions of the plane. They identified the symmetry motions of small (finite) designs using polygons as a main example, i.e. they studied various types of rotations and reflections, and their compositions – a result of one motion followed by another. The classification of designs with various symmetries and the development of symmetry group tables, led to the underlying definition of the dihedral groups and cyclic groups, and, finally, to the definition of an abstract group. Students verified the associative, identity, and inverse properties of the transformations for various symmetry groups, and re-visited the art designs that initially motivated the study of group symmetry and discussed how their new understanding of group theory may assist them in gaining new insights in art. They generated their own designs using symmetric transformations, and discussed the utility of group theory with respect to the generation of repetitious designs.

The symmetries of strip patterns were analyzed next to discover that all seven symmetry groups for repetitious (periodic) strip patterns. The natural next step was to study plane patterns such as wallpaper and quilting patterns, that is, designs where the repetition of the theme occurs in more than one direction. It was noted that there are exactly 17 plane symmetry groups, which correspond to 17 types of patterns and could be analyzed or generated using various symmetries. The sophistication of the students and complexity of the patterns studied was increasing. The notion of the fundamental region for a pattern lead to the study of tilings – when is it possible to cover the plane with a single tile or combination of tiles. The most intriguing and interesting tilings of Escher especially lent itself for symmetry investigations on tiling. Finally, the study of symmetric groups was extended to three-dimensional solids (mostly Platonic solids) and their tiling.

Data collection and analysis: For this study we collected students’ sketches and designs from the workshops for review and analysis. Further, students were administered a pre- and a post-test that focused explicitly on their understanding of various symmetries and were asked to complete a survey which focused on the students’ attitudes towards mathematics and the class.

Responses to each problem were first coded for mathematical correctness. When responses included images, then these were coded for the presence of mathematical principles and their correctness. When responses included verbal descriptions, these, too, were coded for the extent to which mathematical ideas and concepts were used and, subsequently, for the correct use of mathematics. In this case, we differentiated between explicit, formal use of mathematics concepts and language and general, or vague references to mathematics. We also differentiated between different strategies that students employed when they approached tasks or designs that involved the use of symmetry in various forms. Finally, when coding was complete, frequencies were
RESULTS

Recognizing and using symmetry. Our first coding scheme concerned the overall recognition of the existence of symmetry in designs and students’ subsequent attempts (or lack thereof) to utilize symmetry principles. To code students’ understanding of symmetry we used the criteria suggested by Gardner, i.e. the “ability to use ideas in appropriate contexts, to apply ideas to new situations, to explain ideas, and to extend ideas by finding new examples” (Gardner, 1993; Shaffer, 1997). Using this definition, our results indicate that all students were able to make designs using mirror symmetries and rotational symmetries (Table 1). In fact, students reported that they regularly used symmetry in their designs, both in and out of the course. By contrast, early in the of the course (pre-test), when asked to make a design which incorporates mathematical ideas, only 2 students used symmetry. The remaining 23 students used, or made references to mostly measurement concepts (dividing areas in parts, measuring) and, in a few cases, attempted to construct polygons.

Students also developed an ability to apply the concept of symmetry to their analysis and discussions of various designs and art works. Before the course, students made references to symmetry an average of 0.36 times (total of 9 references made by 25 students) while describing two images (see Figure 1). Note that all references to symmetry were made with respect to mirror symmetry only; no mention was made to either translations, rotations or glides. As the course progressed, all students mentioned symmetry, and the mean rose to 3.16 references over the same 2 images (79 references). These included references to mirror reflections (59 references) and rotational symmetries (16 references), as well as to the lack of symmetries (see Table 1). But, perhaps, more striking is the qualitative change in students’ responses to the designs they were discussing. Students used a richer, more formal and mathematical vocabulary to describe images. In fact, 4 students made direct references to symmetry groups (i.e., dihedral and/or cyclic groups). Indicative of this qualitative change in students’ discussions are the comments of one student, Julie, whose pre- and post-course discussion of the designs appears below:

Pre-test comments: “You can fold this design either up or down in the middle and each side is the same, like a mirror. There’s lots of symmetry.”

Post-test comments: “This has 2 symmetry lines; they divide it in 4 regions. There are four pieces in the square. When you divide it in half you can rotate [each piece] by 180°. Or each piece, each fourth, can be rotated 90°. It’s like a D_{11} group [Dihedral 2]. All dihedral groups have both symmetry lines and rotations. The other one has 11 regions. No symmetries. It’s a cyclic group. C_{11}. All cyclic groups just have rotations. No mirror symmetries…”(note that Julie used the word “symmetry” to denote mirror symmetry)

Julie’s first mention of symmetry was made in general terms – “there’s lots of symmetry”. At the end of the semester though, Julie made specific references to
both mirror and rotational symmetries and connected these to a more formal understanding of symmetry using group theory terms.

Table 1: Frequency in symmetry use

Approaching Symmetry via Art              | Approaching Art via Symmetry
- (a) Use of a local, one-to-one correspondence between one specific piece of art and an instance of a mathematical concept - (a) Use of local mathematical concepts related to symmetry to understand art designs
  - recalling design examples when asked to discuss the mathematics
  - e.g., “Cyclic group $C_4$ is like that four-leaf rosette”
  - recalling a collection of symmetry concepts when trying to understand the structure of an art design, or to create one.
- (b) Use of a global correspondence among types of objects - (b) Use of global, abstract concepts related to symmetry to understand and create art
  - connecting broader math concepts to broad art concepts
  - e.g., “cyclic groups are like rosettes”
  - deriving specific facts and concepts from abstract symmetry concepts to aid in art creation.

Table 2: Types of symmetry use

Task 1: Discuss the mathematics of the two designs shown below.

Task 2: Fill in the circle with a design and explain the mathematics of your design.

Figure 1: Two of the pre- and post-test tasks: Analyzing and creating symmetric designs
Towards a formal understanding of symmetry. All students developed their understanding of symmetry groups in the sense of recognition of symmetry in designs and in their ability to use symmetry to generate their own designs. Our coding suggested that students approached symmetry in two distinct ways: A number of students approached the mathematics of symmetry using art. Others, however, gave clear indications that, after a certain point, they used abstract mathematical objects as a gateway to art.

The former approach, math-through-art, did not surprise us; it was a clear expectation that students in this class engage in mathematical thinking and problem solving at a certain level, and art could be used as a tangible tool to help explain or apply the abstract concepts of mathematics. Since all of our students were well-versed in the language of art, we helped them build bridges to mathematics via art, so that underlying mathematics also becomes tangible and real. For example, students were expected to understand that cyclic groups have the characteristics of an asymmetric rosette - no mirror symmetries, but with a rotation symmetry, while the angle of the smallest rotation determines the type of the underlying cyclic group. This math-through-art approach was manifested in two ways:

(a) recalling design examples when asked to discuss the mathematics (e.g., “Cyclic group $C_4$ is like that four-leaf rosette”) – a local one-to-one correspondence between a specific piece of art and an instance of a mathematical concept, and

(b) connecting broader mathematical concepts to broad art concepts – a global correspondence among types of objects in art and in mathematics (e.g., “cyclic groups are like rosettes”).

The latter approach, however, that is, using abstract mathematical concepts to understand art, deserves further attention. In this case, students used their understanding of a cyclic group to convince themselves that, once a design is identified as equivalent to a cyclic group, there is no need to look any further for mirror symmetries – they do not exist. Students were able to use abstract mathematical thinking in generating their own designs and to make short cuts in designing repetitious patterns using certain group properties. The art-through-math approach was also manifested in either a local or global perspective:

(a) Use of a collection of mathematical concepts related to symmetry to understand and create art designs – a local use of mathematics as a way to approach art. For example, a student may look at a given art design and look for the existence of mirror reflections, translations or rotations and attempt to understand the overall “behavior” of the art work, or attempt to reproduce the design using, partially, these symmetry principles. We often observed this behavior when students were exposed to the work of M. C. Escher – students examined the tessellation designs by looking for symmetries and, based on that understanding, attempted to reproduce Escher’s work, or to create their own tessellation designs.
(b) Use of abstract concepts related to symmetry to understand and create art designs—a more global way to approach art via mathematics. In this case students derived information regarding a design by thinking of symmetry as a collection of organized and relatively abstract objects. This was a process of deduction. Students who developed an understanding of the structure of dihedral or cyclic groups systematically derived the characteristics of a group that were of use to them in their designs, or helped them justify their claims. The effect of this approach to the understanding or creating designs was obvious when asked to produce wallpaper patterns; a few students attempted to make use of their understanding of dihedral and cyclic groups—some students recalled that cyclic groups have no mirror symmetries and used this fact to produce wallpapers with rotational themes.

**DISCUSSION**

One of our goals for this study was to examine the potential of a learning environment created by combining mathematics and art activities, and, specifically to document students' understanding of symmetry. Furthermore, we aimed to examine the ways in which students come to understand symmetry via the use of art, their strategies and approaches. Willett (1992), Loeb (1993), Gura (1996) and Shaffer (1997) among others argued that an art studio can facilitate the learning of mathematics and the mathematics of symmetry can be a meaningful organizing principle when teaching a course in this setting. Indeed, we found that our students over the course of the semester developed their ability to detect the existence of symmetry in its various forms in art designs, and to classify various designs using familiar properties (in this case properties of symmetry groups). Furthermore, students regularly incorporated symmetry in their own designs. This involved not only the use of relatively elementary concepts such as mirror lines, but they also gave evidence of a thoughtful use of specific types of symmetries in order to achieve certain visual effects (e.g., students often explicitly mentioned that they chose to use a cyclic or rotational design to avoid having mirror images). Students' overall behavior suggests that they learned to appreciate an abstract approach to symmetry as a way to create designs and had begun to appreciate abstraction in mathematics in general.

Our second goal was to examine the ways in which undergraduate students use art as a gateway in their attempts to develop an understanding of symmetry. The findings suggested that students developed the ability to approach symmetry beyond the one-to-one correspondence between a specific piece of art and a mathematical concept, but they also develop a correspondence between types of art designs and abstract types of symmetry concepts. Further, familiarity with symmetry concepts allowed students to use abstract mathematical concepts as a tool in their art creation.

Finally, we focused on the learning of symmetry and the implications that this may have on the overall mathematics learning and attitudes of students towards mathematics. Students' comments suggested that they developed a positive attitude
and, often for the first time, they could see a role for mathematics in their lives and their creations.

Overall, students who participated in our study learned about the mathematical idea of symmetry and discovered a new meaning for mathematics. An important question to ask is what facilitated the learning of mathematics in an art studio. Shaffer (1997) in a study involving middle school students in a similar environment suggested two venues to explore as factors in students’ learning: the issues of control, that is the freedom to make decisions in one’s own learning (Dewey, 1938) and expression (Parker, 1984). Shaffer suggested that expressive arts-based activities put students in control of their own learning. Observational evidence suggested that in our course, the freedom for students to choose the means in which to apply the concepts they find most useful in the context of art with which they feel familiar, also facilitated the learning of mathematics. Students often talked about using ideas of symmetry out of class in their own project and the transfer of ideas of symmetry to their art projects. Our results suggest a framework for thinking about the teaching of mathematics in the context of other courses. We believe symmetry to be only one of the many possible principles that can be used as powerful vehicles to build mathematical bridges for students that are often difficult to reach.

The role of calculators in instrumental genesis: the case of Nicolas and factors and divisors

Jose Guzman

Université du Québec à Montréal, Canada
kieran.carolyn@uqam.ca

We present in this paper a case study of instrumental genesis involving a 14-year-old pupil, the multi-line-screened TI-73 calculator, and a family of numerical tasks related to notions of factors and divisors. This study sheds further light on the interaction among technique, task, and theory in the instrumentation process by showing the crucial importance of the role played by the pupil's need for control of the mathematical situation.

Introduction

In research on the use of technology in the teaching and learning of mathematics, increasing mention is being made of two distinct ways of viewing tools, according to a theory elaborated by Verillon and Rabardel (1995), that is, as artefacts and as instruments. For example, Mariotti (in press, p. 10) states:

It is useful to make the following distinction; on the one hand there is the artefact, that is, the particular object with its intrinsic characteristics, designed and realised for the purpose of accomplishing a particular task, and on the other hand there is an instrument, that is, the artefact and the modalities of its use, as are elaborated by a particular user.

In accord with this theoretical approach, remark that it is the subject who transforms the artefact into an instrument by means of precise and well-organized actions, identified as "utilization schemes." Thus, a finer definition of instrument can be formulated:

An instrument is an internal construction, the development of which is a long-term process; that means that at different moments, different instruments are concerned, although the same artefact is actually used. (ibid)

According to Verillon and Rabardel (1995), the transformation of artefact to instrument is a complex construction:

A machine or a technical system does not immediately constitute a tool for the subject. Even explicitly constructed as a tool, it is not, as such, an instrument for the subject. It becomes so when the subject has been able to appropriate it for himself--has been able to subordinate it as a means to his end--and, in this respect, has integrated it with his activity. (p. 85)

Trouche (2000, p. 242) has described instrumental genesis as a combination of two processes: "A process of instrumentation by which the subject adapts self to the tool and a process of instrumentalization by which the subject adapts the tool to
In the former process, "instrumental genesis is directed towards the subject, and leads to the development or appropriation of schemes of instrumented action which progressively constitute into techniques which permit an effective response to given tasks" (Artigue, 2001, p. 5). Recently, researchers (e.g., Guin & Trouche, 1999; Lagrange, 2000) have attempted to focus on related factors involved in the instrumentation process by which techniques are constituted. They point, for example, to the role played by technique and the task itself in the development of mathematical theory by the student. In fact, according to Lagrange (in press, p. 2), it is helpful to view technique as a link between tasks and conceptual reflection:

A technique is generally a mixture of routine and reflection. It plays a pragmatic role when the important thing is to do the task or when the task is a routine part of another task. It plays also an epistemic role contributing to an understanding of the objects that it handles particularly during its elaboration. It offers also an object for conceptual reflection when comparing with other techniques or discussing its consistency.

Within the framework of the above research studies, we present in this paper a case study of instrumental genesis involving a 14-year-old pupil, the multi-line-screened TI-73 calculator, and a family of numerical tasks related to notions of factors and divisors. This study sheds further light on the interaction among technique, task, and theory in the instrumentation process by showing the crucial importance of the role played by the pupil's need for control of the mathematical situation.

THE RESEARCH STUDY

GENERAL BACKGROUND

The research project consisted of two phases--the first in 2000 and the second in 2001. In each phase, six classes of Secondary 1, 2, and 3 students (12 to 15 years of age) participated, from schools in Cuernavaca and Montreal. The same basic problem situation was used in both phases, and the technological tools were similar (the TI-83 Plus in the first phase and the TI-73 in the second). The general aim of the research project was to investigate the nature of the mathematical strategies that emerged, as well as their evolution, in the context of particular calculator activities both within and across grade levels. The experience of the first phase led to three main adjustments in the second phase: a modification of some of the tasks; a refinement of the theoretical framework, along the lines described above; and the introduction of the classroom view-screen as a methodological tool that provided a trace of all the calculator attempts of certain students for a given task. The basic problem situation, "Five steps to zero," was as follows:

"Take any whole number from 1 to 999 and try to get it down to zero in five steps or less, using only the whole numbers 1 to 9 and the four basic operations +, -, x, ÷. You may use the same number in your operations more than once." (based on Williams & Stephens, 1992)
A set of 10 worksheets were developed to accompany the basic problem, with questions such as, "Here is a way of getting 432 to zero (a six-step method was given); show how you would do it in fewer steps; explain your strategy"; "The number 266 has as divisors 2, 7, and 19; what would you say is the best strategy for getting 266 to zero in the fewest number of steps; why?"; "Pick a number (less than 1000) that you think would be a hard one for the other group to get to zero in five steps or less; say why you think it is a hard number." Students were also given a brief pretest inquiring into their: (i) use of and attitudes toward calculators; (ii) knowledge of divisors, multiples, and primes. An individual interview with four students from each class was carried out at the end of the week-long activities.

The research was carried out in each class during five consecutive mathematics periods (50 minutes each). The students worked in groups, each student having her/his own calculator. While students were busy with their worksheets, there was always one student at the front of the class doing his/her work with a calculator hooked up to the view-screen that was video-taped (Phase 2). As well, the ensuing classroom discussions and student demonstrations of their strategies were videotaped.

The analysis of student strategies that emerged at each grade level and the way in which they evolved over the course of the first phase of the study was reported at PME last year. For the second phase of the study, rather than focusing on global trends, we decided to concentrate our analysis on the development in the thinking of individual students in the participating classes and to situate that analysis within the theory of instrumentation. Of the series of case studies emerging from this phase of the research, we present in this paper the story of Nicolas—a rather bright, Secondary 2 student, who seemed to enjoy mathematics.

THE CASE STUDY
Nicolas's initial strategy and its evolution
From the beginning, Nicolas's strategy was to find the largest divisor possible for the given number, and if it was not immediately divisible to then use trial-and-error until he obtained a number that would be divisible. However, by the third worksheet, this method was proving itself to be rather unsatisfactory to him (see Figure 1). The given number was 732. The way in which his first two attempts are crossed out—with large Xs and scribbling out of some of the steps—suggests the frustration that might have been mounting. Even though Nicolas's third attempt with 732 was successful in the required five steps or less, we notice that he continued in his efforts. In the fourth attempt, there seems to be no trial-and-error, as would be evidenced by mid-step additions/subtractions, and he arrives at zero in only four steps. One wonders whether his strategy is changing, but nothing to that effect has been made explicit.

It was not until the sixth worksheet where the technique that was hinted at, on the fourth attempt with 732 of Worksheet 3, was stated explicitly. On Worksheet 6,
when he was asked explicitly for his strategy at getting 731 down to zero in fewer than 5 steps, he wrote (translated from the Spanish text): "First I multiplied 9x9x9 and I obtained 729. After that I noticed that 731-2 was 729. So I did the same operation, but in reverse."

The interview with Nicolas during the following week

It was during the individual interview with Nicolas that we were able to explore further Nicolas's use of his new, instrumented scheme, which had progressively become constituted as the product-of-factors technique. At a certain moment during the early part of the interview, Nicolas was asked what he would do if the given number was not divisible by a number between 2 and 9 on the first step (I = Interviewer; N = Nicolas), to which he said that he would add or subtract:

L2: ansx3 243  
L3: 9x9x4 324  
L4: 9  
L5: 9x9x5 405  
So, like that, I arrive more quickly  
L6: 9x9x5 405 | Legend for calculator screen transcription: Ln--refers to line on the screen (note that the TI-73 can display seven lines at a time, and then scrolls); A screen-line that is crossed out is one that the student has deleted from the screen. |
37. I: But I said 431. With this strategy that you have just described, how do you begin?

38. N: First, 9x9xsomething, no? Until arriving close to the number. For example, 
   L7: 9x8x6 432
   He now controls the last two factors at the same time. The 9 is reduced to 8 while the 5 is increased to 6. Quite astonishing!

39. I: Yes, I told you 431

40. N: So, 431 plus 1, divided by 6, divided by 8, and so on.

41. I: Again, to bring the task to its conclusion

42. N: So, 431 plus 1, divided by 6, divided by 8, and so on.

43. I: Let's see.

44. N:
   L8: 431 + 1 432
   L9: 432/6 72
   L10: ans/8 9
   L11: ans - 9 0
   He enters his solution into the calculator.

Our analysis of the technique developed by Nicolas suggests that, in lines L2, L3, and L5, he may have been thinking about 81 as the basic unit and realized that 4 groups of 81 (9x9x4) would yield a product that is 81 units larger than 9x9x3. This would have given him rapid approximations of the increasing order of magnitude of the successive products. However, it is not at all obvious when he reached 9x9x5 (yielding 405) why he decided to decrease the second 9 to 8 and increase the 5 to 6 as a means of reaching a number close to 431. Did he "see" that the difference between 9x5 groups of 9 and 8x6 groups of 9 was 3 groups of 9, thus increasing the product of 405 by 27? However, he never did elaborate on how he was able to arrive so quickly at the appropriate factors.

As well, we never witnessed him using this technique with numbers larger than 738, which is 9 more than the product 9x9x9, and thus solvable in four steps. We are of the opinion that, while he could control three factors, four were beyond his range. Thus, by the end of the study, Nicolas appeared to possess the following hierarchical array of instrumented techniques for the tasks of the given family of situations: i) See if the given number is immediately divisible by a largish number, such as 9,8,7, or 6--the division technique; ii) If not, and if it is less than 739, use the product-of-factors technique that he had seemed to generate within the course of the research study; iii) Resort to various trial-and-error combinations of addition/subtraction and division.

DISCUSSION

USE OF SEVERAL INSTRUMENTS FOR THE SAME ARTEFACT IN THE COURSE OF A GIVEN SITUATION

Within the context of this study, there are two issues that arise in the process of instrumentation. One is related to the development of new instrumentation schemes, and the other to their use in given situations. Treating the latter first, we refer to a
comment made earlier: "At different moments, different instruments are concerned, although the same artefact is actually used" (Mariotti, in press, p. 10). The Instrumented Activity Situations model as developed by Verillon and Rabardel "does not cover all the characteristics of situations where activity is instrumented: for instance, the fact that a same subject may use several different instruments in the course of a complex action" (1995, p. 85). Thus, a question of interest in our analysis was whether the subject was aware of his/her use of several instruments within a given task and what might be the mechanism driving their differentiated use.

As will be seen from the following protocol extract, Nicolas was quite aware of the two schemes of instrumented action that he was using (see especially the episode of line 64, along with the follow-up in line 66), as well as his reasons for trying the division technique before going on to use the product-of-factors technique. It was simply a question of speed and efficiency (line 48).

Drawing on the information that his product-of-factors technique had produced for the previous problem (L5 of 64), he does a quick check (L1). From L2, he applies the results of the technique.
NEED FOR MATHEMATICAL CONTROL AS A MOTIVATION FOR THE DEVELOPMENT OF NEW INSTRUMENTATION SCHEMES

The driving force behind Nicolas's development of new schemes of instrumented action is conjectured to be the need to use the calculator artefact in the search for problem solutions in the most efficient manner possible. The scribbled-out work of his third worksheet, included above in Figure 1, suggested a distaste for his initial technique, one that combined division and repeated trial-and-error. This technique did not always allow him to advance in a clear way towards a solution. Quite quickly (by Worksheet 3), he seemed to tire of the trial-and-error component and want to have more control of the problem situation. We postulate that this mathematical need was the basic mechanism underlying the generation of his new instrumented scheme, a scheme oriented toward working in the opposite direction by means of multiplication of factors.

Obviously, Nicolas's technique of manipulating sequences of three factors was presently limited, within the context of the given family of tasks, to whole numbers less than 739. We have little doubt that, had the research activities continued over a longer period of time, his mathematical needs would have pushed him to extend the utilization scheme that he had developed so as to handle larger numbers. "An instrument is rarely definitively constructed; schemes evolve" (Trouche, 2000, p243).

ROLE OF THE TOOL IN THE CONSTITUTION OF TECHNIQUES

A thornier issue concerns a subtler question, that of the role played by the technological tool, in this case the multi-line calculator, in the development of the product-of-factors instrumentation scheme. When we consider the triad, technique-theory-task, it seems likely that, for Nicolas, the technique was constituted in response to the task and that the technique contributed to his further understanding (the theory) of the mathematical object--in this case, the interplay between divisors and factors. What is less evident is the extent to which the constitution of the technique was provoked by the affordances and constraints of the artefact. Clearly, the task was one that lent itself to the use of the calculator artefact. And perhaps the speed with which the calculator is able to carry out the demands of the user leads him/her to think about developing new approaches that would not have occurred in a paper-and-pencil environment. However, this factor is much harder to access. Certainly, Nicolas was NOT of the opinion that the calculator "helped him to think."

At the end of the interview, he was asked what role the calculator had played for him in these problems:

N: Well, for the operations, I did them more rapidly and I knew if the numbers were divisible or not. The other way [i.e., with paper and pencil] I would have to do each operation: divide like we do normally and that would take me much more time in everything that we have just done.

I: Do you believe that the calculator helped you to think?

N: No.
I: When you told me: 'First I look at the number, I do multiplications by 9, and I see if I am approaching the number.' Doesn't that mean that it helps you to think?

N: In my opinion, no. Because I think first about a procedure and how I could do it, and only afterwards I enter the numbers into the calculator and see the results.

Despite his claim that he thinks first before using the calculator, there were rarely any noticeable pauses on his part while using the calculator during his interview—even when he was manipulating various factor combinations. Even though the result presented on the calculator screen served as a basis for his next thought, Nicolas was unwilling to give it any more status than the result he might have generated by paper and pencil. Thus, the use of the calculator as a "tool to think with", in tasks of a numerical nature, is a concept that certain calculator users seem unwilling to entertain.

It was pointed out earlier that, according to Varillon and Rabardel (1995, p. 85), a tool becomes an instrument for the subject when "the subject has been able to appropriate it for himself--has been able to subordinate it as a means to his end--and, in this respect, has integrated it with his activity." Nicolas had certainly subordinated the calculator as a means to his end, and it had thereby become an instrument for him. However, the instrumented scheme he developed, which became constituted as the product-of-factors technique, did not—in his opinion—include explicit ties to the artefact, despite the fact that the tasks were calculator-based to begin with. Nicolas seemed to view his need to control the mathematics of the situation (the task) in a 'thinking' way (the theory) as the basis of his new technique.

REFERENCES

The goal of this paper is to exemplify a model of design-oriented research, based on four different analyses of an inquiry activity, concerning proving in geometry. The designers' intention in this activity, was to create geometrical situations in which students will confront contradictions between their conjectures and findings, face uncertainties concerning the right conclusions, and thus search for explanations that will settle the uncertainties. In this way normative explanations in geometry might stem from students' need for justification. The first two analyses reflect the beliefs, hypotheses and intentions of the designer-researcher concerning the potential of appropriate situations to lead to a meaningful activity. The third and the forth analyses are experimental: students' conjectures and explanations serve as the database against which the task potential is validated.

INTRODUCTION

In this paper we exemplify a model of design oriented research, based on four different analyses of an inquiry activity, concerning proving in geometry. This model is based on the hypothesis, that it is possible to design geometrical inquiry situations, in which students are confronted with contradictions between their conjectures and the findings of their investigations in a Dynamic Geometry (DG) learning environment. These contradictions might lead students to uncertainties concerning the right conclusion, and thus push them to search for explanations, which may settle the contradictions. Since the only satisfactory explanations for this kind of situation are deductive (satisfactory in the sense that they can settle the mathematical contradictions), students might naturally appeal to such explanations.

For investigating this hypothesis, a few inquiry activities were designed in a DG environment in a process of design-research-design, as described in Hershkowitz et al. (in press). The design of these activities, intended to lead students towards contradictions in two ways, (see Figure 1).

\[\text{Design of activities with potential for contradictions between conjectures and conclusions in two different ways.}\]

\[\begin{align*}
\text{(1) The findings contradict} & \quad \text{Explanation for the surprising conclusion.} \\
\text{the conjecture.} & \quad \text{An explanation that points to the right conclusion, and provides conviction.} \\
\text{(2) The findings do not lead} & \quad \text{to a definite conclusion and} \\
\text{thus, create uncertainty.} & \quad \text{An explanation that points to the right conclusion, and provides conviction.}
\end{align*}\]

Figure 1: Two ways to contradiction

Our approach to the design of meaningful ways for teaching/learning to prove in geometry, is in agreement with the wide consensus of mathematics educators and researchers that proving activity should involve different actions, like discovery and
reinvention, conjecturing followed by confirmation or refutation, including confrontation with situations of uncertainty (Chazan & Yerushalmy, 1998; Hoyles, 1997; Goldenberg, Cuoco & Mark, 1998; de Villiers, 1998).

THE TASK AND THE RESEARCH POPULATION

In this paper we will relate to one activity and exemplify the four analyses mentioned above.

The task:

Divide the side AC of a dynamic triangle into 3 equal segments. Connect the division points to the vertex B (Figure 2).

Make conjectures about the 3 varying angles (\(<ABD, <DBE, and <EBC\)).

Use the software to decide when (if ever) the three angles are equal. You may change your conjecture and check.

Describe your investigation and explain your conclusion.

Figure 2: The three angles task

The above task is the product of a first stage of the design-research-design process, described in Hadas & Hershkowitz (1998), and has served as the "research tool" for the model mentioned above, and which will be described in detail below. The task was first used in semi-structured interviews with three pairs of students and then given as a written activity to all students in three classes, which were invited to work collaboratively in pairs. The students were all ninth graders, and had already had a year-long course in Euclidean geometry. Altogether 32 reports were collected (three from the interviews and 29 from the three classes in two different schools).

The interviews enabled us to qualitatively trace the changes in students' conjecturing and explanation processes. The transcriptions of the interviews and the written reports of students working in pairs in classrooms were collected and analysed. The results of these analyses enabled us to investigate quantitatively and qualitatively students' conjectures and explanations, and hence to clarify to what extent students faced contradictions as well as to make categories of students' explanations.

THE FOUR ANALYSES

Analysis no. 1: Epistemological analysis of the activity

The epistemological analysis demonstrates all possible investigation paths in the designed activity, without giving preference to any of them. This analysis is summarised in Figure 3.
The 3 angles are always equal.

The 3 angles are equal in special cases.

The 3 angles will never be equal.

Starting with the conjecture in ellipse 1, 'the three angles are always equal', may lead students towards experimentation, which refutes this conjecture. This path exemplifies the first way of contradictions, (see Figure 1). After refuting this conjecture students may omit the 'always', and join those who conjecture 'equality in special cases' (ellipse 2). For checking this conjecture students may move from example to example, checking with the software and refuting every new conjecture concerning a special case in which equality seems possible (left and middle 'bold paths'). Thus, students are led to a situation of uncertainty where they don't know whether an example of equal angles exists. This may lead them either to raise a different conjecture about equality or to the conjecture that 'the three angles will never be equal' (ellipse 3) followed by an explanation (represented in the path on the right side of Figure 1).

Analysis no. 2: Didactical characteristics of the activity

This analysis is based on the previous one, and reflects our intention as designers, to create favourable conditions for contradictions and uncertainties. In this design we took into consideration students’ common belief that opposite equal segments in a triangle, there are equal angles, and the power of DG to check if there are ‘equal angles situations’ ('bold paths' starting at ellipses 1 or 2 in Figure 3.) As the angles' equality situation is impossible, it was hypothesise that students will confront repeating refutations ('bold middle path in Figure 3). Thus the investigation involves uncertainty, namely not knowing whether one must look for an existence example or for an explanation why such examples do not exist (ellipse 3). The role of the DG software in this activity is not to provide an answer but to enable students to
experiment (i.e. to manipulate geometrical entities involved, to refine their conjectures, then to refute them). The DG environment may also influence students’ explanations.

The following third and fourth analyses describe the data concerning the students’ real actions (their ways of investigating the task), and study their meaning.

**Analysis no. 3: Conjectures raised by students**

Here we describe students’ initial conjectures and investigate to what extent they contradict the findings. We also describe how these conjectures are changed during the students’ work. The analysis of the conjectures is based on the first analysis of the possible investigation paths (Analysis no. 1), and will be described here on the basis of Figure 3.

From the 32 reports that were collected, we had altogether 35 conjectures (the students in the three interviews conjectured individually).

Stage I: In 18 conjectures it was claimed that the three angles ‘would always be equal’. The other 17 conjectures specified that the angles ‘would be equal in special cases’ like in isosceles or at least in equilateral triangles. At this stage, no one raised the conjecture, represented in ellipse 3, that ‘the three angles would never be equal’. Constructing, measuring and dragging actions, using the software, immediately refuted the conjecture in ellipse 1, and convinced the 18 students that the angles ‘are not always equal’. After this conjecture was refuted these students joined the 17 others and dragged the figure, trying to find cases of equality. This first stage of conjecturing is demonstrated in Figure 4 (Stage I).

![Figure 4: Stages I and II of conjecturing](image)

Stage II: In 15 out of the 35 reports, after dragging the figure and measuring, students moved towards the conjecture that ‘the angles will never be equal’. The
remaining twenty moved in circles, from the search for examples to new conjecture. This second stage of conjecturing is also demonstrated in Figure 4 (Stage II).

Stage III: This process, of moving in circles, continued until 19 of the pairs joined the previous 15, in conjecturing that the three angles ‘might never be equal’ (ellipse 3). These 34 pairs of students began to search for a satisfactory explanation for the impossibility. The 35th pair removed vertex B so far from edge AC that the angles became small and numerically equal on the computer. They then concluded that there is a case for which the angles are equal. This Third stage of conjecturing is demonstrated in Figure 5.

Stage III

The 3 angles are equal in special cases.

The 3 angles will never be equal

15+19

Experimenting

Refutation

Explanations

Figure 5: Third stage of conjecturing

In summary: All students began their work with conjectures, which contradict their final conclusion. Following the stages demonstrated in Figures 4 & 5, we conclude that all students choose investigation paths that lead to refutations and confrontation with uncertainty, and thus acted out the didactical intention described in Analysis no. 2.

Analysis no. 4: Explanations

In the previous analysis we concluded that all but one of the pairs followed at some stage the path starting in ellipse 3, which led them to search for an explanation why the three angles will never be equal (see Figure 5). We collected 34 explanations, which were categorised by the first author and two experienced teachers with agreement among all three in 88% of the cases. When full agreement was not attained, explanations were categorised according to agreement between two of them.

The goal of the categorisation is to find qualitatively and quantitatively (1) whether and how students use deductive considerations in their explanations; (2) whether and how students are influenced by the DG environment in their explanations (whether
they use examples created on the screen to explain the findings inductively, or whether they make use of the dynamic variation of the figures on the screen, to explain their findings). Thus, we defined five categories emphasising these aspects.

In the following we will first describe each of the five categories with examples. (Examples from two other activities of the research are described in Hadas, Hershkowitz & Schwarz, 2000.) Then some quantitative information, concerning the number of explanations classified in each category will be given.

**Categories of explanations**

* No explanation

This category includes responses without any argument, and responses that were mainly tautological (in which students rephrased their conclusion or the results obtained on the screen).

Example 1: One pair explained why the three angles cannot be equal as follows:

* Such a case cannot be obtained, as there is always something that messed it up.*

* Inductive explanation

This category includes responses in which students based their explanations on one or more examples. Sometimes students’ examples were taken from what appeared on the screen and sometimes students drew their own examples on paper.

Example 2:

* There is no possibility that the three angles will be equal because we checked with the computer several triangles (equilateral, isosceles etc.)*

* Partial deductive explanation

This category includes responses in which students constructed a chain of deductive arguments but at least one link is missing or wrong.

Example 3:

* There is no situation in which, the three angles will be equal because if there was one, the four segments from B would be equal too (BA=BD=BE=BC), but this is impossible since only two segments from B to line AC can be equal.*

Students in this category constructed a short chain of deductive arguments. It is partial because some arguments were neglected; for instance, they didn’t explain the connection between their conclusion concerning the equality of the four segments from B, and the assumption of the angles’ equality.

* Visual – variation explanation

In this category we include explanations in which students made use of visual variation, as a result of the dragging action or of their imagery. As such this category is typical for explanations in a DG environment.
Example 4: After trying to find a case of equality for the three angles and concluding that such a case doesn’t exist, one girl in an interview explained while dragging the triangle on the screen:

I thought that maybe if I drag B up and angle B will become small, the angles might be equal, but then it [the figure] doesn’t look like a triangle anymore, it will be more like a line. So it is impossible to get the 3 angles to be equal.

She accompanied her explanation with moving her hands up showing how the triangle becomes thinner.

* Deductive explanation

In this category we include explanations that consist of a complete chain of logical arguments.

Example 5:

Let us assume that the 3 angles are equal (see Figure 2 above). EC = ED and thus ΔBDC is an isosceles triangle as the median and the angle bisector coincide. ΔBEA is also isosceles as the median [BD] coincides with the angle bisector. Thus BE and BD must both be altitudes and we have two different perpendicular segments from point B to AC which is impossible.

The quantitative data (number of explanations and percentages in each category) are given in Table 1.

**Table 1: Classification of students’ explanations**

<table>
<thead>
<tr>
<th>No explanation</th>
<th>Inductive</th>
<th>Partial deductive</th>
<th>Visual-variation</th>
<th>Deductive</th>

<td>8 (23%)</td>
<td>14 (41%)</td>
<td>4 (12%)</td>
<td>4 (12%)</td>
<td>34</td>
</tr>
</tbody>
</table>

It is important to note that: (1) The examples of partial deductive explanations (Category 3), described here and in Hadas, Hershkowitz & Schwarz (2000) demonstrate that in spite of the fact that these explanations do not comply with the criteria for normative proofs, students tend to rely on their geometrical knowledge and use deductive strategies to explain their conclusions. Thus, in eighteen out of the 34 explanations, students used deductive arguments (fourteen partial deductive explanations and four deductive). (2) We found that twelve explanations were based on experimenting with the DG software and resulted either in inductive generalisation (eight explanations), or in a visual explanation based on the variations of the figure caused by dragging (four explanations).

**CONCLUDING REMARKS**

This work exemplifies two issues: The first is the ‘four analyses model’ of design oriented research, in which the planning work and the intentions of the designer are the basis for experimental research, and the research findings concerning students’
responses serve as the database against which this planning work and these intentions are validated. The second issue relates to the specific content, in which the model was demonstrated, namely proving in geometry. Through the four analyses of the above model we demonstrated our approach to teaching/learning this controversial topic.

REFERENCES

This report builds on our previous work on graphical conceptions using a diagnostic tool specially constructed to elicit graphical misconceptions, but also designed to function as a questionnaire for assessing teachers' pedagogical content knowledge (PCK). In this study we investigated 12 teachers' judgements of the difficulty of the items, their proposed learning sequences and their awareness of errors and misconceptions. We present a teachers' perception of difficulty hierarchy and contrast it with the learners' difficulty hierarchy. Results showed that teachers' judgement of what is difficult is structured by their curriculum and also their knowledge to be highly sensitive to the methodology adopted to collect it. This provokes us to develop a situated, social practice perspective on teacher knowledge, in which tools and instruments mediate teacher knowledge and its impact on practice.

INTRODUCTION AND BACKGROUND

This paper extends previous work on teachers' awareness of their pupils' errors and misconceptions, in the context of graphs, which Shulman (1986) classified as Pedagogical Content Knowledge (PCK). Shulman refers to PCK as knowledge 'which goes beyond knowledge of subject matter per se to the dimension of subject-matter knowledge for teaching' (p.9), which includes 'the ways of representing and formatting the subject that make it comprehensible to others' (p.9) and hence relies on an appreciation of learners difficulties and misconceptions. This categorisation was designed to draw attention to the traditional (but not historic!) underemphasis on PCK as opposed to other forms of teacher knowledge such as subject matter knowledge. He proposes that such knowledge is required in the triple forms of propositional, case-based and strategic knowledge. These might include research knowledge transformed for teaching, e.g. empirically-based propositions organised theoretically or conceptually, but rich in examples of memorable, prototypical cases (the analogy with case study seems applicable) and the strategic judgment to use the knowledge effectively in practice. In this paper we discuss teachers propositional and case knowledge of their learners' graphicacy.

Leinhardt et al (1990) reviewed the literature on functions and graphs and said, "of the many articles we reviewed almost 75% had an obligatory section at the end called something like 'Implications for teaching' but few dealt directly with research on the study of teaching these topics" (p. 45). A little later, Norman (1993) characterised research on teachers' knowledge on functions and graphs as insufficient or even non existent. He also stresses that 'there is little in the research literature documenting either what teachers know or the nature of their knowledge' (p.180). Williams (1993) also argues that 'the study of functions and graphs with an eye
towards informing teaching and learning is in its infancy’ (p.314).

We would add that the ‘teaching implications’ drawn from research on the psychology of learning mathematics are in any case in general problematic: for many reasons these rarely impact on practice. In particular teachers need to know at which stages of their development pupils are likely to exhibit the researched misconceptions and errors and where in the curriculum they are relevant. Williams and Ryan (2000, 2001) produced such data for errors scattered across the curriculum. Hadjidemetriou & Williams (2001) developed similar work by focussing in depth on the area of ‘graphical understanding and interpretation’ relevant to years 9 and 10 of the mathematics curriculum, using a diagnostic instrument based on previous cognitive research in the field. In this study we have developed this instrument to function as a questionnaire for assessing teachers’ awareness of the difficulties and errors this diagnostic instrument reveals.

**METHOD**

The development of the original pupils’ diagnostic assessment instrument is described in Hadjidemetriou and Williams (2001). Briefly, we mention that it involved the tuning of, or the development of, diagnostic items from the research literature on graphacy which related appropriately to the following errors: slope-height confusion; linearity-smooth prototypes (Leinhardt et al, 1990); ‘y=x’ prototype; the ‘origin’ prototype; graph as ‘picture’ (Clement, 1985); reversing or misreading co-ordinates; misreading the scale (Williams and Ryan, 2000). The test can be seen in full on the web at http://www.education.man.ac.uk/ita/ch/.

In this study the diagnostic test was then given as a questionnaire to the teachers (N=12) with instructions that they should answer all the items and:
- predict how difficult their children would find the items (on a five-point scale starting form Very Easy, Easy, Moderate, Difficult, Very Difficult)
- suggest likely errors and misconceptions the children would make and
- suggest methods/ideas they would use to help pupils overcome these difficulties

Teacher’s predictions of the difficulty of the items were subjected to a rating scale analysis (Wright and Masters, 1982). This provides an item-perception difficulty measure and consequently items can then be ranked according to their difficulty estimate. Their pupils’ test results (N=425) were analysed using the Rasch model in order to get a pupil difficulty estimate for each item.

This data is used to explore the state of the subject matter and pedagogical content knowledge of this small group of teachers. The teachers were chosen as being thought to be knowledgable, leading teachers involved in training and management. We ask: ‘What do teachers know and what can they recall about their students’ problems/difficulties in graphacy’? The teachers were also interviewed using a semi-structured format based on the way they introduce graphs to their classrooms, problems and difficulties students have in graphacy, and how they teach graphs. These themes were used also in categorisation during transcript analysis.
RESULTS

The questionnaire data were subjected to a rating scale analysis and the item-perception-difficulty measures that resulted were correlated with the pupils 'actual' difficulty as estimated by the test analysis (rho=0.395). However, the teachers' estimates were significantly awry on seven items. When the seven worse items (having an absolute difference more than 2) were excluded from the analysis the correlation increased to rho=0.65. Their mis-estimation of their (relative) difficulty could be explained by one of the following reasons:

1. in at least three items the teachers underestimated the difficulty for the children because they apparently misunderstood the actual question themselves, i.e. they had the misconception the item was designed to elicit, or they had a limited understanding that did not receive full credit. We interpret this as subject knowledge.

2. on two items the teachers' overestimated the difficulty because they did not realise the children could answer the question without a sophisticated understanding of gradient. This was interpreted as pedagogical content knowledge.

'Story 3', was the name of the most discrepant item with teachers underestimating its difficulty. It required pupils to draw the 'Height of a person' from Birth up to late thirties. A closer look at some of the teachers’ graphs below illustrates the problem. Prototypes such as the 'Origin' (pupils’, and here teachers’, tendency to draw all their graphs through the origin) and 'Linearity' are dominant.

Figure 1: Two teachers’ graphs for the ‘Story 3’ Item

‘Transport 1’ (shown below) was an easy question according to pupils’ answers but some teachers seem to have given quite high difficulty ratings. These teachers believed that pupils had to be aware that the slope of the distance-time graph represents the speed of each transport. Pupils’ transcripts verify that they could find the answer by looking at the time taken for each transport to travel to school:

INT: How can you see that it (A) is quick and that D is slower?
Sara: Because ...
Andrew: It takes more time.
Sara: Yes it takes more time. It takes more time to get to the same part. It takes 40 minutes to get to school and the others it takes 15, 10...

The graph shows journeys by four different means of transport from home to school, a distance of two kilometers: Bus, Car, Walking, Bicycle. Match each line with the appropriate transport.

Distance traveled from home

Table 1 shows teachers’ proposed difficulty sequence described in 5 levels. Compared to pupils’ hierarchy (Hadidemetric and Williams, 2001) it yields significantly different results.

The table suggests that teachers have ranked the items in a ‘curriculum’ hierarchy. The bottom of the teachers’ difficulty sequence is centred around pointwise reading. Further on teachers rate as slightly harder, items involving scales, parallel graphs and calculating the gradient. Interpretation of simple travel graphs is also included in this level.

In addition, this hierarchy matches the sequence of teaching evident in 6 teachers’ descriptions of their curriculum during the interviews. They usually neglected the qualitative/interpretative perspective of graphs at the beginning of their teaching sequences and were preoccupied with abstract and algebraic aspects of graphs. For example:

SW: Starts of co-ordinates, study of co-ordinates. Exercising and using co-ordinates as positioning on a grid relative to a given plane, the origin. This is lower down the school, Year 7 Year 8. And then from there taken on to ordered pairs connections between x and y, mapping diagrams giving ordered pairs and then from that trying to take it on to equations. Straight lines and then on to curves.
INT: Straight line and then curves.
SW: And then when they’ve done that the use of obviously, em, apply to everyday sort of situations as well.

Table 1: Teachers’ Perception of Scale of the items of the Diagnostic Questionnaire  
(in bold are major teachers’ misjudgements i.e. relative misordering compared to pupils’ hierarchy and in brackets, whether the items became Harder or Easier)

In the first two levels then, construction/algebraic related items are dominant. Teachers have only included here one contextualized task (the item called ‘Transport 1’ described above) and this resulted in the algebraically related items shifting downwards from their actual difficulty. For example calculating the gradient was an item located at the top of the pupils’ difficulty sequence whereas teachers have awarded it a rather moderate difficulty.

Another underestimated item (Interpreting the meaning of \((0,0)\) in context), located at the bottom of the teachers’ difficulty scale (together with the rest of the coordinate-related items) was an item asking ‘Why does the graph pass through the origin?’
Teachers’ failure to consider possible terminology problems (pupils who were not aware of the meaning of the word ‘origin’) shifted this item downwards in difficulty. Teachers’ attention to the abstract perspective of graphs also explains why the difficulty of several qualitative tasks involving interpretation (the slope height confusion) and sketching graphs to tell a story were overestimated.

This bias also had an impact on the errors and misconceptions they mentioned during the interview. The transcripts refer mainly to errors/difficulties such as: reversing the x and y, mapping an equation to the graph, substituting negative numbers, inaccuracy in plotting, calculating the gradient as ‘x over y’, generating points from equations and misreading the axes. However in the questionnaire the teachers were also encouraged to list the misconceptions that children might exhibit. Here we summarise the misconceptions they mentioned during the interview or in the questionnaire:

Table 2: Misconceptions mentioned by 12 teachers in interview or in the questionnaire
q/i/qi: indicate whether the misconception/error was mentioned in the Questionnaire (q), Interview (i) or both (iq)*: indicates the teachers who were both interviewed and answered the questionnaire.

In summary we found that the 12 teachers had (a) most difficulty in identifying the linearity (1/12 teachers) 'origin' and 'y=x' prototype (2/12 each) conceptions, (b) moderate difficulty in identifying the slope-height confusion, and the problem with order of co-ordinates (5/12 and 7/12 teachers), and (c) least difficulty in identifying the picture-as-graph and misreading of scale problems (8/12 and 10/12 teachers respectively). However, teacher knowledge of the seven different misconceptions varies dramatically, with half the teachers mentioning only one or two of them, and two of the teachers mentioning all but one of them.

Most strikingly, indications of teachers’ knowledge seem highly sensitive to whether the data comes from the Questionnaire or the Interview. The different data sources suggest that much of the teacher’s knowledge is tacit, and elicited when provoked by an example question. Only explicit propositional knowledge is usually suggested spontaneously in interview without the questionnaire prompt.

CONCLUSIONS AND DISCUSSION

A diagnostic test designed from the graphicacy research literature and calibrated for
pupils diagnostic errors was here further developed as a tool to investigate teachers’ knowledge about their learners. This was supported by semi-structured interviews.

The conclusion is that:

(a) some teachers harbour misconceptions themselves, revealing some weaknesses in subject knowledge: eg the linearity prototype

(b) very few of the common errors or misconceptions are called up spontaneously in questioning at interview, and these generally concern the technical and algebraic aspects, not the 'interpretative' misconceptions, but

(c) a much wider range of errors are offered in response to the ‘diagnostic’ questionnaire, and

(d) there is some mismatch of the teachers' perception of difficulty and the students actual difficulty, with teachers underestimating technical aspects of graphing and overestimating the difficulty of the interpretative.

Empirical evidence suggests that teachers' knowledge as elicited from the interviews was structured around their curriculum descriptions, was rich in algebraic and abstract elements of graphs but lacking in the interpretational. However, the questionnaire acted as a tool that bridged the gap, apparently bringing to the surface tacit awareness of their children. This is consistent with a theoretical approach which insists that knowledge is situated, even distributed (Hutchins, 1990), and confirms our belief that researchers can have an impact on teaching through the development of such pedagogical tools and instruments. As Engestrom (1987) puts it, one of the roles of R&D activity on an activity system is to develop more advanced tools and artifacts of various kinds which mediate the practice of the system. In our case we see a well-designed diagnostic assessment as just such an instrument for advancing practice.

However, we are less sanguine about the nature of the knowledge that these teachers were able to evidence with the diagnostic tool. We draw a distinction between an error, i.e. erroneous responses to a question, and a misconception which may be a faulty cognitive structure that lies behind, explains or justifies the error. (Some errors may be symptomatic of a misconception, while others may not). If teachers can predict their pupils’ errors, does this mean they can diagnose them? This diagnosis is an essential link between 'case knowledge' (in the sense of knowledge about typical errors based on classroom practical experience) and 'propositional knowledge' (in this case knowledge of students conceptual development and misconceptions). We suggest that the link between ‘case knowledge’ and ‘propositional knowledge’ is generally best conceptualised not just as a cognitive one, but one which is socially structured, and in particular it can be mediated by tools-in-practice. We will develop this theoretical analysis of cognitive and situated perspectives on Shulman's categorisation further in the presentation.
The purpose of the paper was not to generalise empirically from these teachers’ pedagogical content knowledge but to suggest a methodology for evaluating and maybe developing this knowledge. There seems to be a gap between pupils’ difficulties and teachers’ perception of these difficulties. Our concern is to provide research findings and propose a methodology that will help to bridge this gap.

DEVELOPING TAKEN AS SHARED MEANINGS IN
MATHEMATICS: LESSONS FROM CLASSROOMS IN PAKISTAN

Anjum Halai
Aga Khan University, Karachi Pakistan

This is a study of the role of social interactions in students’ learning of mathematics. The study was based in two classrooms in Karachi, Pakistan. A small group of students (10-12 yr.) doing mathematics was observed in each classroom.

Methodology used was qualitative in nature. Participant observation was the primary mode of conducting the research. To follow up on questions emerging from ongoing observations students were interviewed under stimulated recall. Analysis was through grounded theory procedures (Strauss & Corbin, 1998).

The teachers had initiated a change in the social and socio-mathematical practices in the classroom. Findings showed that the purpose of changed mathematical practices introduced by the teacher did not necessarily come to be taken as shared by the students. Developing a taken as shared meaning of the purpose of classroom practices involved mutual negotiation between the teacher and the students.

This paper reports on the findings from my doctoral research. I examined the role of social interactions in students’ learning of mathematics. My study was located in two secondary schools (10-15yrs.) in Karachi, Pakistan. It involved observing two small groups of students, each engaged in working at mathematics tasks set for them by their teacher.

METHODOLOGY

Methodology was qualitative in nature. Participant observation was the primary mode of conducting the research. Questions emerging from ongoing observations were followed up in stimulated recall interviews with students. Meetings were scheduled with the teachers who were seen as a significant part of the socio-cultural context. Observations were recorded on videotapes and interviews were audiotaped. Analysis was through grounded theory procedures (Strauss & Corbin, 1998).

THEORETICAL PERSPECTIVE

To study learning in the social context necessitates taking account of those shared understandings and invisible meanings that establish a classroom culture, and that provide meaning to the interpretations being made by the participants of the classroom i.e. the students and the teacher. A sociological construct used to describe

---

1 Tentative findings of this work while it was in progress were presented as a short oral presentation in PME 25.
the shared understandings of a culture is ‘norm’ which refers to understandings or interpretations that become normative or taken-as-shared by the group (Yackel, 2001). She goes on to elaborate that these norms are inferred by identifying regularities in patterns of social interaction in the classroom. Those classroom participation structures that are stable facilitate in inferring the social norms prevalent, while the notion of taken-as-shared implies that individual interpretations fit with the purpose at hand.

The teacher necessarily represents the discipline of mathematics and the culture of the mathematics classroom, therefore, the teacher is a significant force in initiating and stabilising the social norms in the classroom (Wood, 1994). However, understandings do not become taken-as-shared or normative through teacher’s initiation alone. Wood (1994) suggests that one way to establish classroom norms, would be to for teachers and students to negotiate mutual expectations and obligations that are constituted in the classroom. Wood’s position implies that in a classroom activity, participants in the activity would have expectations from others, and obligations from self which guide their participation. The collaboration among the various participants would then take place as a consequence of fulfilling these expectations and obligations.

From the discussion so far I deduce social norms to mean normative understanding of the ways of collaborating with others in the classroom. For example, when learning in small group settings, the understanding that students are expected to share their thinking with others in the group would be a social norm. As such, the social norms are shared understandings that could be found in any classroom irrespective of the specific discipline, and are not unique to mathematics. For the analyses of students’ learning of mathematics, the construct of socio-mathematical norms is taken to mean normative aspects of mathematical discussions that are specific to students’ mathematical activity (Yackel, 2001). Hence, a socio-mathematical norm would be a shared criterion of what is valuable, in a mathematical explanation or solution.

RESULTS & DISCUSSION

In this paper I discuss my findings from class VI (10-11 yrs) where I observed four girls, Maheen, Shabnum, Samina and Naima. The teacher Mohammad Aslam had initiated a change in the social and socio-mathematical practices in the classroom. He taught lessons that required students to work together in small groups at specially designed problem tasks. At the end of each group session the small groups were expected to report back their work to the whole class. This was a change from his previous social setting of the class. The problem tasks prepared by Mohammad Aslam were different from those that he said he had used previously. The difference was that the tasks that he prepared often had questions that were open ended in nature. For example, questions like, “can you decide the reasons for the mistakes shown?” opened up the possibility of more than one solution to be put forward.
Furthermore, students were free to use their own strategies to solve problems and share their solutions with the whole class using their own words.

From the above I inferred the teacher to have a goal that students should learn mathematics meaningfully i.e. students would rationalise their solutions and/or propositions, and at the same time the solutions and/or propositions should be acceptable mathematically. For example, enabling students to interact frequently with each other in small groups, use their own solution strategies, and explain their thinking to others meant that students had opportunities to explore their own interpretation of the mathematics embedded in the problem tasks. While, setting up the groups to report in the whole class ensured that the teacher could monitor those interpretations. However, this goal was implicit in the teacher’s practices. There was very little evidence of explicit negotiation of the purpose of changed practices between the teacher and the students.

**Episode: Alina’s Mistake**

Alina has drawn some angles in her maths book, but has measured them wrongly. Can you decide what she has done wrong?

1) 100°

2) 60°

3) 30°

4) 160°

To locate the discussion of findings in the classroom context I present an episode from my lesson observations. The students in this episode worked in groups at the task shown in the box above. Different groups shared their work with the whole class. Through this episode I illustrate the issues that arose for students’ learning as they worked in the changed social setting of the classroom.

**Task Interpretation:** A recurring feature in the findings was that students interpreted the purpose of task based on their prior experiences in the classroom. In this case, the
students approach to the work on the task above suggested that they had interpreted the purpose of the task to measure angles. Once all angles were measured they considered their work finished and Samina read out the answers in the microphone left on their table for my data collection. This reading of answers stood out as a separate activity illustrating a pattern where one person would suggest reading the answers and the others would comply by reading the answers in turn. Moreover, every time they finished a task or a portion of a task they raised their hands to indicate to the teacher that work had finished. This implied an implicit belief in the answer as a valued product of the mathematics problem tasks, and a dependency on the teacher.

A possible reason for students' interpretation of task, as angles to be measured, could be that they were interpreting the task from their previous experiences of participating in classroom mathematics practices. The geometry curriculum in Pakistani primary and secondary schools has a heavy emphasis on Euclidean plane geometry. A consequence is that such cultural artefacts as protractors, compasses and work sheets and/or textbooks with diagrams of angles and other figures in plane geometry are common in the classroom milieu. Among other things, students are expected to measure and/or construct angles.

However, in this case the question statement “can you decide what she has done wrong?” is not clear in its intent because Alina’s mistake (that she has ‘measured the angles wrongly’) has already been identified in the statement “had measured them wrongly”. That the task requires a reason for Alina’s mistake is difficult to infer from the question statement as it is phrased. Hence, the reason for student’s interpretation of task as one of measuring angles could be because of the way the problem statement was phrased.

**Mathematics being Learnt:** The mathematics topic that was being addressed by the students was “acute angles and obtuse angles”. The conversation being reported below is when Shabnum had placed a protractor on the second angle in the box above and the other three girls looked on. The numbers 60 and 120 refer to the readings on the protractor. The word ‘degrees’ is not used by the students it is implied

1. Shabnum: (reading the protractor) err sixty
2. Maheen: 120 120
3. Naima: (refers to the position of the protractor) bring it down, bring it down
4. Maheen and Naima: 120
5. Samina: 120 or 60?
6. Maheen/ Naima: 120
7. Maheen: 120 because our base line starts from here (points to the baseline on the protractor). So it is starting from here so 60 will come here (traces her finger on the protractor from 0 to where 60 degree angle comes).
The above conversation suggests that Shabnum (line 1) thought the angle that Samina measured was of 60 degrees. Samina (line 5) was not clear whether the angle was 120 degrees or 60 degrees and raised the question. Maheen and Naima (line 4) provided their answer and Maheen (line 7) went further to elaborate why the angle was 120 degrees and not 60 degrees. Samina’s subsequent response (line 8) exposed her confusion not only about acute and obtuse angles, but also about what constituted the base line in an angle and how to read the protractor. From her statement in line 8, it seemed that in measuring an obtuse angle she first read the protractor from 0 to 90 and from 90 onwards she read the readings given on the top line of the protractor. However, Maheen (line 13) urged Samina to accept her (Maheen’s) answer. This urging on Maheen’s part had the effect that the group moved on to the next task while Samina was left with confusions regarding the difference between acute and obtuse angles. Questions also remained about Shabnum’s understanding of acute and obtuse angles. It was not clear to me whom she addressed in line 10? Was she refusing to accept Maheen’s correct explanation or was she addressing Samina? The former would imply that her knowledge of acute and obtuse angles was weak.

Different Answers in Small Group & Whole Class: A pattern was that students provided a different answer to the same task in the small group and in the whole class presentation. The responses in the whole class presentation were richer in terms of quality of thinking, longer, more detailed, with examples. For example, the conversation reported below is when Maheen reported the work her group had done.

1 Maheen: (points at the vertex of the acute angle already drawn on the black board) This is, this is, when we, err the base line is here so we show the base line here. From here we go this way
(with movement of hands shows a turn from the base line of the angle on the blackboard in an anti clockwise direction)
2 Teacher: Inaudible
(Maheen picked up the large black board protractor that was used by the teacher in the geometry lessons, and placed it on the angle already drawn on the blackboard by Shabnum).
3 Teacher: Yes that is right. Should I hold it? (comes forward and holds the protractor leaving Maheen free to give the explanation)
Maheen: First of all this is 100 and this is coming inwards. (points to the acute angle already there on the blackboard) This is an acute angle. An acute angle never goes above 90 (paused and looked at the class) and our base line is---

Data item: 2

(A disturbance in the classroom. The teacher asked Maheen to repeat herself)

Maheen’s answer to the task was qualitatively different from the answer she had given in lines 2 & 4 (data item 1), during group work. Why was this expectation, not just to perceive why Alina was wrong, but to be able to explain and justify her mistake, not made evident in the group? Did the teacher’s request in the plenary session to give the reason for Alina’s mistake provide Maheen with the push to articulate the reason that led to Alina’s mistake? Yackel (1995, p.148) identified similar occasions in the ‘classroom teaching experiment’ where children proposed solutions using methods during class discussions that were markedly different from those they developed during small group work. She goes on to show that this difference is due to a reconceptualisation of the problem. She suggests that the reconceptualisation occurred because the whole class session was more than a report back session. It involved discussion and questioning when students did not understand an explanation or a solution method. In the case of my research, students reported back their solutions to the whole class. However, it was rare for other children to challenge or question them (as in Yackel’s work). Here, the teacher played the role of challenger and questioner. For example, in the above task ‘Alina’s mistake’ the teacher asked the question ‘what was the reason for Alina’s mistake?’ The question apparently led to Maheen, reconceptualising the question where she elaborated on her earlier answer in line 2 (data item 1), to a more detailed answer in line 1 & 4 (data item 2). An interpretation could be that Maheen articulated differently what she had conceptualised earlier because in line 7 (data item 1) she did give the reason for Alina’s mistake. However, this explanation in line 7 was in terms of the mistake Alina might have made in selecting the wrong starting point on the base line. Whereas, in the whole class she extended her explanation of starting the reading from a wrong end of the base line to link it with her knowledge of acute and obtuse angles to explain the reason for Alina’s mistake. Yet another interpretation could be that it was the social setting of whole class presentation as opposed to that of small group work that influenced students’ responses. It could be that the students did not expect their peers to ask them questions and so did not feel obliged to answer them by providing a rationale for their arguments.

To get a deeper appreciation of the questions raised by these different responses, I followed this issue further in the stimulated recall interview with the students. In the following segment from the audiotape transcript Maheen reports on what she believed were her reasons for the difference in the work in the small group and whole class sessions.

1 Maheen: When I went in front of the whole class so there I had to explain all. I had to explain the mistakes in detail so it came to my mind there
3 Maheen: It is in group also, but I thought that in the group they must have understood.

4 AH: Okay.

5 Maheen: When all (questions) were answered so it was obvious that they must have understood.

6 AH: Okay so you thought they must have understood. Would any of the group members like to say something about this point? Yes Naima?

Data item: 3

Maheen’s statement (line 1) indicates that she believed that in the whole class an explanation of her answer was required. It could be that the teacher’s request to provide the reason made explicit the expectation in the problem task that the students were required to give the reason for Alina’s mistake and not just point out her mistakes. Maheen’s subsequent remark (line 5) implied that she did not provide the explanation in group because she assumed that her peers in the group had understood the task in the worksheet. So, a consideration guiding her responses were the needs of the participants in the social interaction. She judged the need to have been met once all answers had been given. Implicit in Maheen’s statement is the message that being a student she is not used to thinking critically about her peers’ answers and to taking responsibility for whether the other students have understood. Hence, once she had understood and once all answers had been given she assumed that her peers had also understood. Naima on the other hand gave a slightly different perspective.

1 Naima: err I think she(Maheen) did not tell us (the explanation) because we were thinking that we only had to measure the angles-----

2 AH: Okay

3 Naima: ------and we had not thought that sir could ask us these questions. When sir asked these questions, strange possibilities started coming to our mind, that it could be like this, or like this. Like she told.

4 AH: Okay

Data item: 4

Naima indicated (line 1 and 3) that it was the teacher’s question that led to the reinterpretation of the problem so that different possibilities were raised for the solution. Naima’s remark confirmed my own interpretation that it was the teacher’s questions that led to a change in thinking about the demands of the question. Naima’s remark indicated a sophisticated level of thinking as regards the dawning realisation that the ways of working in the classroom were changing. Her statement in line 3, about “these questions” leading to “strange possibilities” suggested that she recognised the teacher’s questions as not being ordinary routine questions that she might have been used to encountering in her class. Rather, these were questions that led to strange possibilities, probably, those of a non-numerical verbal answer or a variety of answers to the same task. This was a significant appreciation on Naima’s
CONCLUDING REFLECTIONS

As students worked in the new social setting what appeared to be missing was some evidence of how the changed practices linked to the teachers' goal of learning mathematics meaningfully. Students appeared to work in groups through interpretations made from the perspective of old norms prevalent in the classroom. Hence, while ways of working in groups came to be taken as shared to some extent, mathematics rationalisation in the group did not. For example, working at specially designed problem tasks in groups and later presenting this work to the whole class appeared to be an accepted part of the classroom practice. Besides these new practices in the classroom that students appeared to regard as normative there were certain old understandings that also appeared to be taken as normative by the students. For example, a norm prevalent in the classroom was that a purpose of the mathematics problem task was to find the right answer. Hence, there appeared to be agreement among the students regarding this purpose when they engaged in mathematics tasks in the classroom. Although, wide experience of prevailing norms in Pakistani classrooms supports this interpretation I refer to these as 'old norms' because I did not have direct evidence of them. My interpretation is that two main factors led to students working through old ways in new settings. First, the teachers' communication of the purpose of change was largely implicit in his practice so that the students were expected to infer the purpose implicit in the change. Second, students' perceptions of mathematics and the purpose of classroom tasks did not support critical reasoning of mathematical ideas. Hence, classroom evidence led me to conclude that students and teacher are both participants in the classroom culture, so that meanings do not come to be taken as shared as a consequence of teacher initiation alone.

GOAL REGULATION: NEEDS, BELIEFS, AND EMOTIONS

Markku S. Hannula

University of Turku, Department of Teacher Education

Using the theoretical framework of self-regulated learning as a starting point, this article will elaborate students' self-regulation of goals. Three aspects of goal regulation will be discussed within the context of mathematics classrooms. 1) Goals are seen as elements of a needs-goals structure, and goal choices may be derived from needs values. 2) Self-efficacy beliefs are interpreted as beliefs about accessibility of goals. Goal accessibility belief is seen as a necessary, but not sufficient condition for adoption of a new goal. 3) Automated emotional reactions are seen as a possible inertia force. Some qualitative data of a three-year longitudinal study will be presented to illustrate the presented conclusions.

INTRODUCTION

To understand student behaviour we need to know their motivations. In the literature (e.g. Ryan & Deci, 2000) one important approach to motivation has been to distinguish between intrinsic and extrinsic motivation. Another approach to motivation has been to distinguish three motivational orientations in educational settings: learning (or mastery) goals, performance (or self-enhancing) goals, and ego defensive (avoidance) goals (e.g. Linnenbring & Pintrich, 2000; Lemos, 1999). When further elaborated, motivation can be conceptualised through a structure of needs, goals and means (Shah & Kruglanski, 2000). Such construct of goals and goal structures is an important part of the theory of self-regulated learning (SRL) (e.g. Boekaerts, 1999).

The importance of human needs as motivator for mathematical behaviour has been addressed, for example, by Vinner (2000) and Lerman (1998, p. 69). However, in a sample of five PME proceedings, there were surprisingly few papers explicitly on motivation or goals. Yates (1998, 2000) uses motivation (operationalised as task involvement and ego orientation goals) as one variable in a longitudinal survey, and Bikner-Ahsbahs (2001) and Moyer (1999) write about intrinsic motivation (interest) towards mathematics.

This paper will focus on students' goal regulation in mathematics and we shall discuss three aspects that influence students' goal choices. The first aspect is the students' needs. Students' different goal choices can be derived from different needs. The second aspect is students' beliefs - more specifically beliefs about accessibility of different goals. The third aspect is emotions that may function as inertia forces that restrict goal choice changes. Some data of a three-year longitudinal qualitative study will be presented to illustrate the theory.

The main theoretical framework for this paper is self-regulated learning. Boekaerts (1999) presented a three-layer model of self-regulated learning (SRL). Inner layers include choice of cognitive strategies, and use of metacognitive knowledge and skills...
to direct one’s learning. The focus of this report is in the outermost layer, which includes choice of goals and choice of resources. This least developed area of SRL is essential in understanding student behaviour in classrooms:

information about ... the goals [students] set for themselves ... provides an indication of why students are prepared to do what they do and why they are not inclined to do what is expected of them. (Boekaerts, 1999, p. 451)

Although SRL is the main theoretical framework for this paper, the standpoint needs to be specified. For example, Lemos (1999) writes about “internalisation of goals”, “non-goal oriented behaviour”, and that “strengths of self-directed behaviour lie in its flexibility”. Instead of perceiving self-regulation as an advanced learning style, it is seen as a general psychological process that is part of every action. Thus, present approach assumes that student behaviour in classroom is always goal-directed and self-regulated. Students’ goals are always self-chosen and internal, and behaviour is always goal oriented. However, the goals may differ from the learning goals set by the teacher and some students may be more flexible in their goal directed behaviour than others. Furthermore, it should be noted that present approach assumes that a lot of self-regulation is automatic and not conscious.

GOAL REGULATION: NEEDS, BELIEFS, AND EMOTIONS

Goals are part of a structure of needs, goals and means. The structure is personal and dynamic in time. There are individual differences in structure dynamics: some may pursue multiple goals simultaneously and elegantly navigate between them, while others put their goals in serial position and pursue one goal at a time. Students may also decide not to pursue learning goals when they feel that one or more of their psychological needs (autonomy, competence, social belonging) are thwarted. (Boekaerts, 1999)

For the purposes of the present paper we shall distinguish within mathematical behaviour two individualistic needs (autonomy and competence) and two social needs (belonging and status). Autonomy is the need to have a control over own actions and to feel self-determining. Competence is the need to be able to comprehend and influence own environment. Social belonging is the need to be part of a social group, and social status is a social equivalence for competence – a need to have influence within a social group.

As a starting point for goals we take the three motivational orientations: learning, performance, and avoidance. However, we do not regard them as alternative orientations, but as goals that may be pursued simultaneously (the case study below will illustrate this). Thus, when a student is given a mathematical task, he or she might adopt a goal to master the topic, to demonstrate high ability, and/or to avoid public failure. Furthermore, we can use the empirical results by Lemos (1999), who observed and interviewed Portuguese sixth grade students. She concluded that students’ activities in class could be classified under following goals: working goals, evaluation goals, learning goals, complying goals, interpersonal relationship goals,
enjoyment goals, and discipline goals (in order of decreasing frequency). Some of these goals are on a more specific level, but evaluation goal roughly equals performance goal and learning goal equals mastery goal. Enjoyment, however, should not be accepted as a goal. Emotions regulate goal directed behaviour, and enjoyment is a general reaction that may be related to a variety of different goals (for further elaboration, see Hannula, in print).

Within the goal structure we can distinguish two kinds of relations (Fig.1). Firstly, there are personal beliefs about how goals are related to other goals and different needs. One may perceive a single goal to satisfy multiple needs and a need to be satisfied through multiple goals. Goals may also be seen as contradictory in a sense that reaching one goal might prevent achieving another goal. For example, it is not possible to show high performance without taking a risk of failure. Another kind of relations are the values of needs and goals (seen as comparative evaluations). Needs values are relatively stable characteristics of the personality although when a need is fulfilled at a moment it may be temporarily given lower priority. Goal values are partly derived from respective needs values and partly from the beliefs about how reaching a particular goal will affect different needs and other goals. In the given example (which shall be further elaborated later) the student gives higher value for social status compared to competence. In classroom context this leads to lower derived value for understanding (learning goal) compared to performance and failure avoidance goals.

A second aspect behind goal choices are beliefs about accessibility of goals. This aspect is usually discussed under the term ‘self-efficacy beliefs’ (e.g. Philippou & Christou, 1999, Risnes, 1998). Here, I only stress the importance of goals in relationship with beliefs. Beliefs as obstacles for an educational change have been discussed by Pehkonen (1999). Furthermore, Lemos (1999, p. 482) pointed that “in the absence of valued personal goals, individual’s beliefs do not seem to play a helping role in overcoming stressful situations.” It seems, that in order for change to take place two conditions must be met. Firstly, there needs to be a goal that motivates the change and, secondly, one’s beliefs must support the change.

Earlier at PME (Hannula, 1998a) the author has reported a case study of a radical change in student beliefs and behaviour that includes these two aspects. Using the present terminology of goals, we may say that the case student had self-defensive goals dominating her behaviour in the beginning (‘You don’t need math in life’). However, this was later replaced by performance goals (‘I will raise my math number’). Behind this change there was a new awareness of the importance of school success in general (change in goal values) together with more positive self-efficacy beliefs (success is possible).

The third aspect to be discussed here are automated emotional reactions as an inertia force to students’ goal choices. There are two fundamentally different ways how emotional state may be changed (Power & Dalgleish, 1997). One way is the
(possibly unconscious) cognitive analysis of the situation with respect to one's goals. Another

![Figure 1. A part of a needs-goals structure. In top row are two needs and their relative value (competence is more important). In bottom row are goals and their values. Thin arrows represent beliefs about the relationships between goals and need.]

route to change emotional state is through association to one element of the situation. Emotional associations are learned via classical conditioning and they are the core of attitude as an emotional disposition (Hannula, submitted). Although they allow shorter reaction times to possible threats, they lack flexibility and are an inertia force of behavioural changes. Once formed, these associations are difficult to change. During school years students usually develop some emotional disposition to different mathematical actions and goals. Therefore emotional associations may function as an inertia force against change, even when change would be 'rational'.

**METHODOLOGY**

There is a serious methodological problem with research on such mental constructs as beliefs and goals. We can't directly access student’s all beliefs and goals. Some of the goals and beliefs are always hidden even to the student him/herself and they need to be reconstructed through interpretation of the observable. Even if we succeed in explaining all the utterances and actions of the student, we have constructed only one possible mental configuration behind the observable.

In present study the solution to overcome these methodological problems has been to collect a large and varied data (classroom observations, individual and group interviews, interviewing parents and teachers) on a small number of students. The study was longitudinal (three years) and the researcher interacted a lot with the students as their teacher and thus gained tacit knowledge that has guided the interpretations. Furthermore, the use of multiple frameworks to analyse students’ beliefs and attitudes has enriched the understanding of students (Hannula, 1998a; 1998b; 2001; submitted). However, using a broad spectrum of analytical frameworks has its inevitable cost in lack of depth.
Laura, performance through mastery

Laura was the student whose goal structure was used as an example above (Fig 1). She had been a successful student in elementary school. There she never had needed to prepare for mathematics tests, and it took some time (and unsuccessful tests) before she realised that in secondary school she needed to start working. She thought that studying mathematics was boring at times, but that it was nice in the class when she was able.

One ground to claim that performance goal was more important to Laura than learning goal was that understanding alone was not enough for her. She also wanted to get praises for her good performance.

“If you have been thinking yourself crazy and if you have got them right, so that makes you feel real good except, if ... you have been thinking really hard, and ... the teacher does not say ‘Good!’ either.”

Furthermore, her best memories in mathematics were when she could outperform the others at school.

[The nicest thing in elementary school in math was to] “learn addition the first day ... because I could do them all and it was real fun.”

There was consistent evidence that the social status was an important need for her. In classroom context she did not get to a leading position and the conclusion adds up from minor events, as a tacit knowledge gained through three years of observation. More explicitly, she expressed her pride and happiness for gaining a leading position in her hobby and her relationship with her younger brother also reflects an enjoyment of having power over others.

“Maria asked, the other day, advice for what to tell her younger brother, who always is depressing her somehow, saying things like ‘I’m better in math than you’. And Maria asks what she can do. I told her to grab him by his shirt tightly and yell: ‘I am you elder sister!’”

Although Laura’s main goal was performance, she also had a mastery goal to really understand mathematics, and this goal she approached often with her father.

... all the interesting discussions that I have with my father, that why 4*(-4) is not, for example, + 16 instead of -16. And about what is to power of zero, such really interesting issues that I do not comprehend.”

In this context she could achieve both need of competence and need of social belonging. This example illustrates how goal choices depend on context and situation.

Above, I have only presented a selected sample of Laura’s interviews. That data alone would, of course, be open to several different interpretations. However, the
interpretation that I have presented is supported by further data that can’t be presented due to space limitations.

**Maria, competence through performance**

Maria was another student in the same class, who was mentioned by Laura above. She was a high achiever, and she wanted to be perfect in everything. At primary school she had felt that it had been difficult to keep up the fast tempo that some of her classmates had kept. She also had felt that it had been difficult to avoid mistakes, even though she had understood what to do. She had been bored by calculating long lists of routine tasks, and preferred doing word problems. At grade six she had started to understand mathematics better, had achieved higher, and had started to like mathematics more.

Maria had clearly a performance goal in mathematics, as she admitted in an interview:

"But usually I like tests, I have always liked. ... Some say that I am the kind of person who likes so much to compete. ... Usually it’s nice to show it, when you are good at something."

She did not like group work, because she felt that the others didn't work as hard as she did. Furthermore, when she worked alone, she would get all honour for the result herself. However, Maria did not boast with her success in the class.

Maria had also a mastery goal. She was challenged by more difficult problems even when nobody would know about her performance. She was driven by a will to overcome the challenges and she enjoyed especially tasks where she could see their applicability.

"I do not know if that is allowed, but I do sometimes look the more difficult tasks" [while others check homework]

"[If a task is not solved] I can not go peacefully to sleep, because you still think how it would go."

"I like [equations], because it feels natural and purposeful when, for example, with world problems you need to think and apply, so it is not only that you move figures, but there is a purpose. Such problem could exist in real life and so it is not just calculations."

My understanding of Maria is that she was, deep inside, uncertain of herself. Therefore she had a strong need to feel competent. Her goal in the math class was to learn and convince to herself that she is intelligent and competent. As a sub-goal she wanted to monitor her own success. Tests and challenging tasks were her way to convince herself that she is doing well enough.

**SOME CONCLUSIONS**

Altogether eight students’ goal structures have been analysed. As a general finding it should be noted that there is great variation in goal structures and they do not
provide easy means for classifying students. As it became evident in cases of Laura and Maria, performance and mastery are not contradictory goals. There also seems to be a developmental trend towards mastery goals. However, we do not know if this is a general developmental trend or due to teacher's efforts to promote such orientation. This development towards mastery goals seems to co-evolve with a view of mathematics as a sense-making activity. As an unsurprising finding we see that avoidance goals occur together with a belief of self as untalented in mathematics.

Three aspects of goal regulation were specified in the theory: deriving goals from needs, the influence of goal accessibility beliefs, and emotions as an inertia force. Within the empirical data it was possible to identify examples of all three aspects. The cases of Laura and Maria were presented as examples of the first aspect.

Hannula, M.S. Submitted. Attitude towards mathematics: emotions, expectations and values

Power, M. & Dalgleish, T. 1997 Cognition and Emotion; From order to disorder. UK: Psychology Press

The knowledge of concepts is essential for students when they start to learn proof. Empirical findings of a study with 106 grade 8 students show that there are deficits in students’ concept understanding scheme for quadrangles. These deficits are particularly based on a different idea of classification of quadrangles and difficulties in the understanding of the mathematical language and thinking - problems which will cause difficulties regarding learning and teaching proof.

INTRODUCTION

The mathematical definition is one of the basic terms which together with axioms, theorems, proofs, corollaries, lemmas and propositions constitutes the skeleton of the mathematical theory. Though it is clear that a definition has to satisfy certain necessary properties like noncircular, non-contradictory, there is little agreement which properties are sufficient to constitute a good and elegant definition (cf. Shir & Zalavsky, 2001). However, elegant or not, mathematical definitions are prerequisites for the formulation of theorems and proofs and, therefore, they are essential for the development of mathematics as a deductive theory.

Teaching definitions in mathematics classroom is a task which depends on more than only mathematical requirements. In particular, in geometry classroom on the primary level students do not learn geometry as a deductive theory. Based on pedagogical and psychological reasons, geometry is introduced to young students as a theory of the visual space. It is obvious that in this stage the concept formation and the recognition of simple mathematical “theorems” is not undertaken by teaching formal definitions but mainly by examples and visual representations. The transition from everyday life thinking in the theory of the visual space to a scientific thinking in deductive geometry in higher grades is afflicted with many problems. These problems cause students’ difficulties in advanced mathematical thinking as it is required in problem solving, reasoning and proof. One of the basic deficits can be found in the students’ personal knowledge of concepts and its usage in a mathematical context.

THEORETICAL FRAMEWORK

Scientific thinking skills and prerequisites for learning reasoning and proof

The last decades many researchers from cognition psychology and mathematics education contributed to the description of the development of students’ thinking skills. Research in this area shows that there are several restrictions in the preadolescent scientific thinking (e.g., Kuhn, 1989). For example, an empirical-inductive reasoning is typical for students on the concrete-operational stage, whereas
A more hypothetical-deductive reasoning is typical for the formal-operational stage (Flavell, 1977). This hypothesis is supported by empirical findings of studies with grade 8 and grade 10 students' ability in mathematical reasoning and proof (Healy & Hoyles, 1998; Reiss & Thomas, 2001).

In a former study with students in upper secondary level we identified different prerequisites for the understanding of proofs in the geometry classroom. As described in Reiss, Klieme & Heinze (2001) geometrical competence is specifically influenced by methodological knowledge, declarative knowledge, metacognition and spatial reasoning. For the evaluation of students' declarative knowledge we chose the concept "congruence", a central concept of school geometry. The students were asked to give a definition, an example, a visual portrayal of the word "congruence" and to name a mathematical theorem in which the concept features. Our analyses have revealed considerable deficits in declarative knowledge. It emerged that even students at the end of secondary level often have only a vague intuitive understanding of concepts such as "congruence", that this understanding is restricted to examples, and that they have no exact mathematical knowledge of the respective definitions and theorems.

The last point corresponds to findings of several other studies: students' ideas about a geometrical concept and the definition of this concept are frequently inconsistent (e.g., Hershkowitz & Vinner, 1982; Wilson, 1990). The use of examples as an interpretation of definitions is often restricted to certain prototypes which, in addition, contain irrelevant characteristics. Distinguishing between these irrelevant characteristic properties and the relevant definitional properties is difficult for students (e.g., Burger & Shaughnessy, 1986; Wilson, 1990). Other problems related to definitions are the students' understanding of necessary and sufficient conditions in definitions and their imprecise use of words if they give definitions (Burger & Shaughnessy, 1985, 1986; Wilson, 1990). These deficits in students' ideas about geometrical concepts are strongly affected by the representation of these concepts in mathematics classroom and textbooks (e.g., Burger & Shaughnessy, 1985).

**Concept definition, concept image and concept usage**

As mentioned above we have to distinguish between the mathematical definition of a concept and the personal image of this concept in student's mind. To describe this fact Vinner and others introduced the theoretical model of the personal *concept image* (Vinner, 1991) which was used to identify students' ideas of different mathematical concepts like function, limit etc. (e.g., Tall & Vinner, 1981). The concept image is described as

"... something non-verbal associated with the concept name. It can be a visual representation of the concept in case the concept has visual representations; it can be a collection of impressions or experiences" (p. 68, Vinner, 1991).
The concept image is evoked in the memory by the concept name. It is specific for an individual. The existence of a concept image is a necessary condition for the understanding of a concept. "To acquire a concept means to form a concept image" (p. 69, Vinner, 1991). The knowledge of a concept definition may be independent from the formation of a concept image: to know a concept definition does not imply to understand the concept.

Moore (1994) extended the ideas of Vinner to the concept-understanding scheme. The concept-understanding scheme contains three aspects of concept understanding: the concept definition, the concept image and, as a third aspect, the concept usage. The concept usage "refers to the ways one operates with the concept in generating or using examples or doing proofs" (p. 252, Moore, 1994).

Both, Moore (1994) and Vinner (1991), described the main problem for students using concepts in their mathematical activities. If a student is confronted with a mathematical problem in which a certain concept appears, then in his or her mind the associated concept image is evoked. To get a correct solution of the problem the student has to check, if the operation done with the evoked personal concept image is compatible with the concept definition. Here a difference between every day thinking and scientific thinking appears: in every day thinking, in general, it is not necessary to check the concept definition (in many cases such a concept definition even does not exist, e.g., for the concept "tree"). In a mathematical context, in general, it is indispensable to compare the personal concept image with the concept definition. The ability to “switch” between the personal concept image and the concept definition is essential for the solving processes in a mathematical context. It can also be observed in the research process of mathematicians: mathematicians do not retrieve definitions and theorems from their memory to construct logical deductions. On the contrary, first they do not pay attention to each detail in the process but consider the line of argumentation in broad terms and recognise important properties and connections. Finally, if they know how to argue they will construct a mathematical proof using formal definitions and theorems (cf. Koedinger & Anderson, 1990).

**Partitional and hierarchical classification**

When discussing the concept understanding scheme of geometrical concepts like triangles or quadrangles, we must also consider the classification of these concepts. As described in de Villiers (1994) there are two main classification types: the hierarchical and the partitional classification. Hierarchical classification means the classification of a class of concepts in such a manner that the more particular concepts form subclasses of the more general concepts (class inclusions). In contrast, in a partitional classification the various subclasses of concepts are considered to be disjoint from one another. For example, in the first case we can define squares as special rectangles and rectangles as special parallelograms. In the second case a square is not a rectangle and a rectangle is not a parallelogram. Since in mathematics
classifications and the associated definitions are arbitrary in a certain sense, the choice for a hierarchical or partitional classification is a question of convenience and economical and personal reasons. In general, mathematicians prefer a hierarchical classification for triangles and quadrangles.

There are several studies which show that students in lower secondary level still tend to a partitional classification in the case of quadrangles (e.g., Burger & Shaughnessy, 1985; de Villiers, 1994, 1998). Moreover, de Villiers (1994) showed that even students who exhibit excellent competence in logical reasoning still prefer to define quadrangles in partitions, if given the opportunity. He suggests to treat the classification of concepts like triangles and quadrangles in such a way that a meaningful discussion is possible. As described in de Villiers (1998) by comparison of advantages and disadvantages the students will then realise that hierarchical classifications are more economical than the partitional ones.

RESEARCH QUESTION AND DESIGN OF THE STUDY

According to the theoretical framework described above we investigated aspects of the concept understanding scheme of students who started to learn proof. As concept we chose quadrangles, in particular, squares and rectangles which are well known to these students. The research question to be addressed in this paper is the following:

- Are the students' concept understanding schemes of (special) quadrangles sufficient for solving problems in different situations like recognising equivalent descriptions, finding counterexamples and distinguishing between sufficient and necessary conditions?

For this research question we considered three items of a study which was carried out for the investigation of informal prerequisites for informal proofs. In this study five mathematical principles (definitions, equivalent descriptions, arguments and proof, logical implication and counterexamples) were represented by ten items in a paper and pencil test. This test was administered by a teacher in four classes of grade 8 in a German Realschule (Realschule means lower secondary school for students with an average proficiency level). Altogether the sample comprises of 106 students (50 female, 53 male, no data 3). The students were asked to answer the test in 45 minutes. A detailed description of this study is given in Heinze (to appear).

The three items related to the research question are the following:

1. The recognition of equivalent descriptions of a square: Six descriptions of quadrangles were given and the students had to mark which of them describe squares (multiple choice).

2. The finding of a counterexample: We presented the following problem: "Klaus considers squares and rectangles. He says: 'In each quadrangle each angle is 90°.' Karin says: 'This is not true'. How can you show, that Karin is right?".
3. The distinction between necessary and sufficient conditions: Here we asked: “If a quadrangle is a rectangle, then the opposite sides are parallel. Consequently: If the opposite sides of a quadrangle are parallel, then it is a rectangle. Is this true?”

RESULTS

Table 1 shows the results of the first item (Which quadrangles are squares?):

<table>
<thead>
<tr>
<th>Quadrangles with ...</th>
<th>Frequency</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>(a) four sides of same length and all angles of 90°</td>
<td>88</td>
<td>83,0 %</td>
</tr>
<tr>
<td>(b) four angles of 90°</td>
<td>48</td>
<td>45,3 %</td>
</tr>
<tr>
<td>(c) three angles of 90° and two neighbouring sides of same length</td>
<td>6</td>
<td>5,7 %</td>
</tr>
<tr>
<td>(d) all sides of same length</td>
<td>34</td>
<td>32,1 %</td>
</tr>
<tr>
<td>(e) opposite sides are parallel</td>
<td>63</td>
<td>59,4 %</td>
</tr>
<tr>
<td>(f) four sides of same length and one angle of 90°</td>
<td>19</td>
<td>17,1 %</td>
</tr>
</tbody>
</table>

Table 1: Correct answers for the recognition of a square as a special quadrangle

If we consider the alternative descriptions of a square (answers (a), (c) and (f)), we see that 83 % of the students know that quadrangles with four sides of same length and four angles of 90° are squares. Answer (f) (four sides of same length and one right angle) is recognised by 17,1 % and statement (c) (three angles of 90° and two neighbouring sides of same length) is accepted by only 5,7%. Conversely, more than half of the students think that each quadrangle with four right angles is a square (b) and more than two thirds believe that each equilateral quadrangle is a square (d). The fact that, in general, a parallelogram is not a square (e) is known by nearly 60 % of the students. It is interesting to see that about two thirds of the students think that an equilateral quadrangle is a square (d) but only 17,1 % gave the answer that an equilateral quadrangle with one angle of 90° is a square (f).

The total number of correct answers for each student is presented in Table 2:

<table>
<thead>
<tr>
<th>corr.</th>
<th>Frequency</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>0</td>
<td>0 %</td>
</tr>
<tr>
<td>1</td>
<td>21</td>
<td>19,8 %</td>
</tr>
<tr>
<td>2</td>
<td>35</td>
<td>33,0 %</td>
</tr>
<tr>
<td>3</td>
<td>34</td>
<td>32,1 %</td>
</tr>
<tr>
<td>4</td>
<td>15</td>
<td>14,2 %</td>
</tr>
<tr>
<td>5</td>
<td>1</td>
<td>0,9 %</td>
</tr>
<tr>
<td>6</td>
<td>0</td>
<td>0 %</td>
</tr>
</tbody>
</table>

Table 2: Total number of correct answers for each student

Furthermore, if we consider only the correct descriptions in the first item (answers (a), (c) and (f)), then 71,7% of the students recognised one of these, 13,2% two and only 2,8% (three students) recognised all three correct descriptions of a square among the six given answers.

A deeper analysis of the students’ answers for this first item shows that there is indeed a certain ordering of the different descriptions by difficulty: the easiest cases are (a), (e) and
(b) (in this ordering), i.e., students with three or more correct answers mostly have these three cases correct.

Table 3 gives the results for the second item (In each quadrangle each angle is 90°):

<table>
<thead>
<tr>
<th></th>
<th>Frequency</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>correct</td>
<td>68</td>
<td>64.2 %</td>
</tr>
<tr>
<td>false</td>
<td>22</td>
<td>20.7 %</td>
</tr>
<tr>
<td>no response</td>
<td>16</td>
<td>15.1 %</td>
</tr>
</tbody>
</table>

More than 60 % of the students gave a correct answer, nearly all of them gave a counterexample. About 20% gave a false answer, half of these students said that it is true that each angle in each quadrangle is 90°.

Table 3: Results for the second item

Table 4 presents the answers for the third item (necessary and sufficient condition):

<table>
<thead>
<tr>
<th></th>
<th>Frequency</th>
<th>Percentage</th>
</tr>
</thead>
<tbody>
<tr>
<td>correct with reasons</td>
<td>2</td>
<td>1.9 %</td>
</tr>
<tr>
<td>correct without reasons</td>
<td>8</td>
<td>7.5 %</td>
</tr>
<tr>
<td>correct with false reasons</td>
<td>30</td>
<td>28.3 %</td>
</tr>
<tr>
<td>false</td>
<td>24</td>
<td>23.1 %</td>
</tr>
<tr>
<td>no response</td>
<td>42</td>
<td>39.6 %</td>
</tr>
</tbody>
</table>

About 37% gave a right answer, whereby many students (28,3 %) gave false reasons for their response. More than half of these cases with false reasons (16%) was based on a partitional classification of quadrangles (without class inclusions).

Table 4: Results for the third item

Typical answers were “The opposite sides of a square are also parallel, but a square is not a rectangle.” In addition to this, we noticed that many students do not distinguish between the concepts of square resp. rhombus and quadrangle. Furthermore, it is remarkable that nearly 40% of the students gave no (mathematical) response to this item. Often they wrote, that this item is too complicated or that there is no logic in this question.

DISCUSSION

For an interpretation of the described results it is necessary to analyse the different items and their requirements. In particular, the six problems in the first item require different kinds of thinking. For example, for the cases (c) and (f) it is not possible to find a correct answer without an analytical process of thinking. For these cases we get only a small number of correct answers which indicate that the students mainly did not use analytical approaches. The results for the two cases (d) and (f) (Is an equilateral quadrangle resp. equilateral quadrangle with one 90° angle a square?) supports this fact: 61 students (57,5%) said that an equilateral quadrangle is a square and an equilateral quadrangle with one 90° angle is not a square. The problems in this case may be based on the students’ difficulties with sufficient and necessary conditions and the understanding of the “mathematical language” (“one 90° angle” means “only one 90° angle”).

Restrictions in the understanding of sufficient and necessary conditions and the language resp. thinking in mathematics can be also identified in the third item (If the
opposite sides of a quadrangle are parallel, then it is a rectangle). Though this item is similar to case (e) in the first item, it is more difficult for the students (37.7% to 59.4% correct answers). This may be caused by the explicit question if the necessary condition “opposite sides are parallel” of a rectangle is also sufficient. A fact that is also influenced by deficits in mathematical language is the students’ preference of the partitional classification of quadrangles. Nearly half of the answers which were accepted as correct (16% of 37.7%) were based on this classification. The frequently given reason “a square is not a rectangle” may also be caused by the interpretation of the word “is” as “is equal to” (cf. de Villiers, 1994).

The best results the students obtained for the second item (“In each quadrangle each angle is 90°.”). Here, about 64% gave a correct answer. Nevertheless, 15% of the students gave no response and 20% gave a false response. For 12% of the students with false response we identified a restricted concept image of quadrangles (In a quadrangle each angle is 90°). As one can expect, these students also achieved poor results for the other items.

The results show that many students have deficits in the concept understanding schemes for the discussed quadrangles. In particular, if they have to use the concepts for certain problems they remain on using their personal concept image and ignore the concept definition. In addition, the findings support the results of de Villiers (1994) that many students prefer a partitional classification for quadrangles. This seems to be related to a wrong understanding of the mathematical language and thinking.

The difficulties described above are problematic in a stage where the teaching and learning of reasoning and proof begins. In particular, the fact that in mathematics classroom teachers and a part of the students have a different understanding of the classification of concepts and of the mathematical language and thinking cannot be considered as a basis for first steps in advanced mathematics. It is essential for a successful instruction in advanced mathematics that teachers and students agree on a common view on the basic mathematics.

FLEXIBLE MENTAL COMPUTATION: WHAT ABOUT ACCURACY?

Ann Heirdsfield

Centre for Mathematics and Science Education, QUT, Brisbane, Australia, 4059

Flexibility in strategy choice in mental computation is considered to be a component of number sense. This paper reports on an investigation into cognitive, metacognitive, and affective factors that support both flexibility and accuracy in mental addition and subtraction in Year 3 students. While some factors appeared to be essential for flexibility, additional factors were necessary for accurate employment of strategies. Further, there were qualitative differences between the mental strategies employed by the students who were accurate and those who were inaccurate.

While standard computational algorithms (both written and mental) are still taught in many classrooms around the world, there is reduced emphasis on the importance of these algorithms and increased emphasis on "number sense" (e.g., National Council of Teachers of Mathematics, 1989). Several interpretations exist for number sense; however, "flexibility" and "inventiveness" seem appropriate ones in this discussion (Anghileri, 2001). It has been recognised that the development of flexible mental computation strategies are a component of number sense (e.g., Klein & Beishuizen, 1994; McIntosh, 1998; Reys, Reys, Nohda, & Emori, 1995), and that when children are encouraged to formulate their own mental computation strategies, they learn how numbers work, develop number sense and develop confidence in their ability to make sense of number operations (Kamii & Dominick, 1998).

It would appear that the purpose of the inclusion of mental computation in any mathematics curriculum would be to develop flexible computational strategies, and thus promote number sense. Some teaching experiments have focused on the successful development of students' flexible computational strategies (e.g., Buzeika, 1999; Kamii, 1989). Other literature reports that children have the ability to develop their own efficient mental strategies, even without instruction (e.g., Heirdsfield, 1999). While flexibility might be one of the foci of this research, proficiency (defined here as both flexibility and accuracy) would appear to be important as well. It is posited that the study of proficiency in mental computation extends beyond the development of flexible mental strategies, but also encompasses the study of associated factors that might contribute to both flexibility and accuracy.

Associated factors have been reported elsewhere (e.g., Heirdsfield, 1996; Kamii, Lewis, & Jones, 1991; Sowder, 1994; Van der Heijden, 1994). These include (a) number sense (number fact knowledge, estimation, numeration, effects of operation on number), (b) affective factors (beliefs, attributions, attitudes, self efficacy, social context), (c) metacognitive processes (strategies, beliefs, knowledge), and (d) memory (short term memory, long term memory – knowledge base).
This paper reports on a study of Year 3 children’s mental computation (addition and subtraction), which was conducted in three classrooms (2 schools, A and B). In all of these classrooms, students were taught traditional pen and paper algorithms (mental computation is not mentioned in the existing Queensland Years 1-10 mathematics curriculum document and is not treated consistently in Queensland schools). Mental computation appeared to only refer to number facts and extended number facts (e.g., 30+40=70, because 3+4=7). However, in one of the classrooms (School B), students were also encouraged to consider alternative strategies, and would have been permitted to use them. Of interest here is those students who were identified as being flexible in their mental addition and subtraction strategies. While it appears that the students developed their own flexible mental strategies, not all were successful (i.e., accurate) in applying them. It could also be argued that not all were “efficient” either.

THE STUDY

Participants. Seven flexible Year 3 students were selected from three classes in two Brisbane Independent schools (Schools A and B) that served high and middle socioeconomic areas. The students were selected on the basis of their responses to a structured addition and subtraction mental computation selection interview. All students were identified as being flexible in their employment of mental strategies, 4 were accurate (2 from School A and 2 from School B) and 3 were inaccurate (School A). Accurate computers were those who were more than eighty percent correct in their responses on both the addition and subtraction selection items. Inaccurate students generally attained between thirty and eighty percent accuracy on either the addition and subtraction items (more errors were made on the subtraction items).

Procedure and instruments. All students from the three classes were withdrawn from class and interviewed individually in a structured mental computation interview. Students who employed a variety of strategies were selected to participate in further interviews. These interviews constituted a series of videotaped semi-structured clinical interviews in a quiet room in the school. The interviews addressed mental computation strategies, number facts, computational estimation, numeration, effect of operation on number, metacognition, affect, and memory. These have been described in more depth elsewhere (Heirdsfield, 2001; Heirdsfield & Cooper, 1997).

Analysis. For the purposes of identifying flexibility in mental computation, mental computation strategies were identified using the categorisation scheme (based on Beishuizen, 1993; Cooper, Heirdsfield, & Irons, 1996; Reys, Reys, Nohda, & Emori, 1995; Thompson & Smith, 1999) that divided the strategies into the following categories: (1) separation (e.g., 38+17: 30+10=40, 8+7=15=10+5, 40+10+5=55); (2) aggregation (e.g., 38+17: 38+10=48, 48+7 = 55); (3) wholistic (e.g., 38+17 = 40+17-2 = 57-2 = 55); and (4) mental image of pen and paper algorithm – following
an image of the formal setting out of the written algorithm (taught to almost automaticity in the schools the students attended).

Mental computation responses were analysed for strategy choice, flexibility, accuracy, and understanding of the effects of operation on number, numeration, computational estimation, and number facts. Analysis of the interviews investigating these individual factors was also undertaken, with the intention of exploring connections with mental computation. Students’ responses were also analysed for metacognition and affects, and scores and strategies were recorded for the memory tasks. Each student’s results for aspects of number sense, metacognition, affects and memory were summarised. These summaries were combined for each of the computation types: accurate/flexible and inaccurate/flexible, so that comparisons could be made between the two types. The knowledge shown by the students of each type were analysed for commonalities and these commonalities were used to develop a composite picture of a typical student of that type. The two resulting knowledge structures, one for accurate and one for inaccurate, were depicted by networks.

RESULTS

Both the accurate and inaccurate students spontaneously employed a variety of strategies (separation, aggregation, and wholistic) although the inaccurate students tended to have less variety, using predominantly separation strategies. When encouraged to access different strategies, both accurate and inaccurate students were able to do so but with different outcomes. The accurate students were successful in their use of the new strategies while the inaccurate experienced difficulties in completing the strategies (although they had sufficient understanding to access the strategy).

Accurate students. Although both accurate and inaccurate students were identified as flexible, there was little in common between the two groups. The students who were accurate showed in their responses to the interviews that they possessed well-integrated knowledge bases. The composite picture of their knowledge is depicted as a network in Figure 1.

As can be seen in the figure, the accurate mental computers were fast and accurate with their number facts, used efficient number facts strategies (e.g., 8+6=14, because double 6 and 2 more make 14) when facts were not known by recall, and had extended their number facts strategies to efficient mental computation strategies (e.g., 9+6=10+6-1=15 is similar to 246+99=246+100-1). Although it might have been expected that estimation would contribute to mental computation, only one of the accurate students exhibited proficiency in estimation. This student also employed estimation in mental computation to get a feel for the answer and check the solutions.

The accurate students used good numeration understanding (particularly canonical, noncanonical, multiplicative, and proximity of number) and some understanding of
the effect of operation on number to support their efficient use of a variety of strategies. This was particularly so for the wholistic compensation strategy (e.g., 246+99=246+100-1) for which numeration understanding (particularly proximity of number) and understanding of the effect of operation on number appeared to be essential. The accurate students had accurate perceptions of their ability to solve the mental computation tasks (metacognitive beliefs), and they used metacognitive strategies (e.g., monitoring, reflecting, regulating, and evaluation). Beliefs in self seemed to be associated with a belief about the place of the teacher in the student’s learning; for instance, accurate students tended to have confidence in self-initiated strategies (c.f., teacher-taught strategies). Although there was not always evidence of the belief that mathematics makes sense, that belief was strong in one student.

![Diagram](image)

Figure 1. Network showing knowledge for accurate/flexible mental computation (shaded - present, speckled - partially present)

Accurate students showed reasonable short-term memory (STM) and central executive functioning. This would have provided them with efficient retrieval of number facts from long-term memory (LTM), effective holding and rehearsal of interim calculations, and efficient processing and coordinating of strategies. However, the study also showed that STM was not as important as might be
predicted as efficient mental strategies place less demand on STM and require fewer interim calculations.

In summary, the composite accurate/flexible mental computer was shown to have a rich integrated network of cognitive, metacognitive and affective components.

**Inaccurate students.** Although the inaccurate students in this study were categorised as flexible, they did not exhibit the same degree of flexibility as the accurate students. They did employ a variety of strategies, but they tended not to be high-level strategies (e.g., wholistic), and there was very little in common between the two groups. The composite picture of their knowledge is depicted as a network in Figure 2. It shows that the inaccurate students had much less knowledge and fewer connections between factors than the accurate students.

All knowledge exhibited by inaccurate students seemed to be at a threshold level, rather than at an optimum. The inaccurate students exhibited some flexibility and efficiency (although not always speed and accuracy) in number fact strategies. However, these strategies did not always support interim calculations in mental computation, as the students often calculated interim calculations by counting, rather than by employing more efficient *derived facts strategies*, which they used in the number facts test. Similarly, numeration understanding was evident at a threshold level, particularly, canonical and noncanonical. A further attribute of numeration, proximity of number appeared to be at a threshold level, as the students attempted to use this when accessing the *wholistic compensation* strategy. However, their knowledge of the effect of operation on number did not support high-level strategies and their estimation was poor. There was evidence of some metacognitive strategies, such as reflection, evaluation, and checking solutions. However, unlike the accurate students, metacognitive beliefs were poor.

Beliefs, in general, were difficult to elicit from the inaccurate students, and when elicited, were inconsistent. There might have been several reasons this. These students might not have held any strong beliefs about themselves, about mathematics (e.g., whether mathematics should make sense), or about teaching. Also, they might have been unaccustomed to verbalising their beliefs.

Finally, as with the accurate students, the inaccurate students had reasonable STM and central executive functioning (e.g., planning and allocation of attention). However, these abilities were little help to the students because number facts were not sufficiently well known to be retrieved by STM, interim calculations were completed so slowly that they placed a heavy load on STM, and the students’ knowledge base was so poor that the central executive could not successfully retrieve information.

The question remains: Why were the inaccurate students flexible? The answer might lie in what appeared to be the lack of understanding of taught procedures. When these students were unable to use these procedures, they compensated by inventing
strategies. These strategies tended to be lower level (i.e., separation) and their use unsuccessful, as the inaccurate students’ knowledge (particularly of numeration and effect of operation on number) was insufficient to enable higher-level strategies to be attempted and any calculation to be completed accurately.

In summary, the composite inaccurate/flexible mental computer was shown to have knowledge at a threshold level that was insufficient for employment of advanced mental strategies and accurate use of other strategies.

DISCUSSION

Although flexible use of mental computation strategies is an important component of the development of number sense, this study shows that it is not sufficient for accurate computation. A well-connected knowledge base (where number facts,
numeration, number and operation, and to less extent, estimation were part of that knowledge base), metacognitive strategies and beliefs, and an efficient central executive (to coordinate retrieval from LTM and allocation of strategies and facts for short-term storage and manipulation of numbers) supported accuracy and flexibility in mental computation. Without this knowledge base, students were inaccurate.

It seems that with a strong connected knowledge, accurate students had more options available for mental strategies. With a less connected and weaker knowledge base, inaccurate students’ use of strategies was an attempt to compensate for their lack of knowledge. The inaccurate students compensated by inventing strategies when the teacher-taught strategies could not be followed. However, although STM was sufficient, these students’ knowledge base was so minimal and disconnected that the use of the strategies was not efficient, and resulted in errors. Further, the knowledge base did not support high-level strategies.

This demonstrates the need for teaching practices to go beyond developing flexible use of strategies in mental computation. The practices should not focus on the strategies in isolation; they have to focus on the development of an extensive and integrated knowledge base to support the strategy use. This means covering number facts, numeration, effect of operation on number, and estimation. Other factors that need to be addressed are metacognition and affects.

Students can and do formulate their own strategies and this should be encouraged because of the learning that results with respect to number sense (e.g., Reys, Reys, Nohda, & Emori, 1995). However, if accuracy in mental computation is one of the aims of computation, more has to be done than encouraging students to formulate their own strategies. While research (e.g., Buzeika, 1999; Kamii, 1989) has reported success with teaching experiments that encourage students to formulate their own strategies, it is obvious that other cognitive, metacognitive and affective factors come into play. In this study, it was shown that accurate (and flexible) mental computation was supported by a complex interaction of cognitive, metacognitive and affective factors. Further research is warranted as to teaching practices that can develop flexibility and the supporting knowledge necessary for accuracy and flexibility, possibly following the lines of Cognitive Guided Instruction (Carpenter, Fennema, Franke, Levi, & Empson, 1999), but including children’s affects and metacognition.

REFERENCES

This article is part of a larger study that examines the development of pupils’ proportional reasoning through classroom teaching. In a fifth-grade classroom, five pupils with varying proportional reasoning ability were studied by using qualitative research method. In this article, the pupils’ approaches to the same proportion problems before and after a series of 11 lessons on “quantity-per-unit” are compared. Results show that the major change after the lessons was their more active use of notations in dealing with the aspect of ratio and proportion. Especially there are notations that lead one to make aware of his/her own thinking, i.e., make it articulated, systematic, conscious and intentional. These significant notations were observed clearly in four pupils. Still, specificity of the notations varied depending on the pupils’ conception of invariant relation between two quantities.

BACKGROUND OF THE STUDY
The purpose of this study is to examine how the development of pupils’ proportional reasoning takes places in the mathematics classroom. A great deal of studies on proportional reasoning has shown different strategies children use and relationships of them with task characteristics (e.g., Vergnaud, 1993; Kaput & West, 1994). Along with the result of investigation in everyday life and in workplaces, researchers began to discuss the inextricable links of people’s thinking strategies with contexts (e.g., Nunes et al., 1993; Hoyles et al., 2001). In this study, classroom is also recognized as a unique place where students meet with different culture of mathematical ideas, feelings and discourse, which they will not know in their daily livings (Nagano, 1997). Indeed, in the classroom pupils’ meet different ideas of ratio and proportion, novel notations and specific ways of attending and using the symbols. Here, it is essential not only identify different strategies but also to look closely at pupils’ use of notations and associated meanings they give to them.

Hino (e.g., 1996, 1997) illustrated that pupils’ use of notations, which is introduced in class, is changing in nature. To discern the change, Hino (1999) proposed three-phase model of evolution of pupils’ use of introduced notations: “label use,” “positive use” and “effective use.” Case studies were done in different classrooms where notations such as “a/b” (“a” and “b” belong to different kinds of quantities) or “y=mx” were introduced. They showed that many pupils stayed at the incipient “label use” in spite of the fact that the teacher was hurry in proceeding to the “effective use.” Then what notations are productive and contribute to their evolution of use and eventually their development of proportional reasoning?

To delve into the question, the perspective of mediated action by symbols is taken (Vygotsky, 1978). As shown in the figure, elementary form of behavior is the direct reaction to the tasks in front of one’s eyes (S-R). On the other hand, structure of sign operations requires another form of behavior, in which indirect link between stimulus and response is made and function as a secondary stimulus (S-X-R). This is called
"mediated action by symbols." The intermediate link not only improves previous thought operation, but also makes such operation qualitatively new and enables one to control his/her own action with the help of extrinsic stimuli. Vygotsky says that base of higher psychological processes is one's ability to create and use these artificial stimuli intentionally.

Studies on mediated action in the context of teaching and learning of ratio and proportion are not many. Lo & Watanabe (1997) traced one pupil's change in ratio and proportion schemes in the laboratory setting. The pupil initially found certain correspondence between two quantities by trial and error approach. As the sessions unfolded, he began to express his strategy by way of table. The table gradually contributed to shaping his direction of problem solving process; and later he came to curtail the table process by using multiplication. This process indicates that his thinking became to be mediated by tables ("X" in the figure above). The study shows the potentiality of analyzing pupils' change and role of notations in approaching proportion problems from the perspective of mediation by symbols. Still, there are unanswered questions, e.g., "what and how 'X' is chosen," "whether pupils choose introduced notations in class as 'X'," or "there are some relationships between the chosen 'X' and his/her proportional reasoning ability." In this article, five fifth-graders' approaches to the same proportion problems before and after a series of 11 lessons are compared. Specifically, the following questions are pursued:

- In what way can pupils' changes in approaching proportion problems be viewed by paying attention to the mediation by symbols?
- What kinds of symbols are chosen as the mediator and in what way do they function in pupils' thinking?

**METHOD**

In this study, data were collected in a fifth-grade classroom in a public elementary school, rural area of west Japan. There were 9 boys and 11 girls in the classroom. The author and a graduate student observed the lesson everyday while the teacher taught the chapter on "quantity-per-unit." We recorded each lesson by two video cameras and audio tape recorders, and by our field notes. We also conducted written tests for the entire pupils before and after the lessons. Moreover, as for the focused pupils, we interviewed them before, during and after the lessons. In the interviews, we asked the pupils to explain their approaches to some of the problems in the written test, and also to solve additional proportion problems to look closely at their approaches.

In the present article, the five focused pupils' approaches toward proportion problems before and after the lessons (abbreviations "B-L," "A-L" are used below) are compared on the individual basis. Such comparison is possible since many of the problems used in B-L and A-L are the same. The problems are composed of different situations and different ratio complexities. Their ratio complexities are classified into 4 levels according to Hart (1981):

- **Level 1:** No rate needed or rate given.
  
  *(A car goes 200 km in 5 hours. If it keeps the same speed, how much time will it take to go 800 km?)*

- **Level 2:** Rate easy to find or answer can be obtained by taking an amount then half as much again.
  
  *(15 candies cost 240 yen, then how much will we pay for 20 of the same candies?)*

- **Level 3:** Rate must be found and is harder to find than above.
  
  *(6 candies cost 36 yen, then how much will we pay for 9 of the same candies?)*
(A car goes 200 km in 5 hours. If it keeps the same speed, how much time will it take to go 75 km?)

Level 4: Must recognize that ratio is needed, the questions are complex in either numbers needed or setting.

(A rectangle (length : width = 6 : 8) is enlarged by copy machine. When the width of new rectangle is 12, how will the length be?)

Note: Examples are taken from the problems used in this study.

In the written test, four Level 2 problems and three Level 4 problems were prepared. In the interview, problems were given from the lower level to higher levels by fixing the situations as “speed” and “fertilizer.” For example, in the speed situation, under the condition of driving a car at the speed of 200 kilometers in 5 hours, distance (time) was varied and corresponding time (distance) was asked. For each situation, two Level 1 problems, one Level 2 problem and one Level 3 problem were prepared. In the actual interviewing process, according to the response by each pupil, the interviewer judged whether to give problems with higher levels. Therefore, numbers of problems given to the pupils were not equal.

The focused pupils were chosen based on their performances, learning styles, seat locations and cooperativeness. Three boys (Yoshi, Himu and Honda) and two girls (Kawa and Ueda) were finally chosen (all names are pseudonym). In B-L, Yoshi, Kawa and Ueda had difficulty for approaching both the Level 1 and 2 problems. Himu was okay for the Level 1 but had difficulty for the Level 2 problems. Honda had no problem for the Level 2, did almost correct for the Level 3, but failed for the Level 4 problems.

During the 11 lessons, the teacher introduced quantity-per-unit (intensive quantity) to the pupils. By following the textbook, she dealt mainly with population density and velocity. The series of lessons began with discussing how to decide which of the two places is more crowded. Among different opinions, some pupils proposed to coordinate one of two quantities into the same amount and compare the amounts for the other quantity. The teacher pointed out the important idea of coordination and introduced the quantity-per-unit (number of people per 1 m²). In the sixth and seventh lessons, the pupils were engaged in the activity of measuring speed. For the purpose of deciding the fastest in class, they again used the quantity-per-unit and developed a formula of speed (v=d÷t). In the subsequent three lessons, the teacher introduced the double number lines to represent the relationship among four amounts in two quantities.

RESULTS

Pupils’ Performances across Problems with Different Levels of Ratio Complexity

Table on the next page shows percentages of correct answers for the five pupils in B-L and A-L for all problems given in the written tests and in interview sessions. The percentages were calculated according to levels of ratio complexity. The table shows that their performance for Level 2 problems increased in A-L. Kawa’s percentage for Level 1 problems also increased. On the other hand, Honda’s percentages did not show any change even though he showed highest performance among the five pupils in B-L.

Changes in Pupils’ Approaches to the Same Problems

Then, how did the pupils’ approaches to the same problems differ between B-L and A-L? For this purpose, their approaches to the same problems were put in order. In total, there
were 51 such cases. Among them, it was possible to identify some differences in 26 cases. Almost all cases for problems in Level 4 were discarded at this point because no differences were seen in the pupils’ approaches; they kept using ‘incorrect addition strategy.' Honda’s cases were also excluded due to the same reason. As for the 26 cases, the differences in the pupils’ approaches in B-L and A-L were compared and contrasted, which led to four categories. In this section, they are described briefly with some illustrations.

Note 1: “w” designates that the pupil got correct answers for “a” problems out of “b” problems given to the pupil. Note 2: The shadowed cell designates that the percentage in A-L is higher than that in B-L.

Making one’s thinking process explicit by numerical expressions. Compared with B-L, in A-L some pupils came to denote their process of thinking on the sheet of paper by using numerical expressions. Although the number of such cases was small (2 cases in Yoshi and Himu), the difference was remarkable in the eyes of observers.

The case by Himu is described here. He made his process of thinking explicit by verbalizing and denoting it on paper by both sentence and numerical expression. As the figure below illustrates, in B-L he tried but failed to express the idea of coordinating quantities to make two speeds comparable by using tape diagram. When asked how he did it in the subsequent interview, he again failed to make the idea explicit and showed insecurity in his answer.

Problem: (A table is shown. It shows that Salcura-maru goes 84 km in 4 hours and Kilar-maru goes 66 km in 3 hours) Which ship goes faster, Salcura-maru or Kilar-maru?

B-L:

(writing on paper)

"Let me make both [are going in] four hours, 66 ÷ 3 = 22 22 × 4 = 88. Answer Kiku-Maru"

In A-L, in order to make the two speeds comparable, he transformed the information “66 km in 3 hours” to “88 km in 4 hours” by keeping the rate constant. The idea of coordination was shown clearly in his writing. It is remarkable to know the difference of his notations (diagram vs. numerical expressions).

Becoming conscious of the quantity-per-unit. All the five pupils were observed to use the
unitary strategy in B-L. In using the strategy, pupils need to find the quantity-per-unit and to make use of it to solve the problem. In B-L, even though the pupils used the strategy, they tended to be less conscious of what they try to find and how they make use of it. It was noticed that the consciousness of the quantity-per-unit was enhanced in A-L. Eleven of such cases were discerned, especially in the approaches by Yoshi, Himu and Ueda.

The pupils’ growing consciousness of the quantity-per-unit accompanied the expression of rate orally or in written form. Yoshi came to describe the quantity-per-unit in words, to interpret the quantity and use the information in making decisions, and to apply the quantity to the relevant problems. For example, in B-L he calculated “66 ÷ 3 = 22” and “84 ÷ 4 = 21” for the ship problem above. However, he was not able to describe what “22” and “21” refer to. In A-L, he said clearly that both numbers refer to “the distance that the ship would go in 1 hour.” Becoming conscious of the quantity-per-unit and being able to use it better was his most notable change.

The growing consciousness was seen in various places in their thinking processes. Himu was unclear in finding the quantity-per-unit in B-L. He seemed to exclusively rely on his guesswork in head. In A-L, he came to find the quantity-per-unit at some time by using division, and at other time by using multiplication (e.g., “はたな掛けける4は20” (meaning “? × 4 = 20”)). Here, his guesswork was replaced by more systematic and reliable means. Compared with the others, Ueda showed scalar operator strategy more in B-L, though she was clever in using numerical patterns rather than making sense of the strategy. In A-L, her use of the unitary strategy increased. Thinking of quantity-per-unit enabled her to overcome difficulty where the scalar operator strategy induced remainder.

Problem: This wire weighs 390 grams in 6 meters. How much does it weigh in 10 meters?

B-L: Ueda tried the division 10 ÷ 6 but got confused because it would not divide evenly. So, she did “10 ÷ 6 = 4 390 × 4 = 1560 (g).”

A-L: Her reasoning is seen from her work on paper, “390 ÷ 6 = 65 65 = weight in 1 meter.” It continued such as “6 meters = 390. Still 4 meter less. 65 × 4 = 260 390 + 260 = 650 (g).”

These two cases show that the pupils took the idea flexibly and made use of it in the specific problematic situations they were facing with.

**Emergence of notations that assist thinking.** One notable feature of pupils’ behaviors in A-L is that they put some notations down on paper when they had difficulty in proceeding their thinking. There were 4 such cases. It occurred when the level of ratio complexity was raised to Level 3. In such situations, they were either degenerated into the incorrect addition or quit their thinking in B-L. The pupils’ restorations by the help of notations were seen in Yoshi, Himu and Kawa.

Both Yoshi and Himu wrote down the notations that designate correspondence between two quantities (e.g., “1 hour = 40 km”). Both pupils used the notations in the context of burden to proceed to their thinking. The case of Yoshi in A-L is illustrated below. He was approaching one of the speed problems (Level 3) that was totally out of his reach in B-L.

**Problem:** When a car goes at the speed of 200 km in 5 hours, how much time does it take to go 75 km?

Yoshi: 75 km? It sounds hard... (Hino reads the problem again.) Oh, 75... (he catches glimpses of the wall clock.) for 30 minutes it’s 20 km (he is thinking with his eyes to the clock) Well, well... it is difficult (he looks bitter.) well... to go 75 km, how many tens of minutes? mm... what is the answer, answer, answer (he wrote...
“Answer” and “1 hour”) well... 7 minutes 30 seconds, oh, wait a second (he wrote “since ‘5 km = 7 minutes 30 seconds’)

Hino: You don’t need to get the answer. Would you tell me how you thought about it?

Yoshi: How about the remaining 30 km? well, let me put this, since 2 (meaning 20), km is for 30 minutes, so, as for 10 km, let’s make both just a half, well for 15 minutes, 15 minutes, it’s 10 km (he writes “10 km = 15 minutes”) and, for 20 km it’s 30 (writing), since [the problem asks] 75, for 1 hour, it’s 40 km, for 1 hour, it’s 3, no, no, no... 35 remain, so let me add these two, 45, 45 (he adds 15 and 30), and add 7 minutes (he developed written calculation of 45+7=52.) it’s 52, so, 1 hour 52 minutes 30 seconds (writing).

His inscriptions are shown in the figure. In his writing, the correspondence between the two was taken for granted and even stressed by the symbol “=.” He was also aware of the distinction between the two quantities (which is on the left and on the right) and kept balance between the two (if you multiply one, you must multiply the other). This type of notations must have assisted him greatly to sort out the different amounts and quantities at hand.

In the case of Kawa, not numerical expression but drawing served as a clue in recognizing the correspondence. In B-L, she approached one of fertilizer problems by guesswork and eventually paid attention to the difference (minus 0.5 m² of land). In A-L, she was appealed by the difference again. However, this time she modified her thinking toward building up strategy. Here, Kawa relied on the picture she had just drawn (see the figure at right). She recognized that one small rectangle (1 m²) corresponds to half package and therefore she needs to minus 1 m² to find the area for one and a half packages of fertilizer (“then this part is here, this part is here, and this part is here..., and this part is missing....”). She had written the same drawings in B-L, however, they were not functioned as a clue to modify her approach.

**Attempting to use introduced notation.** In A-L, uses of introduced notation, double number lines, were observed in 3 cases of Kawa and Ueda’s thinking. However, neither used the notation in the way that the teacher taught. Even when they successfully represented the four amounts on the two lines, it was another hurdle for them to reason from the two lines. In addition, there were 4 cases that show the pupils’ confusions for meaning of division. Using the number lines requests the pupils to identify and connect four amounts in two different quantities and to relate them with quotative division. This hurdle was high enough for them who had already possessed misconceptions on division in B-L.

**DISCUSSION AND CONCLUSION**

The pupils’ performances on different levels of ratio complexity did not show steady change between B-L and A-L. Since the quantity-per-unit was taught in class, problems with Levels 2 and 3 were more to be targeted. Accordingly, the pupils’ correct responses to Level 2 problems increased. Still, their development was not clearly seen across levels. Nor were their performances stable. In A-L, they still had difficulty in lower level problems.

Nevertheless, the results show that major change was seen in their more active use of notations in dealing with the aspect of rate and proportion. Notations that appeared in A-L
varied, including different numerical expressions, drawings, expressions of correspondence between two quantities and the double number lines. They mediated the pupils’ thinking by modifying the stimulus situation as a part of the process of responding to it (Vygotsky, 1978, p14). Such notations were recalled or generated according to the pupils’ needs. They may be classified into three types by the extent to which they contribute to the pupils’ thinking:

- Notations borrowed (e.g., Kawa & Ueda’s use of the double number lines).
- Notations making aware of one’s thinking (e.g., Yoshi’s use of expression of correspondence, Kawa’s use of drawing)
- Notations inseparable to thinking (e.g., Honda (described later)).

An important observation of this article is that there are notations in the second type, or the notations that lead one to make aware of his/her own thinking. The categories outlined supports this argument. The pupils became more articulated in their reasoning both orally and in written form, which enabled them to reason beyond guess and ambiguous image. Their uses of the quantity-per-unit became more conscious. They came to find the quantity-per-unit systematically, to make decision based on information of the quantity, modify their thinking, and use the quantity-per-unit in order to complement their insufficient parts of reasoning. The pupils who previously depended only on memory also came to proceed by controlling their own thinking with the help of notations. Vygotsky & Luria (1994) regard that changing relationship between speech and action is characteristic to the process of emergence of higher-order mental functioning. According to them, child speech is at first accompanied by activity and simply reflects on it, but it gradually shifts to the starting point of the process of activity, precedes the action and comes to possess the function of directing the activity itself. The observations of using notations in more articulated, systematic, conscious and intentional ways made in this article do indicate that this crucial change is seen in their approaches between B-L and A-L.

Notations that came to play these significant roles in the pupils’ approaches to proportion problems also varied. Importantly, the notations that express correspondence between two quantities are widely used. Not only in written form, they were also heard from the pupils.

These significant notations did not exist uniformly out there but depended delicately on the conceptions of ratio and proportion that the pupils had developed earlier. The pupils were building their use of notations on their own strategies. This is shown, for example, in the cases of Ueda and Himu. Both made sense of the quantity-per-unit in A-L. However they began to use it differently. For Ueda, it served as a clue in overcoming the difficulty of division failure. On the other hand, for Himu it gave a reliable way in place of guesswork to find the quantity.

Another observation is the pupils’ difficulty in the use of double number lines. For those pupils, this introduced notation did not necessarily become significant notation. It again suggests its dependency on the pupils’ conception of ratio and proportion, especially invariant relation between two quantities. In developing the expression of correspondence, it is speculated that they attend only statically to the two quantities (c.f., “ratio” by Thompson, 1994). On the other hand, the double number lines request them to conceive the quantities as varying each other while they maintain the rate invariant. This gap must be profound for the
pupils. Honda seems to be the only pupil who had mastered the double number lines. He solved them in the following way.

**Problem:** This wire weighs 390 grams in 6 meters. How much does it weigh in 10 meters?

<table>
<thead>
<tr>
<th>B-L:</th>
<th>A-L:</th>
</tr>
</thead>
<tbody>
<tr>
<td>$6 \times 5 = 30 \div 3 = 10$</td>
<td>$6 \div 3 = 2$</td>
</tr>
<tr>
<td>$390 \times 5 = 1950 \div 3 = 650$</td>
<td>$390 \div 3 = 130$</td>
</tr>
<tr>
<td>$650 \text{g}$</td>
<td>$2 \times 5 = 10$</td>
</tr>
<tr>
<td>$130 \times 5 = 650$</td>
<td>$650 \text{g}$</td>
</tr>
</tbody>
</table>

Honda's approach can be said to be an interiorized version of the use of double number lines. His conception of invariant relation was stable and also flexible. For Honda, parallel expressions with multiplication/division by the same numbers were inseparable to his thinking, or functioned as more than significant notations.

**TASKS FOR THE FUTURE**

The analysis is still going on. It is now analyzed what had occurred in the course of learning of the five pupils during the series of lessons on "quantity-per-unit." Questions that lead the analysis include: what kind of notations did they bring to the instruction?; what kind of notations did they generate and modified during instruction?; what had influenced on such notational activities?; and when and where the pupils came to develop significant notations? Preliminary observations show that from the very beginning the pupils select specific notations based on their taste, and that instruction influences the emergence of consciousness of the pupils' uses of notations indirectly. Information on these matters will contribute to revealing how social aspects of learning impact individual's development of proportional reasoning and to designing lessons that take care of each pupil's positive resources to be used in refining their conceptions (Moschkovich, 1998).

BUILDING NEWTON–RAPHSON CONCEPTS WITH CAS

Ye Yoon Hong & Mike Thomas
The University of Auckland

In this study the computer algebra system (CAS) Derive in TI-92 calculators was used to encourage an inter-representational approach to the study of the Newton-Raphson method. Students in both New Zealand and Korea were given the opportunity to use CAS to build an understanding of how and why the method works. In addition they were able to construct some of the key concepts of function underpinning the method. The results of the tests and questionnaire suggest that students can integrate CAS into an overall strategy in a way that assists them in their conceptual understanding of this method.

Background

A deep understanding of mathematics involves an appreciation of how different representations contribute in often subtle ways to concept formation. A number of aspects converge in building this type of understanding for students: forming conceptual links between different representations; the ability to translate between representational systems (Lesh, 2000; Hong, Thomas, & Kwon, 2000); and the qualitative nature of the interactions with each representation (Thomas & Hong, 2001). None of these aspects is straightforward. For example, as Greer and Harel (1998) point out, students may have a surface ability to form links between procedures in two representational systems without forming an understanding of the deeper, conceptual links which are imbedded in the transformations between representations. In the case of interactions, Thomas and Hong (2001) have described up to nine qualitatively different types of interaction with representations which students may engage in. These are divided into those which involve procedural interactions, such as calculating the gradient of a function at a point from an algebraic formula, table or a graph, and those which require either a conceptual process (CP) or a conceptual object (CO) perspective of the representation. Examples include investigations of whether a function has points where the gradient is the same (CP), or conservation of properties under transformations of the graph of a function (CO).

CAS calculators provide an opportunity to promote investigation and discovery through a multi-representational approach to problem solving, enabling manipulation of mathematical concepts both within and between different representations. However, it is becoming increasingly apparent that using CAS is not as straightforward matter as it might once have appeared. First there is the question of what prerequisites students need in order to use CAS effectively. Pierce and Stacey (2001) have described a framework to analyse algebraic insight, which they believe is crucial in advance of CAS work. Secondly, others have expressed doubts about the extent to which students generally form inter-representational thinking (e.g. Tall, 1996). Finally, there is the issue of the choices facing teachers and students in the implementation of CAS calculators. Students have to be able to form an overall strategy to solve a given problem and to decide where, and how, to integrate CAS use. They may be faced with a considerable number of choices with regard to such implementation. This involves
the issue of instrumentation (Trouche, 2000), the change from calculator as tool to its use as an instrument, with the instrumentation process being separate from the conceptualisation process. This instrumentation process involves the nature of student interaction with CAS, and the integration of pen and paper methods with CAS use (Lagrange, 2000). In the former case the CAS can be used in a procedural way, as a form of ‘black box’ which simply produces results of calculations on demand, or as a window onto concepts, or a combination of these. In the latter students have to form a partnership with the CAS, making individual decisions within an overall strategy on when thinking with pen and paper is appropriate and when and how to use the CAS.

**Method**

This study considers the above issues in the context of New Zealand and Korean students using CAS in the Newton–Raphson (NR) method. We investigated whether CAS use improved students’ conceptual understanding of this method of calculating approximations to roots of equations; what factors were influencing this; what kind of partnerships with CAS students formed; and whether there were any cultural differences (based on the different languages and diverse cultures).

The diagram below shows the graph of \( y=f(t) \) for \( 0 \leq t \leq 42 \).

3. Use an initial estimate of \( x_0=15 \). Find the first iterate, \( x_1 \), of the Newton–Raphson method to solve the equation \( f(t)=0 \). Round your final answer to two decimal places.

4. Use an initial estimate of \( x_0=15 \). Use the above to show geometrically how the first iterate, \( x_1 \), and then the second iterate \( x_2 \), are found using the Newton–Raphson method. Clearly indicate on the graph \( x_0, x_1, \) and \( x_2 \).

*Figure 1. A Newton–Raphson examination question requiring geometric understanding.*

The NR method was considered a suitable subject for research because: CAS use is beneficial in calculus (e.g. Heid, 1988; Hong & Thomas, 1997; Trouche, 2000; Drijvers, 2000); it is an area where teaching can concentrate on the procedural symbolic, with little attention to visualisation; and CAS can be used in a 'black box' mode without understanding of the process. For example, for New Zealand university entrance examination questions such as that shown in Figure 1, students often fail to demonstrate any geometrical understanding of the NR method. Typical comments on the geometric aspects of questions like this from New Zealand examiners' reports over a number of years, include: "Very poorly done. It is apparent that many candidates had no geometrical appreciation of the Newton Raphson method. For such students, this topic becomes nothing more than an exercise in evaluating a number of arithmetic expressions." A case study methodology was employed in each country with a partial qualitative and quantitative comparative analysis superimposed.

**Subjects:** Two high schools were used in this study, one in Auckland, New Zealand (NZ) and one in Seoul, Korea. The NZ school is an independent co-educational school with a relatively high socio-economic intake. The seventeen 16–17 year old students in this advanced Form 6 class had previously covered all the university entrance work, including the calculus and the NR method, but without using the CAS calculators. The twenty 16–17 year old Form 6 Korean students were all volunteers especially
interested in mathematics, attending a co-educational school with an average socio-economic intake. The Korean students had no background in calculator use and none had ever used a graphic or a CAS calculator. In contrast, while the NZ school has a positive view of technology use, its students had not previously used CAS.

Since the NR method is not included in the Korean curriculum, after their normal classes on differentiation the procedure was first taught without the calculators. This was to mirror the experience of the NZ students in order to be able better to make comparisons. Also Korean Form 6 students do not learn about exponential function and differentiation of sine and cosine functions, so one short lesson on these was added before the pre-test. The research project was carried out in New Zealand during 16th to 26th July, and in Korea from the 12th to 20th November of the same year.

Example. Solve the equation \(\sin x = 2x - 1\) using the Newton-Raphson method. Give the answer accurate to 4 d.p.

The first step is to define the graph of \(y = \sin x - 2x + 1\) and sketch the graph:

<table>
<thead>
<tr>
<th>Method 1.</th>
<th>See</th>
<th>Explanation</th>
</tr>
</thead>
<tbody>
<tr>
<td>Press: (\sin x - 2x + 1)</td>
<td></td>
<td>The function is defined using (y_1 = \sin x - 2x + 1)</td>
</tr>
<tr>
<td>(F5\ A: Tangent\ [ENTER])</td>
<td></td>
<td>The first tangent line starts at the point (x_1 = 1). The equation of the tangent is given as (y = -1.46x + 1.301). This will be used to find (x_2) (which should be closer to the root than (x_1)), by seeing where it crosses the (x)-axis.</td>
</tr>
<tr>
<td>Tangent at? 1 [ENTER]</td>
<td></td>
<td>We can see that the next point (x_2 = 0.8911)</td>
</tr>
<tr>
<td>(F\ [HOME]\ F2\ [ENTER])</td>
<td></td>
<td>The equation of the tangent is given as (y = -1.372x + 1.218) at the point (x_2 = 0.8911). This will be used to find (x_3) (which should be closer to the root than (x_2)).</td>
</tr>
</tbody>
</table>

Return to \([GRAPH]\) \(F5\ A: Tangent\ [ENTER]\) | |
| Tangent at? 0.8911 [ENTER] | |

This process was then repeated until \(x = 0.8882\) was obtained.

**Figure 2.** A section of the module showing the layout and calculator screens.

*Instruments:* A module of work using the TI-92 calculator was prepared. It addressed key mathematical concepts and ideas required for understanding NR, including: variable, expression (function), equation, tangent, graph, limit, differentiation, and the NR method, doing so in an inter-representational manner. Each section of the module was set out according to a ‘Press’, ‘See’, and ‘Explanation’ format (see Figure 2 for an example). Two NR methods were presented. The first comprised an intuitive approach seeing visually how we can often get nearer to a zero \(x\) of a function by drawing successive tangents and using the CAS to find the equation of the tangent in the graphical mode and its zero on the algebraic home screen. The second method used two derivations of the standard algebraic formula: rearranging the equation of the tangent: \(y - f(x) = f'(x) (x - x)\) with \(y = 0\) when \(x = x\), and a more visual approach, using the triangle created by the tangent and equating the gradient written as the quotient of the two sides and the derivative, i.e. \(f'(x) = \frac{f(x)}{x - x}\). \]

\[
\text{Figure 3. Some section B post-test questions on the Newton–Raphson method.}
\]

The tests were divided into sections A and B, with the former containing essentially procedural skills but the latter demanding greater conceptual understanding, especially geometrically. We wanted to know if they knew how and why the method worked and could apply this. We were also interested in when and how they would make use of the CAS. In B3, B4 and B5 (see Figure 3) a general function \( f(x) \) rather than an explicit function was given, discouraging immediate use of a procedure, instead necessitating understanding and application of relationships.

**Procedure:** The module, written in English, was given to the New Zealand teacher, and a Korean translation was given to the Korean teacher. Once the teachers were comfortable with the calculator and the material they taught their class for four lessons covering basic facilities of the calculators and describing ways to find a limit, a gradient function, and roots of an equation. Each student had access to their own TI–92 for the whole study, including time at home. In each country the teacher stood at the front of the class, who sat in the traditional rows of desks, and demonstrated each step using a viewscreen while the students followed in the module and copied the working onto their calculator. Afterwards the students worked while the teacher circulated and assisted with any problems.

**Results**

Comparing the overall results of the Korean and New Zealand students on the pre- and post-tests there was a significant difference on both section A (\( m_{\text{Korea}}=3.15, m_{\text{NZ}}=5.35, t=3.51, p<0.005 \)) and B (\( m_{\text{Korea}}=2.7, m_{\text{NZ}}=5.6, t=3.14, p<0.005 \)) at the pre-test. It was not surprising that the New Zealand students were performing better initially since they had studied the topic previously. However, at the post-test an interesting difference emerged. As expected, for the section A skills questions, the Korean students improved considerably, and although there was no significant difference between the scores on this section (\( m_{\text{Korea}}=7.15, m_{\text{NZ}}=6.35, t=1.17, \text{n.s.} \)), there was a highly significant difference in the gain scores in favour of the Korean
students (see Table 1). In contrast both groups improved about the same on section B (see Table 1), and so the New Zealand students remained significantly better than the Korean students here ($m_{\text{Korea}}=5.90$, $m_{\text{NZ}}=8.53$, $r=1.97$, $p<0.05$).

Thus it seems that the use of CAS calculators was effective for both procedural and conceptual understanding in both countries, for those familiar and not familiar with the method, but for the former the main benefit was in conceptual understanding.

**Understanding concepts:** Our analysis of the NR method indicated that students needed to form a partnership with the CAS interacting with its representations (Thomas & Hong, 2001) in a way that would help them to construct an inter-representational understanding of at least four key ideas:

1. The sign of $f$ and $f'(x)$ (gradient of the tangent) affects whether the second estimate is $>$ or $<$ the first estimate.
2. The size of $f'(x)$ (gradient of the tangent) affects the existence and value of the second estimate.
3. The sign of $f''(x)$ (concavity of the curve) at the first estimate affects whether the second estimate is $>$ or $<$ the root $a$.
4. A geometric understanding of how and why the method works i.e. tangent intercepts getting progressively closer to a root and a sense of where the algebraic formula comes from.

Solutions to question B3 (post-test mean 0.996 out of 2) gave some insight on student thinking on point one. For example, Figure 4 shows the post-test solutions of two students, NZ1 and NZ2, who were both unable to answer at the pre-test.

**Figure 4.** Student working on question B3 showing appreciation of the sign of $f'$.

NZ1's solution involved interacting with the algebraic formula representation rather than visualising the graph and the tangent. It was based on general principles of the sign of the two functions $f(x)$ and $f'(x)$, showing that for $f$ and $f'>0$ $x_2<x_1$. Evidence that he was also able to think visually about them in the graphical representation was apparent from his comments in the questionnaire. Showing that he had understood the way the tangent influences the solution process he responded to the question 'How does the Newton-Raphson method work?' with "Tangents on the graphs bring you closer to the root of the graph." Thus while he had an inter-representational perspective he chose not to use it on this occasion. This is an important point. Student NZ2, however, connected the symbolic representation of the
1-4. WILLI MUNGLER'''. Ul uiG &Lapilli:ill representauon atm 11.CIaCle11

with this representation to demonstrate the influence of the sign of the function (drawn as positive), and the gradient, on the position of the second approximation.

Point two, learning the role of the size of \( f' \) can be illustrated by the post-test working of students NZ3 and NZ4 on question B4 (post-test mean 0.947 out of 3, see Figure 5). Interacting with the graph both have appreciated that the first estimate has to be sufficiently close to \( a \) for the gradient to be large enough for the tangent to cut between \( x=a \) and \( x=b \).

Further evidence of this understanding was provided in questionnaire comments. When asked 'What is important about the choice of the first approximation to a root when using the Newton–Raphson method?', students showed an understanding that a gradient which was too small or zero would cause problems:

NZ1: You can't choose a max or min point or else you won't cut the x-axis. Also the tangent could go towards the wrong root.
NZ5: It is very important that the approximation is close enough the root and not on a turning point. Otherwise you might be finding the wrong root.
NZ6: It must be close to the root so the tangent gives you the nearest value. Also you can't choose a stationary point as a first value.

Some students gained understanding of the role of concavity in the NR method. Figure 6 shows the post-test working of three students NZ7, KR1 and KR2 on question B6 (post-test mean 1.13 out of 4). In each case they have managed to construct a function whose graph has the required concavity (concave down to the left of \( a \)) to put the first and second estimates on opposite sides of the root, as requested (although KR2 has an error - drawing a function which is concave up on the right and mistakenly trying to show the third estimate as greater than \( a \)). Interestingly NZ7 has constructed a function with 2 zeros, which was not required, and has arranged the gradient of the tangent at \( x_2 \) to be small enough so that it crossed the axis near \( x=a \),
rather than close to the nearer zero. This shows a good grasp of principles in this conceptual interaction with the graphical representation. KR1's written explanation shows that she understands that all further estimates of the root will be greater than \(a\) for her function. Student understanding of the way in which the NR method works (point 3 above) was provided in answers to the question 'How does the Newton–Raphson method work?' Some of the responses were:

KR3: Take some point \(x_1\), draw the tangent line at the point. Find the other intersection point \(x_2\) on the graph. In the same way, finally find the intersection point \(x\) on the \(x\)-axis.

NZ2: It finds a root of a graph by finding out where the tangent of a close guess cuts the \(x\)-axis.

NZ7: Start with the initial point. Draw the tangent line. Take the approximation closer to the root.

These (one translated from Korean) and others, refer to tangents, and they clearly have the idea of how NR uses these to get closer to the root. They are developing representational fluency (Lesh, 2000) and are no longer limited to working only within an algebraic representation.

*CAS Partnership*: One of the methods used in the study for integrating CAS into the method of estimating the roots using NR required the students to have a good overview of the strategy and to see clearly when and how to employ the CAS and when pen and paper techniques (point 4 above).

Figure 7. Students KR1, KR5 and KR6's pen and paper working for the CAS method.

Figure 7 shows work from three students on question B7 (post-test mean 0.729 out of 2), which asked them to solve \(2e^x+\cos x=2\), without specifying a method. All have correctly identified the function to use and KR6 has also written the standard algebraic formula for the NR method. In each case they have chosen to integrate CAS into an overall strategy, as encouraged in the module. First they select a reasonable initial estimate, \(x_1=1\) in all three cases. Moving to the CAS they enter the function using the \([Y=]\) facility and then plot the graph, making sure that the viewing window is satisfactory. Next they use the CAS graphing screen to find the equation of the tangent at 1, and write this down using pen and paper. They have to know what the
strategy requires them to do with this tangent equation, namely using the CAS algebraic home screen to find its zero. Appreciating the role of this value, 0.5411, as the next estimate in the overall method they can return to the graphical representation and use the CAS to find the equation of the tangent at the point \( x=0.5411 \). Finally they have to be able to see that this cycle is repeated until the accuracy required is obtained. This is a fairly sophisticated integration of CAS into a strategy, and shows that these students had become competent users of CAS for the NR method, able to form a good partnership with the technology. Of course, once students have a good overview of the method and its concepts then there is no reason why they should not use the CAS in 'black box' mode and enter \( \text{solve}(2e^x+\cos x=2, x) \) to obtain the root.

There were some differences between students in the two countries. For example, the Korean students were caused some anxiety by the calculator commands, since these appeared only in English. The teacher translated them into Korean for the students but some confusion ensued until they became more accustomed to the English. The psychological anxiety caused by this could have affected their self-confidence and hence their ability to build mathematical understanding. In spite of this the students from both countries have improved in their understanding of concepts associated with NR method. They have increased the versatility of their representational interactions (Thomas & Hong, 2001) and begun the process of instrumentation of the CAS calculator. This has enabled them to be more comfortable with overall strategies integrating CAS with pen and paper methods.

HAVE ALL CHILDREN BENEFITED?
A Perspective on Curriculum Initiatives and Low Achievers

Abstract
This paper considers whether or not curriculum initiatives within England are in fact leading to qualitatively improved levels of thinking amongst children identified as lower achievers in arithmetic. Revisiting data from two earlier studies and introducing current data, the paper draws comparisons in the strategies that 8-year-old children use to solve a range of addition and subtraction combinations on numbers to 20. It considers the outcomes in the context of current theories of concept development and national requirements of expected levels of achievement for such children. The results suggest that these requirements and the way in which they are implemented may seriously impede these children’s cognitive development in elementary arithmetic.

Introducing a Perspective

The analysis of the strategies young children use to solve simple arithmetical problems can provide a framework to study the development of their arithmetical skills and the level of sophistication they employ to engage in numerical activity (Gray, Pinto, Pitta, & Tall 1999). It is the purpose of this paper to consider these notions in the light of initiatives implemented within English primary schools over the past decade. In doing so we focus particularly on children who, despite these initiatives, have difficulty recalling number combinations to 20. The evidence suggests that children within the lower quartile of arithmetical achievement are continuing to operate at a procedural level in the sense that they attempt to use a step by step routine such as counting to obtain solutions to elementary number bonds.

In the context of elementary arithmetic the initiatives have placed an emphasis on the ability to recall basic facts and use them to derive others. The latter feature lies at the heart of a strong emphasis on the development of flexible mental approaches to the calculation of two and three digit number combinations. Within this paper we present comparative evidence to illustrate that difficulties remain for some children. Fusing evidence drawn from three distinct studies over the past ten years we consider cognitive and pedagogic reasons as to why the situation has not changed. In doing so we are aware of social and cultural factors that may have a strong influence on the mathematical behaviour of the children we are considering (see for example, Cobb, 1987; Gruszczk-Koczynska & Semadini, 1988) but that is for a bigger story.
The construction of mathematical knowledge is a central platform from which the considerations within this paper are developed. It takes the view that hypothesised notions of development may not fit reality, particularly if children at the lower extreme of achievement are considered.

The development of early numerical concepts is heavily associated with physical activity and the pervading belief is that these concepts evolve from an interaction with the environment (Tall, 1995 after Piaget, 1973). Actions on physical objects can lead to the development of procedures through which processes are named, symbolised, and conceptualised. Establishing an appropriate conceptualisation is seen as the product of a suitable form of abstraction (Piaget 1985, Dubinsky, 1991). However, the knowledge and beliefs that learners bring to a given learning situation can influence the meanings that they construct in that situation. This would suggest that learners might select different aspects of an activity to focus upon which in turn leads to different forms of abstraction. When the latter is based upon perception of physical objects it is termed *empirical*. Alternatively such abstraction may not be based on the perception of objects but on the common feature of a series of actions. In such a case it is termed *pseudo-empirical*. The repeated practice of counting leading to the concept of number provides an example of this form of abstraction. The metamorphosis of actions with physical objects through a variety of increasingly abstract representations to form numerical concepts is outlined by Steffe, von Glaserfeld, Richards and Cobb (1983). Through such transformations it becomes possible to act upon the results of carrying out processes without bothering about the processes themselves.

Stages in the process of pseudo-empirical abstraction are frequently discussed in the context of process/object theories (see for example Sfard 1991; Cotterill et al, 1996) and they form the basis for the encapsulation or reification of new objects. There is much to be gained from such a move. Cognitive strain is reduced if it is possible to think of a concept as a single object rather than a lengthy process. However, it is difficult (Sfard, 1991) and its difficulty can lead to qualitatively different outcomes (Gray & Tall, 1994) which can be associated with success or failure.

The observation that some individuals are more successful than others in mathematics has been evident for generations. Piaget provided a novel method of interpreting empirical evidence by hypothesising that all individuals pass through the same cognitive stages but at different paces. Such a foundation underlies the National Curriculum (DfEE, 1999a\(^1\)) with its sequence of levels

---

\(^1\) Although only the most recent is referred to within this paper, The National Curriculum has been through three transformations since its implementation in 1991. It outlines both legal requirements (Attainment Targets) and also provides information to help teachers implement these requirements with in schools (Programmes of Study).
through which all children should pass at an appropriate age, some progressing further than others during the period of compulsory education.

Within England and Wales the process of improving standards in numeracy — some aspects of which are seen to improve “confidence and competence with numbers” requiring “an inclination and ability to solve number problems in a variety of contexts” (DfEE, 1999b, p 4) — are specified within two documents. The first, the National Curriculum for Mathematics (DfEE, 1999a), identifies the contents of the mathematics curriculum that should be taught during Key Stage 1 (KS1, age 5 to 7) and Key Stage 2 (KS2, age 8 to 11). The second, the National Numeracy Strategy (NNS) (DfEE, 1999b), identifies, almost through a process of genetic decomposition, how and what should be taught to instill a sense of being numerate. The teaching requires that “teachers will teach the whole class for a high proportion of the time and that oral and mental work will feature strongly in each lesson” (ibid. p.2).

Since the inception of the National Curriculum, formal assessment of the level of achievement of each child against the specified targets has been made through Standard Assessment Tasks, which are taken at the end of KS1 (children 7+, the average to achieve level 2) and KS2 (children 11+, the average to achieve level 4). Since this report is looking at early number development it is appropriate to indicate that for a Level 2 attainment a child would need to demonstrate mental recall of addition and subtraction facts to 10, and recall addition and subtraction facts to 20 for Level 3 (age 8/9). It should be noted that the programme of study for KS1 indicates that 7+ children should be using known facts to 10 to derive facts with totals to 20.

Both the programmes of study and the NNS are fully aligned, the latter providing a detailed basis for implementing the statutory requirements. The development of the early number requirements of the National Curriculum are identified within the NNS by an approach that sees a transition from the use of perceptual items to “more sophisticated mental counting strategies” finally sublimated by the acquisition of basic number facts that are taught. By and large we may see a curriculum that can be compared favourably with the Steffe et al (1983) model

To achieve these ends the NNS strategy suggests that a daily mathematics lesson is appropriate for almost all pupils. Individual needs do not necessarily warrant individual attention although the needs of particular children may be met through differentiated work and other teaching strategies.

Comparing Approaches

The question arises as to whether or not the initiatives within the UK have made substantive differences to the quality of thinking of those who are at the lower end of the spectrum of mathematical achievement. Is it possible to detect qualitative changes in the way in which they interpret mathematical symbolism by comparing the general use of strategies by children who have participated
within the NNS with those who have not? If the initiative has been advantageous we would expect to see that there is a greater evidence of the ability to recall basic facts and evidence that the children use these facts to establish the facts not known.

To begin to consider a response we draw upon and compare three pieces of evidence indicating the strategies used by 8/9 year-old children (Y4):

1. The classified strategy responses reported in Gray (1991)
2. Classified strategy responses reported in Pitta (1997)
3. Recent data obtained as part of an investigation into children’s participation within the oral phase of mathematics lessons conducted in accordance with the NNS (2001).

Four different schools are represented within the analysis and these range in type from two small town schools (1991), a small suburban school (1997) and large inner city school (2001). Data collection methods for each of the three samples were essentially similar and included semi-structured clinical interviewing, video recording of these interviews and subsequent analysis of the responses.

Children within each sample represented the lower end of the spectrum of achievement. The 1991 sample, in the class teacher’s view were representative of the lowest quartile of achievement within the year group. In the second and third cases children were chosen from within the lowest 20% of scores within the KS1 Standard Assessment Tasks. Within the chosen year group (Y4) the average child would be expected to recall all number combinations to 20. Schools from which the two most recent samples had been drawn have subject to recent external inspection by the Office for Standards in Education (Ofsted). Mathematics teaching within both was identified as “mostly satisfactory”.

Here we report on strategies used to solve the questions that were common to all children, namely 0+2, 6+3, 3+5, 14+4, 3+16, 4+7, 9+8, 3-3, 6-3, 9-8, 15-9, 13-8, 12-8, 16-10 and 17-13.

Table 1: Comparative responses to elementary addition and subtraction combinations
Figure 1 indicates the cumulative percentage responses of the approaches used by children within each sample. The numbers of children within each sample are given by “n”.

Differences between each year group can clearly be identified, for example:

- Highest use of known facts by the 1997 group, particularly with subtraction combinations to 10
- Evidence of the use of derived facts by the 1997 group
- Highest number of errors by the 2001 group

However, what is more in evidence is the remarkable similarity between the children considered within each year. This can more clearly be seen in Table 2 which identifies distinctions, through the use of percentages outlining the use of processes to do (count-on, count-all, count back, count back to, take away etc) and concepts to know (known fact, derived fact). Essential differences in process driven approaches between the 1991 children, interviewed before the introduction of the initiatives, and the 2001 children are largely accounted for by the errors, mostly procedural, of the 2001 children.

The evidence suggests that subtraction combinations to 20 are more difficult for these children than the other combinations. In every case apart from the 1996 group’s response to subtraction combinations to 10, the use of processes, always counting, is higher than the use of concept driven approaches. Of course, it is difficult to identify whether or not knowing facts is concept based. A clearer confirmation could be obtained if those facts that are known are used to establish those that are not known. This feature is a specified aspect of the programs of study for KS 1 within the National Curriculum and there is a strong emphasis on this aspect of numeracy within the NNS. The indicators suggest that though we may identify differences between process driven and concept driven strategies, for these children those facts that are known are not used to establish those that are not known. The consequence is that we would see these as isolated pieces of knowledge. Reconsidering Table 1 would suggest that for children at the lower end of the achievement spectrum initiatives developed to improve the sophistication of their thinking have hardly had the desired outcome.

The application of a fixed routine procedure was a feature of the approach used by the children if they failed to recall a fact. In some instances these began to emerge very early within the interviews for example in combinations to ten and in the excessive use of fingers. The application of difficult almost non-
generalisable procedures became common when children attempted to apply the same procedure for subtraction combinations to 20. Count-back dominated as a procedure and this caused excessive difficulties with 17-13. Indeed, the greater proportion of errors within all groups is largely accounted for by procedural difficulties associated with counting. Children who successfully used fingers for counting small numbers had difficulty with quantities greater than ten. In some instances this was recognised. For example 17-13 was “too tricky to count” (1997 child). In others children attempted to obtain a solution but miscounted.

“9 add 8. .... It’s hard.” (1997 child)

“One, two, three, four, five, six, seven, eight, nine, ten, eleven, twelve, twelve, thirteen, fourteen, fifteen” (2001 child)

Others simply had no effective procedure and tried to keep a mental check (format)

“9 add 8—I ran out of hands”

“One, two, three, four, five, six, seven, eight, nine, ten, eleven, twelve, thirteen, fourteen, fifteen, sixteen” (2001 child)

This child’s second and third attempts gave the answers 17 and 20.

Thus, though in some instances no suitable counting procedure was identified, in others, particularly when attempting the subtraction combinations, difficulties associated with double counting procedures caused problems:

“I just counted one, two, three, four... sixteen, seventeen then I went seventeen, sixteen, fifteen, fourteen, thirteen and said five” (1997 child)

Discussion

We are drawing our evidence from those having the greatest difficulty in responding to the new initiatives at an elementary level. It is most unlikely that they will be in a position to respond to the initiatives at subsequent levels of difficulty. However, our evidence should not be used to imply that such children will forever be confined to the use of inefficient procedural approaches. Neither do we wish to place an artificial ceiling on their ultimate performance. We do recognise however that should they persist with what is essentially a fragmented knowledge structure, which in some instances is procedurally inefficient and in others is insufficiently compressed, they may be forced into less powerful strategies through trying to cope with too much information.

In one sense both the requirements of the National Curriculum and the pedagogic approaches associated with the National Numeracy Strategy may be attempting to overcome these problems by firstly giving children too many options to consider and then by focusing on rote-learnt procedures to perform as sequential action schemas. If successful, such knowledge can be used to solve routine problems, as we can see where children are successful in their counting, but it occurs in time and may not be suitable to support thinking about the whole entity, which is formed as a result of encapsulating the process.
By their very nature, the National Curriculum and the National Numeracy Strategy are offering a sequence of activities that teachers have to follow. They are grounded within a stage theory that we would suggest is flawed from the very outset. In addition there is also the sense that the teaching strategy has been identified through a form of genetic decomposition (Cotterill et al, 1996) which relies on the teaching of partial structures that may be qualitatively different from the way the whole is to be understood. Resnick & Ford (1981) questioned the reliability of such an approach, but given the Ofsted measures of mathematics teaching within the schools we would suggest that not only can the children not see this whole structure but it is strongly likely that neither can the teachers. Even if we assume that the NNS contains perfectly constructed, sequenced activities it is evident that the children are not seeing things this way. We have to look at the greater number of errors reported within the 2001 sample. Obviously these children have not interiorised (in the sense of Sfard 1991) an appropriate counting procedure to deal with combinations to 20.

Pitta (1999) suggests that children who have difficulty with elementary arithmetic are either unable to, or simply choose not to, see through actions and objects to embrace more abstract qualities. Their disposition has tended to lead them towards an empirical form of abstraction. Developing suitable stages in the process of pseudo-empirical abstraction in the context of counting actions and the development of number concepts has been one of the functions of teaching. The occurrence of a greater number of errors within the 2001 sample would suggest that the considerable emphasis now given to oral and mental strategies and whole class teaching has limited the time available to these children to interiorise and condense appropriate counting actions in order to make the abstraction. Perhaps teachers do not realise its fundamental importance. In the past we have often heard children told to “count” if they had difficulty.

We would suggest that the emphasis on effective mental approaches and institutional and national demands to achieve them have in fact removed the necessary experiences that these children require in order to make appropriate pseudo-empirical abstractions in the field of elementary number. Their focus is very much on physical objects to support counting. In the absence of aids, such as counters, they search for alternatives. The action is supplementary and we would suggest a secondary focus which has not been effectively interiorised (particularly for those who display errors), nor as our few examples illustrate, condensed. Some children now seem to be seriously disadvantaged. Not only are they demonstrating evidence that they have not encapsulated a counting process but they are also demonstrating that they have not interiorised the procedure.

The cumulative evidence is that if they know facts they fail to use them in the way that the initiatives suggest they should. Some reasons for this have already been discussed elsewhere (Gray & Tall, 1994). Now however we seem to see a higher proportion of children who do not seem to have the procedural competence to consider an alternative approach with confidence. It seems that what may truly be a positive initiative for a great number of children may not be so very positive for some of those it was designed to help.

A GROUP AS A 'SPECIAL SET'?
IMPLICATIONS OF IGNORING THE ROLE OF
THE BINARY OPERATION IN THE DEFINITION OF A GROUP

Paola Iannone and Elena Nardi
School of Mathematics and School of Education,
University of East Anglia, UK

The study from which this paper originates aims to contribute to the understanding of the difficulties that mathematics undergraduates encounter in a Year 2 course in Abstract Algebra. Analysis of their written responses to a question regarding a generic group on a set of four elements seems to suggest that such a group is not seen as a pair (set plus binary operation) but as a 'special set' where the axioms describe properties of the elements and not of the operation. Here we focus on certain implications of seeing a group as 'a special set': the students' occasional disregard for checking associativity (especially in a case where the group was presented in a table) and their neglect of the inner structure of a group (especially in their claim that two groups can be isomorphic but have different subgroup lattices).

The study of group theory gathered momentum in the mid-nineties with the work of authors like Ed Dubinsky, Uri Leron and Rina Zazkis (see references). The action-process-object-schema (APOS) theoretical framework was used to infer a general pattern for learning concepts like group, subgroup, cosets and normal groups. Also the learning of the concept of isomorphism (see Leron, Hazzan and Zazkis, 1995) was explored, and so was the use of Lagrange's Theorem (see Hazzan and Leron, 1994). The importance of studying this particular subject was suggested in Dubinsky et al. (1994):

In many colleges, abstract algebra is the first course for students in which they must go beyond learning 'imitative behaviour patterns' for mimicking the solution of a large number of variations on a small number of themes (problems). ...An individual's knowledge of the concept of group should include an understanding of various mathematical properties and constructions independent of particular examples, indeed including groups consisting of undefined elements and a binary operation satisfying the axioms. (p268)

This is still the case in most Universities in the UK, including the university where the present work was based. In this paper we want to show that this first encounter with this 'new' level of abstraction (see Hazzan, 1999) appears to be problematic as the students find it difficult to co-ordinate all the parts needed in a conceptualisation of the notion of group.
Research Issue. The main research issue we want to address in this paper regards the learning of the concept of group. More specifically, our conjecture, in the light of the evidence drawn from our study, is that the most difficult obstacle that the students face while progressing in forming a group schema is understanding that a group is formed by a pair: a set and a binary operation. In a study of the students' written work (see Methodology below) we observed this difficulty in the context of an exercise in which the students had to demonstrate an understanding of the axioms in the definition of a group (closure, associativity, neutral element, inverse element) and appeared to treat these properties, especially that of associativity, as properties of the elements of the group rather than properties of the binary operation. We also note that, while closure, neutral element, inverse element and commutativity are properties that can be checked by applying the binary operation on two elements, associativity involves operating on three elements and in a particular order – which, in the context of the particular exercise we examine here, was significant.

Methodology. This study is funded by the Nuffield Foundation and will last six months (October 2001 - March 2002). It is a small, exploratory data-grounded theory study (Glaser and Strauss 1967) of the mathematical writing of the students (55 in total) in the Year 2 Group Theory course of the 3-year degree in Mathematics at the University of East Anglia in the UK. It is the third phase in a series of small Nuffield-funded projects run by the two authors during the last two years as an on-going collaboration between the School of Mathematics and the School of Education at UEA (see for example Nardi and Iannone 2000). The aims of the study are: identifying the major problematic aspects of the students' mathematical writing in their drafts submitted to tutors on a fortnightly basis; increasing awareness of the students' difficulties for the tutors at this University's School of Mathematics; providing a set of foci of caution, action and possibly immediate reform of practice; and, setting foundations for a further larger-scale research project. The first two phases focused on Year 1 Calculus, Linear Algebra and Probability courses. The current phase focuses on the Year 2 Abstract Algebra course.

The course ran for 5 weeks at the beginning of the Autumn Semester 2001, with 4 hours of lectures per week. There were 3 seminar sessions for each of three groups of 15-20 students. The lectures were traditional front-teaching sessions. The seminars were run by a seminar leader (the first author) and a seminar assistant. The lectures were observed by the first author in order to become familiar with the examples and the notation the students were exposed to as well as with their general reactions to the new content. At the end of each seminar session the students were asked to submit a selection of the exercises in an exercise sheet. Their responses were then marked by the seminar leader and the seminar assistant. These written responses to the problems sheets administered at each of the three seminar sessions form the bulk of data gathered for this project.
The first level of data analysis, Data Analysis Version 1, involved the production of a student-by-question table that focused on the written responses of 15 out of 55 students registered for the course. This table summarised observations and comments of the first author on the students' responses to the set homework. After this table was completed, informal conversations were held with the seminar assistant to record his observations and comments after having marked part of the homework of the remaining student cohort. Following a detailed discussion of Data Analysis Version 1, the second author produced Data Analysis Version 2, a question by question table where the major issues were summarised, characteristic examples of the students' work were referred to and links with current literature were made. In these analyses it became clear that probing further into the students' thinking would be greatly helped if they could be asked to provide justification for parts of their writing, for example, via interviewing them. An initial step in this direction has been taken with an extensive interview of one of the students (parts of the transcript we use here to support the evidence from the students' written work).

**Forming An Image of the Concept of Group.** The data we use to raise the issue of the students' understanding of the concept of group originate in the first cycle of data collection and in the students' responses to the following question:

**Q1.5:** Write down all group tables for a group of four elements. Hence show that there are two essentially different such groups, both commutative. (Consider group tables obtained by merely renaming elements as essentially the same). How are they best distinguished? For each make a list of all the subgroups.

An understanding of group, subgroup and commutativity as well as a "naive" concept of isomorphism (see Leron, Hazzan and Zazkis, 1995: "Two groups are isomorphic if they are the same except for notation") are necessary here. Moreover let us observe that, at this point in the course, students had only just been introduced to the concept of isomorphism, and this is why the question setter suggested a criterion for judging when two groups are "essentially the same".

Fifty-two pieces of homework were handed in that week and all the students but one attempted this question. The most common response consisted of:

- a list of the four tables that can be obtained from a set of four elements;
- a declaration of some of the obtained groups to be isomorphic, hence the existence of "two essentially different groups";
- a list of the subgroups of each of these groups.

Commutativity was dealt with by observing symmetry around one of the diagonals of the tables. In the following we offer certain observations on and exemplify the students' responses.
A major common characteristic of the responses is that none of the students checked whether a group that satisfies these tables actually exists. The students constructed the tables possibly bearing in mind the direction of the lecturer (as recorded in the first author's observation of the lectures) to check that each element of the group appears only once in every column/row. This way of proceeding takes account of the properties of inverse, neutral element and closure but leaves out the checking of associativity. The fact that the table has to be shown to be associative, or else that the students have to produce an example of a group that satisfied the group table, went missed. One interpretation of this fact (see also interview extract later) is that, at this stage, the students deal with the concept of group as a "special set". The schema the students are referring to is the "set" schema and the properties are checked as to be properties of the elements and not of the binary operation defined on the set to form the group. If we agree that, by placing an emphasis on the order in which elements are operated on, associativity is the property of a group that refers more to the operation and not so much to the elements, this is not surprising. In short, instead of having a concept of group consisting of three interrelated schemas: set, binary operation and axioms (see Brown et al. 1997), the set schema dominates leaving the binary operation schema, and the checking of certain properties, neglected.

One implication of this domination of the set schema is evident in the response to Question 1.5, offered by Jo:

```
5.  e  a  b  c  2.  e  a  b  c
    e  e  a  b  c
    a  a  b  c  e
    b  b  c  e  a
    c  c  e  a  b

5.  e  a  b  c  2.  e  a  b  c
    e  e  a  b  c
    a  a  b  c  e
    b  b  c  e  a
    c  c  e  a  b

0 is indecomposable because it is odd.
Then that are in order as the names groups.
so they are isomorphic.
All tables are symmetrical along the line from top left.
To bottom right and are therefore commutative.

The subgroups are:
0 [e, x, y, z, e, e, x, e, y, z, z, x, y, z]
2 [e, x, y, z, e, e, x, e, y, z, z, x, y, z]
3 [e, x, y, z, e, e, x, e, y, z, z, x, y, z]
4 [e, x, y, z, e, e, x, e, y, z, z, x, y, z]
```
In Jo’s script three groups are said to be isomorphic. Yet a few lines later they are shown to have different subgroup lattices. The concept of ‘naive isomorphism’ seems to be affected by a failure to recognise a group as a pair. The notion that the binary operation defined on the set induces naturally an inner structure of the group (its subgroup lattice) is missed and this inner structure is not regarded as something that characterises a group. Therefore, two groups are seen to be ‘essentially the same’ even if their inner structure is different. Another student, Hazel, also does not seem to see any contradiction in the claim that two groups are isomorphic but have different subgroups:

Hazel’s actions, typical in the written responses we have examined, appear to be heavily table-based. Her understanding of the notion of isomorphism seems to involve processes she calls ‘swapping’ and ‘turning into’. Could we suggest that this firm adherence to/dependence on table-based actions, while facilitating the construction of the groups with four elements (and the checking of properties such as commutativity), at the same time places an obstacle in the students’ constructing an image of the group’s inner structure (as well as perhaps distracting them from checking associativity which requires operating upon three, not two, elements)? That
Hazel's notion of isomorphism is problematic is suggested also by the grammar/syntax she uses when she talks about isomorphic groups: she doesn't talk explicitly about, e.g., 1 as isomorphic to 2 but she writes '4 is isomorphic' (to what?). This problematic understanding of the 'naive' concept of isomorphism was widespread across the responses we analysed - as was the exclusion from the list of subgroups of the trivial ones (\{e\} and \{e, a, b, c\}) such as Steven:

\[
\begin{align*}
\text{Subgroups} & \\
\text{1:} & \{e, a, b, c\} \text{ and } \{e, c^3\} \\
\text{2:} & \{e, b^3\}
\end{align*}
\]

and the inclusion of subsets that were not closed or did not include the identity element. For example Wayne - who also throughout his writing does not adopt a consistent and conventional bracketing system to denote a set:

\[
\begin{align*}
\text{Can divide into 2 groups different groups} \\
\text{a) Group has 2 self-inverting elements (tables 1, 2, 5) } \\
\text{b) Group has all self-inverting elements (table 4) } \\
\text{Both commutative as the tables are symmetric on the left diagonal.} \\
\text{Subgroups for a) } & (e), (a), (b), (c) \text{ and } (e, a)^k \text{ for } a, b, \text{ or } c \text{ depending on which element is self-inverse.} \\
\text{Subgroups for b) } & (e), (a), (b), (c), (e, a), (e, b), (e, c), [e, a, b, c].
\end{align*}
\]

This suppression of the role of the binary operation and the tendency to attribute properties of the binary operation to the elements of the group was also evident in one interview with Wayne held at the end of the Group Theory course (we conducted this interview to test whether interviewing could illuminate us any further about the
reasons behind certain parts of students’ writing). The student responded to our question about the difference between a set and a group as follows:

**Wayne:** Hum ... A group has axioms ... certain axioms that have to hold. One is associativity. That is basically if you got elements, I don't know, $a$, $b$, and $c$ in the group then ... then, $a$ plus $b$, well, say that it is plus the operation [...] Yes, Then $a$ plus $b$ ... plus $c$ is equal the same as $a$ plus... $b$ plus $c$. That's the first property. You have got some neutral element. Which basically says that, say call it $e$, ... then if you multiply by any of these elements in the group you still get ... you get the same thing out. And then from that ... And also you have got an inverse. You have got $a$ and some $d$ they come together to come the inverse. $a$ plus $d$ is the inverse. Basically.

In Wayne’s words “a group has axioms” that “have to hold”. These axioms include associativity, neutral and inverse element. In this extract the binary operation is mentioned – albeit alternately referred to as ‘plus’ and ‘multiply’ (which is an often problematic choice of words - see Nardi 2000). He also seems to confuse the use of the words “inverse” and “neutral” in “$a$ and some $d$ they come together to come the inverse. $a$ plus $d$ is the inverse” but still his description of the properties seems to indicate a clear understanding of how they characterise the relationship between the elements. Later on he links these properties to his perception of a group:

**Wayne:** Oh ... I think that the group is a special kind of set, basically, where you got certain properties, basic properties, axioms, basic axioms that have been defined and for groups these hold, no matter what. And so ... that's why I see a group as a special kind of set. That's ... is not a set ... a group is like, ... a group is a set, but is a special kind of set that has properties that can be defined, can be shown to be true. For each group that you have. That's basically...

In Wayne’s words a group is a set whose elements happen to have certain properties, it is a “special set”. No reference is made to the group’s inner structure and to the central role the binary operation plays in the formation of this structure.

**Summary and Conclusion.** In this paper we discussed Year 2 mathematics undergraduates’ developing notions of a group in the context of their first encounter with a generic group on four elements.

Following strictly table-based actions the majority of the students constructed the four possible tables but, by leaving out the checking of associativity, they refrained from checking/showing whether a group that satisfies these tables actually exists. We conjectured that, by strictly remaining within a table-based action schema, the students demonstrated a dominant image of a group, not as a pair (set with a binary
operation), but as a "special set". In this schema the properties of associativity, inverse and neutral element are attributed to the group (and in particular to its elements) and not to the binary operation.

There seem to be certain implications of the above conceptualisation of a group as a "special set" in the students’ responses. One is that an image of a group that neglects the role of the binary operation – namely, the inner structure that the binary operation yields – makes the emergence of problematic images of isomorphism possible. Such images include: two groups can be isomorphic but have different subgroup lattices.

Another implication of the above involves an image of a subgroup as a subset of a group - evident in the students’ responses where subsets that were not closed or did not include the identity element were presented in the list of subgroups of the group.

GROWTH IN STUDENT MATHEMATICAL UNDERSTANDING THROUGH PRECALCULUS STUDENT AND TEACHER INTERACTIONS

Daniel R. Ilaria
Rutgers University

This paper investigates the role of teacher interaction in the development of mathematical understanding of five students who worked together on a math-modelling task. The dialogue between the teacher/researcher and students is analyzed. Preliminary findings suggest that where the mathematical thinking of the students was understood, interventions helped develop students' thinking. The Pirie-Kieren model of mathematical understanding guided interpretation of student mathematical thinking and understanding. [1]

INTRODUCTION

The students, engaged in conversation with the teacher, often give explanations for their ideas. A question arises as to what influence, if any, the teacher's response to those explanations have on student progress. This report examines dialogue between teacher and students and seeks to investigate the effect on students' growth in mathematical understanding.

The data come from a two-week summer institute that was a component of a longitudinal study on the development of proof making in students [2]. The students worked in groups on precalculus level mathematics problems. This paper focuses on one group of students and one of the problems they examined.

THEORETICAL FRAMEWORK

Communication is an essential part of the mathematics classroom providing a means for students to express their ideas and explain their thinking (NCTM 2000). Through communication students can share ideas and discoveries about the mathematics on which they are working. Since the communication process helps students create meaning for their ideas, NCTM (2000) includes communication as one of the standards in Principles and Standards for School Mathematics. Because of the need for communication in the classroom, an environment can be created where teachers and students engage in very important dialogue. Dialogue is important because it helps teachers assess the student's mathematical understanding and allows the students to clarify and express their ideas. Towers (1998) developed several themes to describe teacher interaction with students and illustrated how these interactions occasion the growth of students' understanding. A teacher should be skilled in interacting with students in order to gain access to students' mathematical understanding. Teacher questioning can help students justify and extend ideas, make
connections, and generalize their conjectures (Dann, Pantozi, Steencken. 1995). The development of these skills is not immediate for the teacher, but once gained the teacher has an effective way to facilitate the growth of a student's understanding (Martino and Maher, 1999).

Being a participant in the classroom discourse, the teacher has an important function. In describing a classroom where students are working in small groups on a task, Maher, Davis, and Alston (1991) indicate that the teacher plays many roles: listening to children, offering suggestions, asking questions, facilitating discussions, drawing out justifications. When students discuss with their teachers the meaning of mathematical notions, students are expected to think about concepts, their meanings and their interrelations (Vinner 1997). If students do think about concepts, they are in a conceptual mode of thinking (Vinner 1997). If students do not think conceptually, but still produce answers which seem to be conceptual, then Vinner (1997) states the students are in a pseudo-conceptual mode of thinking. The teacher must continuously assess whether or not the students have learned the mathematical concept, truly understands the reasoning behind their problem solving approach, and can adequately support and defend their conclusions using their previously learned mathematical knowledge. One way to determine what a student knows is to use a model of understanding. While many models exist, this research analyzes student understanding using the Pirie-Kiernen model of mathematical understanding (Pirie & Kiernan, 1994). This model is "a theory of the growth of understanding which is based on the consideration of understanding as a whole, dynamic, levelled but non-linear process of growth" (Pirie & Kiernan, 1994, p. 83). This theory shows that student understanding is an organization of ones knowledge not an acquiring of categories of knowing.

In a regular classroom, it is not always possible to observe what a student does after an interaction with the teacher. Because this observation is not always possible, it is difficult for a teacher to determine if the interaction was beneficial to the student. Videotape data that follows the student when the teacher leaves make possible gaining a better understanding of a student's actions. Interacting with students is a challenging task for the teacher, who has to make instantaneous decisions. The researcher, who has the benefit of studying and referring to videotape data, however, can learn from the interaction after the fact. What the researcher learns from the interaction can be shared with the teachers, who can reflect on their actions, and help facilitate a growth in students understanding.

METHODOLOGY

Participants. Five students seated at the same table (four males and one female) and one teacher/researcher were subjects in this study. All of the students were entering their fourth year of high school. The teacher/researcher involved in the interaction is
an experienced professor of mathematics and mathematics education at the university level.

**Task.** The students were given a picture of a fossilized shell called Placenticeras. The first part of the task was to draw a ray from the center of the shell in any direction. Then with polar coordinates as a way to describe the spiral of the shell, the students were to make a table of $r$ as a function of theta. After creating the table, the students were asked what they could say about $r$ as a function of theta. The students had graphing calculators, transparencies, rulers, and markers at their disposal for completing this task.

**Data Analysis.** The data come from a two-hour videotape session during the third day of a two-week Institute. The interactions were coded to consider perspectives of the teacher and the students. For the students, the following codes were developed and used: S(i): Student ignores the suggestion made by the teacher; S(c): Student asks the teacher for clarification of a statement; S(a): Student attempts the teacher’s idea or suggestion; S(e): Student engages in conversation for the purpose of explaining their own views. For the teacher: T(r): Teacher restates the problem or returns to an old idea; T(f): Teacher follows the student’s idea or suggestion; T(n): Teacher introduces a new idea; T(c): Teacher asks the student to clarify their statements or idea. The codes were used to follow the choices of the teacher and the resulting action by the student. When students became engaged in a conversation, their words were examined for evidence of their understanding.

**FINDINGS**

The students’ own words demonstrate where mathematical understanding occurs, and where their growth about a solution to this problem appears. This dialogue follows a discussion between the teacher and students regarding their solution to the task.

Student 1: S(e) I think it does. I mean if you look, if you look at the regression. It's just like a parabola. And uh your data.

Student 2: It is a parabola.

Student 3: S(e) It is a parabola. A very nice parabola. And like you know. I mean you can't use anything behind past zero on the x obviously because it can't have negative growth. That doesn't make sense. So you can't do that. But I mean the way, the way it goes up and the reason why it goes sharply up is just the fact that. I mean even from here to here like say the distance is 6 then all of a sudden it is 40. It's not going to keep on going little by little. Eventually it's getting wider like this. And that's why it's jumping so high up. It's not the fact that it's off or it's not predicting anything. It's just the numbers are getting larger and larger. It has to go higher and higher. So that's why it goes that steep angle like that.
Teacher: T(f) Ok well. I am still interested in that earlier part because. Are you saying that this animal really started growing where we're saying theta equals zero is.

Student 3: Um hmm.
Teacher: How do you know that?
Student 3: S(e) It’s gotta start somewhere. And it doesn’t start. You can’t start. You can’t start.
Student 2: You can’t start with anything negative.
Student 3: anything past nothing.
Student 2: Yeah.
Student 3: You know.
Student 2: Cause then it doesn’t exist. In which case it’s not there.

The students do not look further into the data beyond a visual fit of a scatter plot and their curve. The teacher/researcher returns to the idea about how the model describes the start of the growth of the shell.

Teacher: T(r) See then I am wondering about that fourth power model cause if you go to the left on it. You are sort of going inward on the shell right. You are going backward in time.

Student 3: Yeah.
Teacher: But then suddenly as you keep going left it goes up.
Student 3: S(e) Oh but there is nothing there though. That is the thing. Like you have to set limitations somewhere because some things are just physically impossible you know.

Teacher: I think we’re beginning to understand each other.
Student 3: Yeah.
Teacher: Ok, Umm.

Student 3: S(e) I mean its like. I guess its like certain things like if you figure out like differences with like electricity or something or like in physics. Like you can't have things that are. Sometimes you can't have things that are negative. There are things that are just physically impossible to have. And that to have something, to have an animal or a living thing that is a negative distance would mean that it isn't there. So it's not physically possible to have that anything past that zero. You know. It just wouldn't be there. This animal would not be there if there was a negative number. Basically.

The teacher/researcher continues to question the students about why their model does not work for certain values.
Teacher: T(c) Oh, so there's a place. Okay then you are agreeing that there's a place where the regression doesn't model the animal.

Student 2: S(e) You can put it so that the restriction has to be greater than zero.

Student 3: S(e) Yes, but that's necessary for other things too. There's limitations.

Teacher: Okay, Okay.

Student 3: S(e) like like the first graph we did with uh with the running thing, with the uh, with the thing you had to put limitations on it cause there were certain things that went past a certain time.

The teacher/researcher and the students continue the discussion by focusing on the accuracy of the model outside the range of their collected data. The question of what a model would look like if the data were collected again moves the conversation topic to the model's general shape. After this discussion, the teacher/researcher returned to the left side of the student's model. By the left and right side, the teacher/researcher and students are using the origin of the co-ordinate plane as their reference point. Therefore the left side would refer to negative values of time, and the right side would refer to positive values of time. When the teacher/researcher returned to the left side of the student model, the teacher/researcher and students revisited discussing the model's accuracy during negative values of time.

Teacher: T(r) So it looks like we are making sense on the right and then we got questions on the left. Is that fair?

Student 3: Sure, why not.

Teacher: Okay.

Student 2: S(c) What possible questions could you have on the left. It's dead. It doesn't exist.

Teacher: Well I just don't.

Student 3: S(e) Not even that. It’s not even born yet.

Teacher: T(r) It's very hard for me, yeah. It's very hard for me to believe that this at some point in the distance past.

Student 2: It doesn't exist.

Teacher: T(r) That that it was very large as the fourth power, as that fourth power curve suggests.

Student 2: S(e) Alright fine, we'll do a third power curve, it'll be very small. It'll be gone.

Student 3: S(e) No, you know what. You know what you got to do. You set a limitation on that graph so there is no left side and then we won't have this problem. Can we do that?
The students have provided a way to adjust the model so that it does not show a large shell when time is negative. Though the two students believe the left side of this model does not accurately portray the growth of the shell, their methods of correcting the inaccuracy are different. Student two wants to change the regression curve to the third power model, which would result in a new equation that models a different rate of change, and continues the inaccuracy of the model before the shell began to grow. Student three explains that he wants to remove the left side and keep the model's representation of the right side.

CONCLUSIONS

The transcript provides evidence of two areas of understanding: the rate of the growth of the shell and the model that represents the growth of the shell. Regarding the first area, the students' understanding of the rate that the shell is growing did not grow during this interaction. For the second area, student three exhibits a growth in understanding from primitive knowledge to property noticing of the Pirie-Kieren model of mathematical understanding.

The dialogue showed the students used a fourth power regression to represent the rate of growth of the shell. However, the students used the word parabola to describe the curve. Student one stated, “I mean if you look, if you look at the regression. It’s just like a parabola.” Student two and three both followed with “It is a parabola”. Their early classification of the graph as parabolic demonstrates an image having level of understanding. Since parabolic and quartic curves represent different rates of growth, the students are just using the visual image of the function and not the properties of their fourth degree regression equation. Later when student two and three recommended changes for their model, they provided different methods for a correction. Student two suggested changing their regression to a third power, and student three suggested restricting the left side of the model. Since student two’s correction used a different regression model, he did not make a connection between the rate of growth and the type of curve needed to model that growth. Neither of the students provided evidence as to why the model is quartic. The students’ earlier understanding about the rate of growth did not grow during this interaction because the have not moved beyond a visual inspection of the model’s shape.

Despite this misunderstanding, the teacher/researcher did not correct or criticize their comments. Rather the focus of the teacher/researcher was to discuss the students’ model for the growth of the shell. By focusing on student three, the transcript shows a growth in his understanding. When questioned by the teacher about the negative values of the fourth power model getting larger, the student responds that there should not be any values because “you have to set limitations somewhere because some things are just physically impossible”. Student three’s explanation showed a primitive knowing level of understanding about their model around zero. The student has demonstrated basic knowledge about when a situation requires limitations.
teacher/researcher returned to the growth of the shell around zero, the student’s level of understanding grew through engagement in the conversation. Without further prompting, the student connected the limitations on the model to other physical situations. This exhibited an image making understanding by using previous knowledge about specific situations that need limitations.

Despite a growth in understanding to image making, the teacher/researcher asked the student to clarify his ideas about where the regression function does not model the shell. As a response, student three referred to “the running thing”, an earlier problem from this workshop. This response moved him to an image having level of understanding. He used a mental construct of that activity to further justify his ideas about the need for a limitation. The teacher/researcher returned to the idea of the left side of the model after a discussion of the general shape of the model. During this engagement, student three explained how to change the model so the left side did not exist. He suggested, “You set a limitation on the graph so there is no left side and then we won’t have this problem”. The student demonstrated another growth in understanding to property noticing. The student recognized that the model should be altered to a model that has the same property as other limitation situations. He suggested changing the model so it contains the property of having no values on the graph for negative time. Previously the student explained why the shell could not exist for negative values, but has now moved forward to provide a possible method for representing the limitation on the model.

Through interaction between the teacher and students, the students made public their level of mathematical understanding. By examining the episodes presented, one can see that the teacher/researcher consistently returned to the idea of how the model demonstrated the growth of the shell over the entire domain of the students’ model. Additionally, the students’ ideas are followed or they are asked to clarify their statements. Using this method of questioning, the students were given the chance to make connections and reorganize their thoughts about their model. By reorganizing his thoughts, student three’s understanding grew from primitive knowledge to property noticing. The opportunity for growth occurred because the teacher continually returned to old ideas. As a consequence, the students had multiple possibilities to become engaged in conversations and articulate their understanding of the mathematics.

This research provides a foundation for continuing a dialogue about the affects of teacher and student interactions in the classroom. These preliminary findings imply that teacher interaction helps the student to express their mathematical understanding. Further research can help to indicate whether the teachers/researchers can learn from their choices during interactions to see if they are constructively contributing to students’ progress. More research is needed to provide a better understanding of how teacher interventions, particularly questioning, can contribute to students’ mathematical understanding.
NOTES

CAN POOR STUDENTS IDENTIFY THE GOOD FEATURES OF A DEMONSTRATED PROBLEM SOLVING METHOD AND USE IT TO SOLVE A GENERALIZATION PROBLEM?

Junichi Ishida & Ayumi Sanji
Yokohama National University, Japan

This study investigated the effect of presentation of a good solution method on poor students' solving generalization problems and the difference between good and poor students' evaluation of a good method. Subjects were fourth, fifth and sixth graders. Three hints were presented: the suggestion of using a "solve a simpler problem" strategy, demonstrating how it is executed in solving a small term problem (n=4,5) and the application of the strategy to the far generalization problem (n=30). The hint was effective for poor students of every grade. Good students evaluated more often the aspect of structure for a good method.

1. Introduction

In mathematics lessons, it is important to learn mathematical thinking, including generalization. Generalization problems are problems that are solvable by finding a pattern of quantitative relationship in a given problem situation. There are three examples in Figure 1. Stacey (1989) pointed out that problems of this type are hard for school students. She contrasted success on and methods used on near generalization problems (where the number of a term is small e.g. finding the number of marbles with 10 marbles on a side in Problem C, Figure 1) and far generalization problems (where the number of a term is large e.g. side of 100 in Problem C). Students even find that near generalization problems are difficult to solve.

Ishida has investigated the processes used by good and poor problem solvers on generalization problems. Good students and poor students showed different approaches. Good students tried to find a mathematical expression when they solve a near generalization problem, and they applied it to solve a far generalization problem. However, poor students tended to use a "draw a figure" strategy on the near generalization and then they tried but failed to find a mathematical expression on the far generalization problem. This
observation was consistent across grades 4, 5 and 6 (Ishida, 1992; Ishida & Sato, 1996).

Sato (1999) showed that it is helpful for some students to be asked to solve a near generalization problem before a far generalization problem. (For example, to be asked to find the number of stars for the 8th figure as a sub question would make Problem A of Figure 1 easier.) Also Sato found that it is helpful for some students to be first asked to draw a small term figure and write a mathematical expression based on it before a far generalization problem. Those hints seem to be useful to remove some of the factors that affect the difficulty of solving a generalization problem. For example, students do not need to realise by themselves that they should use the “solve a simpler problem” strategy or set up a mathematical expression.

Kimura (2001) gave a further hint. In Kimura’s study, two hints were presented: the suggestion of using a “solve a simpler problem” strategy (as Sato) and also demonstrating how it is executed in solving a small term problem. These hints were more useful than those of Sato for Grade 4 and equally helpful at Grades 5 and 6. But Kimura did not demonstrate the application of the strategy to a far generalization problem. If such a demonstration is given to poor problem solvers, can they use such a hint to solve a far generalization problem? This is one of the research questions for the present study.

Many studies have demonstrated the need to develop meta-cognition to work in problem solving situations. Evaluation of the mathematical value of methods relates to this meta-cognitive knowledge. Ishida (1998) has studied the choices that students in Grades 4, 5 and 6 make between four methods of solving far generalization problems. One method involved only drawing a figure and counting; the second provided a mathematical expression which did not reflect a relevant pattern; the third provided an expression linked to a simple generalizable structure; the fourth provided an expression in which the way it could be generalized was difficult to see. Most students (about 85% including both good and poor problem solvers) selected the best method (third in list above). A few students (about 10%) selected the strategy of drawing a figure, which is a poor strategy for a far generalization problem. Their performance on the far generalization problem was lower than that of the others. The study also asked students to write the reason of their choice of method. The reasons were very varied, including references
to the generality of the method, its effectiveness in producing an answer, the fact that it displays a simple structure, and the fact that the method is easy to understand. Effectiveness was often written by students in all grades. In the above study (Ishida, 1998), students selected preferred methods from a list of both good and poor problem solving methods. In the present study, only a good method is offered but students’ evaluation of the good points of this method are examined. This is of greater relevance to teaching, where good methods are usually presented. Do good and poor students form different evaluations of them?

In summary, the present study asks two questions:

1. Is presentation of a good solution method useful to help poor students solve generalization problems?
2. Are there any differences between good and poor students’ evaluation of a good method?

2. Procedure

The subjects of this study are 112 fourth graders, 102 fifth graders and 113 sixth graders, who are students of two elementary schools in Yokohama city, Japan. The three problems in Figure 1 were given to the subjects (each allocated 10 minutes) by a classroom teacher. Problems A and B were used to divide the students into good and poor problem solvers and Problem C was used to investigate the purpose of this study. The 94 students who succeeded on problems A and B were regarded as good problem solvers. The 166 students who failed to solve both problems were regarded as poor problem solvers. The numbers by grade are shown in Table 1. Sixty seven students who succeeded on only one of problems A and B are excluded from further consideration in this study.

Problem C asks students to solve a near generalization (n= 3, Question 2) and a far generalization (n = 77, Question 3), emphasizing the use of the mathematical expression generalized from Akira’s solution. It gives the hints used by Kimura (2001) and also demonstrates the application of the strategy to the far generalization problem (n=30). The number 77 was selected to avoid false proportional solutions, which are common when student see simple multiplicative relations between the questions (Stacey, 1989). Question 1 of Problem C asks students to evaluate the benefits of Akira’s method. The five choices that are presented are based on reasons offered by
Problem A

Figures are made as follows. How many stars are needed in the 100th place?

```
  *  *  *
*  *  *  *  *  *  *  *
  *  *  *
```

1st  2nd  3rd

Problem B

Using matchsticks ladders are made as following. How many matchsticks are needed to make ladder of 100 rungs?

```
  H  H  H
  H  H
  H
```

1 rung  2 rungs  3 rungs

Problem C

Marbles are arranged like the following figures. Find the number of marbles needed to make a figure of 30 marbles to a side 30.

Akira is thinking of this problem. He began by thinking it in the case of 4 marbles on a side and 5 marbles on a side. Then, he thought how to find a mathematical expression to get the answer to the problem.

\[30 \times 30 + 29 \times 29 = 1741\]

Ans. 1741 marbles

(1) How do you evaluate Akira's method? Select two viewpoints from the list.
A I can find an answer correctly.
B I can get an answer fast.
C I can use this method when the number of marbles of a side increases.
D He represents a mathematical expression.
E He finds a group of marbles and uses it to make an expression.

(2) How many marbles are needed to make a figure of 3 marbles on a side?
Using Akira's method, write a mathematical expression to find an answer.

(3) How many marbles are needed to make a figure of 77 marbles on a side?
Using Akira's method, write a mathematical expression to find an answer.

Figure 1. Three problems used in this study.
students in Ishida’s 1998 study, especially relating to use of mathematical expressions. Items A and B are aspects of effectiveness and item C is generality. Both items D and E refer to mathematical expressions but item E links the expression to the structure of the problem. Item D refers only to Akira’s writing an expression.

3. Results
(1) The effectiveness of the hint in problem C.

The effectiveness of the hint given in Problem C is investigated first. In the analysis, we focused on a performance of setting up expression, so the following data was based on a correct answer for setting up a mathematical expression.

Table 1 shows the percentage of good and poor solvers who were correct on question (2) and (3) in problem C. Table 1 shows that the performance of poor students (those who had failed on problems A and B) was good on problem C. In both questions, the percentage correct increases from grade 4 to 6. Therefore the hint used in problem C effectively assists poor students to solve a generalization problem.

How did the hints offered by Problem C assist students? In Problems A and B, in every grade, students frequently gave wrong mathematical expressions by using proportion strategy (for example, 3 times 100 in problem A, 5 times 100 in problem B) and other wrong mathematical expressions which simply combined given numerals. These error types show that they seemed not to try to find a pattern or structure from figures given in problems. The hints in Problem C encouraged them to look at the structure.

Table 1 Percent correct on Problem C for good and poor problem solvers.

(2) How common errors reveal understanding of structure

Error analysis for poor students who failed to solve problem C is important to clarify their difficulty. The main classifiable errors were to give no answer, using the form “a x a + b x b” with wrong numbers, or using the incomplete form “a x a +”. In total there were 26 students in Grade 4 who failed to solve both question (2) and (3) of problem C. For these, most gave no answer or an unclassified error. The “a x a + b x
b" type of error did not appear very often. This trend was the same for Grades 5 and 6 although there were fewer students. On the other hand, poor students who failed only on question (3) in problem C made an error like "a x a + b x b" and "a x a + ". While they set up a correct mathematical expression on question (2), that is 3 x 3 + 2 x 2, they could not generalize it correctly. A high percentage wrote "77 x 77 + " and could not complete this with 76 x 76.

We need to distinguish two types of students who failed on problem C: those who failed on both question (2) and (3) and those who failed only on question (3). In the former case, they did not understand about Akira's method at all. They did not understand that Akira tries to find a pattern in a small term situation to set up a mathematical expression that can be generalized easily. In the latter case, they understand the pattern shown in Akira's method and can easily apply it to the very near generalization problem but cannot apply it to a far generalization problem. This shows that they do not understand the mathematical expression on a small term situation as revealing a mathematical structure.

(3) Comparing good and poor students evaluation of the good method demonstrated in problem C

In question (1) of problem C, students were asked to select two viewpoints to indicate what makes Akira's solution good. The reason why we let them select two items is that this solution method has several good points. Because the hint was not equally helpful for solving problem C for all grades, we analyze the data by grade. Table 2 shows the percentage of students who selected each item. Since the students could select two viewpoints each, the theoretical totals across the rows are 200%. However, not all students selected two, so the totals are less than 200%.

The significant difference between good and poor students' selection appears on
item E in every grade. This item refers that whether they identify as most important the aspect of structure or pattern to help for generalization. Poor students select this aspect less than good students.

This table also shows that most of good students in each grade commonly identified item D (expression) and item E (structure) as an advantage for Akira’s method, while poor students selected commonly item D (expression) more than E (structure). They only paid attention to the surface solution, identifying only that Akira has written a mathematical expression. They did not identify that the expression was linked to the structure.

4. Discussion
(1) The effect of presenting other’s method on poor solvers’ solving a generalization problem

The hint used in this study assisted poor students to solve a generalization problem. Specially, most of Grade 5 and 6 students succeeded. Many of the poor students who could not solve a far generalization problem without a hint, were able to solve the far generalization problem in Problem C. As they can learn how to solve Akira’s problem (n=30) from Akira’s method, they understand the way a pattern and its mathematical expression can be used more generally, but they need to learn to find the pattern and expression for themselves. Kimura (2001) pointed out that offering the hint of a figure that presented the structure and a mathematical expression based on this structure in a small term situation assisted poor Grade 5 and 6 students to solve a generalization problem. The result of this study supported Kimura (2001) and extended it.

This result suggested that one difficulty of poor students in solving a far generalization problem was the lack of a way to approach a generalization problem. If they learn Akira’s method and have a skill to solve it, their performance will improve. However, the hint was not helpful for some poor students. More research is needed to identify which factor prevented them from solving the far generalization problem.

(2) Poor students could not understand the usefulness of structure in solving generalization problems. Error analysis showed that poor students could not understand the relationships of quantity in small term problems. The result of evaluation of Akira’s method also demonstrated that there was a significant difference between good and poor students in selecting a goodness of “structure” from Grade 4 to 6. This may suggest that students who have difficulty for solving generalization problems have difficulty in recognizing the mathematical structure in figures.

It is very interesting that the difference of viewpoint for evaluation between good students and poor students appears to be in noticing a simple structure. Good students
learn the importance of finding a pattern through their regular mathematics lesson, but this is not true for all students. Teachers could use this information to be more explicit about developing pattern finding ability through mathematical lessons. Even students from poor group 1 need to develop their ability to notice the structure of a quantitative relationship.

As noted above, the mathematical structure of Problem C (a quadratic relationship) is different from the linear structure of problems A and B. The structure of problem C is more complex than other two problems, so a further study could investigate the effect of the hint on problems similar to problems A and B.

Most of good students from Grades 4 to 6 selected item E (structure). However, the percentage of good students selecting item C (generality) by good students increased from Grades 4 to 6. This result suggests that understanding of structure is different through the grades and that as they grow older, students come to understand the role of a mathematical expression from both aspects of structure and of generality.

Author’s Note

I wish to thank Professor Kaye Stacey of the University of Melbourne for her assistance with English language.
The article presents the results of an on-going longitudinal research project which was begun in 1993. Initial goals for the research are defined and suitable research tools were determined. Four tasks based on the constructivist approach to teaching were chosen as the tools and these were given to young children, then student-teachers in the Czech Republic and finally to children in the UK. Analysis of pupils' solutions of the tasks allowed us to identify and define cognitive processes on a theoretical level and apply these to particular pupils' solutions. The importance of the communicative processes emerged whilst analysing the early experimental work and the goals and tasks modified to take account of this.

INTRODUCTION
This longitudinal research project began in 1993. It was designed to undertaken by a relatively small number of pupils whose work would be subject to a deep qualitative analysis. The first goal was to investigate the contribution of tactile and visual perception on the building of geometrical images. The second goal was to identify cognitive phenomena which occur in school communication when pupils work with solids then characterise and classify them. Early experiments showed that communication was essential in identifying the cognitive processes and a third goal was added namely the investigation of communicative phenomena (Jirotková, Swoboda, 2001).

The goals relate to the writings of J. A. Comenius (Analytical Didactics, Principle 55) 'the greater the number of senses which are involved in putting an image into the mind, the more familiar we are with the image and the more likely we are to retain it.' This means that the pupils who only use visual perception to learn about solids have a lower quality of understanding of the solids than those who employ tactile perception and even manipulate them (building, cutting etc.). Although this is generally known we find that in the classroom insufficient attention is paid to this fact by teachers. The didactics of mathematics should contribute to the changes of this situation by investigating the mechanisms of particular perception processes. Hence the goals which were chosen for this research.

TOOLS AND METHODOLOGY
To help us to determine the tools for our research we set ourselves a series of questions to set the parameters for this work.
· Are there pupils who prefer learning about solids through a tactile perception rather than a visual one and does the reverse apply?
• Is it possible to gain evidence of the extent to which a pupil's memory can store images of solids which were perceived by tactilely or visually?
• Is it possible to set up a situation from which we can gain evidence that pupils perceive certain spatial phenomenon better tactiley rather than visually?
• Can a situation be set up which gives evidence that a pupil has a precise understanding of certain geometrical phenomena but is unable to express this verbally?
• Is it possible to determine the preciseness of the pupil's understanding of certain geometrical phenomena?

From the consideration of these questions and the researchers' experience, the following four tasks were devised which fulfilled the goals which were set. The latest modification of the tasks done in 2001 are presented here.

In the four tasks a total of 16 solids were used in varying combinations. The solids used were: 1 Cube; 2 Square prism; 3 Large rectangular prism; 4 Small rectangular prism; 5 Right-angled triangular prism; 6 Right-angled isosceles triangular prism; 7 Non-convex pentagonal prism; 8 Hexagonal prism; 9 Tetrahedron; 10 Square-based pyramid; 11 Truncated rectangular-based pyramid (x2); 12 Non-convex pentagonal based pyramid; 13 Sphere; 14 Cylinder; 15 Cone; 16 Truncated cone.

Task 1. Identification

Materials: Two cloth bags A, and B, bag A contains solids 1, 2, 5, 6, 9-16. Bag B contains solid 11.

Instruction: Dip one hand into bag A and feel the solid. Now take your hand out of bag A and dip the same hand into bag B. Try to find the same solid. Tell me if you can find one. Before you take it out give reason(s) why you think it is the same and what is interesting about the solid.

Presentation: Experimenter shows the bags, explains the tasks in language suitable for the age of the pupil, checks to make sure that the pupil understands what s/he has to do. If the pupil does not understand properly, the experimenter will rephrase the task.

Scenario: Individual pupils given task. There was no time limit given for the solution.

It took several experiments before we were able to standardised Task 1 and to represent it in the form of a flowchart. The development of this chart illustrates that although the task appears simple, as soon as you start to analyse the possible scenarios its complex nature is clearly seen. The chart is in an evolutionary state and the latest modification was made in 2001 when the communicative element was added, indicated by the dotted lines.

Legend

**Experimenter boxes**

*a) Instructions*

V1  Dip one hand into bag B and feel the solid.
V1' Dip one hand again into bag B and feel the solid.
V2 Dip the same hand into bag A and find the same solid.
V2' Dip the same hand again into bag A and find the same solid.
V3 Take the solid out of bag A and check visually if your choice was right.
V4 Do you think your solution was correct?
V5 Take the solid out of bag B and compare both solids.
V6 Give reasons for your uncertainty about your choice.
V7 Put the solid back into bag A.
V8 Give reasons for your choice and say what is interesting about the solid.

b) Others
Z Experimenter doubting asks 'Are you really sure?'
β Experimenter decides if the solution is correct or not.
ε Experimenter decides if discussion needed to make pupil aware of mistake and to learn the reason for the mistake (+) or if a second attempt is necessary (-).
S Experimenter decides if the reasoning was sufficient or not.

Pupil's boxes
a) Activities
C1 Pupil perceives solid and makes mental evidence of the solid.
C2 Pupil is searching for the solid and compares the previous and current tactile perception.
C3 Pupil compares current visual perception with the previous tactile one.
C4 Pupil compares current visual perceptions of both solids and confirms the choice was correct.
C5 Pupil replaces the solid in bag A.
C6 Pupil gives reason for the choice of solid.
R1 Pupil stated that the solid was found.
R2 Pupil stated the solid was not in bag A.

b) Decision boxes
α Pupil decides if the solid from B is(+), is not (-) present in bag A.
γ, δ Pupil decides that the choice was correct (+) or incorrect (-).
η Pupil is (+) is not (-) sure about his correct choice.

Administrative boxes
P₁ (abacus) After first entry, exit-path is (+), after second entry exit-path is (-).
P₁,₂ (abacus) After first/second entry, exit-path is (+), after third entry exit-path is (-).
The explanation of the transfer to another task will be given orally.

Task 2 - Selection

Materials: One bag containing solids 1, 2, 6, 9, 10, 11, 16.
Instruction: Put one hand in the bag and from the solids which are there choose one which you think is different from the others. Before you take the solid you have chosen from the bag, tell me why you think it is different.
Presentation: Experimenter shows the bag, explains the task in language suitable for the age of the pupil, checks to make sure that the pupil understands what s/he has to do. If the pupil does not understand properly, the experimenter will rephrase the task until understanding is satisfactory.
Scenario: Individual pupils attempting task. No time limit given.

Task 3 - Classification

Materials: One bag containing solids 1, 4, 5, 6, 7, 9, 10, 11, 12, 13, 14, 15.
Instruction: Both hands may be put in the bag. Arrange the solids into two groups, one group having common attribute(s) which you choose, the solids in the other group will not have those attribute(s). Before you take your two groups of solids out of the bag say what are the common attribute(s) or how they differ. Take out your groups and say whether you are happy with your classification. If not change them and say why you have made the changes.
Presentation & Scenario: As for Task 2.

Task 4 - The game OWL

Materials: The following solids were placed on a table : 1, 2, 3, 4, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15.
Rules: One player to choose a solid mentally. The other player is to discover the chosen solid by asking questions which can only be answered by either YES or NO.
Presentation: Experimenter explains the rules of the game; makes sure everything is clearly understood. If necessary the experimenter amends the rules during the course of the game, to allow only questions that refer to geometrical attributes of the solids.
Scenario: The players may both be pupils or a pupil could play with the experimenter. No time limit is set. The experimenter avoids influencing the game.

RESEARCH SAMPLE

In 1993 ten pupils with ages in the range 7 years to 10 years, were observed. They undertook all the tasks including multiple games of OWL. All verbal communications
were tape-recorded and then transcribed in the form of protocols. An observer was always present to make notes of non-verbal actions and communications. In some cases photographic evidence was taken. The protocols were analysed. We found the tasks, especially the game OWL appropriate for use with University student-teachers and it is now an integral part of the syllabus. From this work we found that the majority of information regarding cognitive processes can be obtained from the analysis of communication of the pupils/students. Hence the tasks were slightly modified to challenge the pupils to verbalise their perceptions as much as possible. This form of the tasks was given to two nine-year old pupils in England in 2001. The analysis of this latest work and our research experience enabled us to construct the mental mechanisms of some cognitive processes which were involved in solving the tasks. These were the mechanism of tactile selection - how the process of choice of a particular solid is made by tactile perception only; the mechanism of tactile-visual verification of the selection - how the process of verification their tactile choice is made visually and tactilely; the mechanism of tactile classification - how the process of classification of the solids into two separate groups is made without visual perception; and the mechanism of tactile-visual verification of the classification - how the process of tactile classification is verified using visual-tactile perceptions. These theoretical descriptions of the mechanisms were applied to the actual solutions of the tasks undertaken by the pupils. In the next paragraph we will describe the mechanism of tactile selection and apply it to the solution of the first task by two pupils. For the description of these mechanisms we used the methodology of analysis elaborated by M. Hejný (Hejný, Michalcová, 2001).

MECHANISM OF TACTILE SELECTION

The process of selection is found in the decision box a in the diagram above. In our research we identified three types of the process and these differ according to the extent the pupil is familiar with the perceived solid.

1. The perceived solid is entirely new for the pupil and s/he does not have any experience of committing tactile images to the short-term spatial memory, that is the pupil has not been challenged to verbalise tactile perceptions. When the pupil is challenged to describe verbally the spatial phenomena perceived tactiley, s/he must perceive the solid analytically that is s/he needs to perceive vertices, edges, shape of face etc. In this case the pupil perceives the solid as a whole, that is s/he perceives its gestalt and not its individual analytical characteristics (Van Hiele, 1986). On the pupil's first attempt to find the identical solid in bag A s/he does not know which solids are hidden in the bag, therefore s/he does not know on which attribute to focus his/her attention. The pupil will try to sort the solid from bag A by using his/her global perception first and if not successful attempts to recall and use at least one analytical characteristic of the perceived solid in bag B.
2. The perceived solid is entirely new for the pupil but the pupil has some experience of committing tactile perceptions to the short-term memory. In this case the pupil tries to commit as many dominant characteristics of the solid to his/her short-term spatial memory as possible. When the pupil is then sorting the identical solid from bag A s/he attempts to find the characteristics, which s/he had put to the short-term memory, on each of the shapes in turn.

3. The pupil is familiar with the perceived solid and it is correctly committed to his long-term spatial memory. When the pupil is sorting the identical solid from bag A, the pupil is led by the good image committed to his/her memory.

The above three types of mechanism of tactile selection are described theoretically. The boundaries between them are not well defined and the reality is often on the overlap of them. The images from the long and short-term memory are mutually penetrating. We gain information about how the short-term memory works either from non-verbal expressions (gestures) or from verbal expressions (pupils generate new expressions eg. 'squangle' for square).

APPLICATION OF MECHANISM OF TACTILE SELECTION

The first pupil we wish to discuss is Jan, a Czech boy aged 10 who volunteered to take part in the research. We worked with him in November 1993. Jan had to find the truncated pyramid in bag A but his first choice was solid 2, the square-based prism. He was not certain about this choice and when he took it out he asked 'Is it right?' Then he perceived the solid in bag B again and he realised that his first choice was incorrect. Nevertheless on the second attempt he again made an incorrect choice by choosing the cube. Jan concentrated a lot during his third attempt and his choice was correct. We explain his mistakes by applying the mechanism of tactile selection. We believe that Jan was working according to the first type of mechanism as defined above. When he perceived the solids in bag B only a global perception was committed to the short-term spatial memory. When he tried to find the correct solid he did not find any global characteristic to help him select the solid. He then tried to recall some analytical characteristic of the solid and he found one characteristic which we could call 'four-sidedness'. This idea is supported by two arguments. There are only three solids in bag B which could be characterised by 'four-sidedness'. Jan chose these one-by-one. The second argument is that when he solved the other tasks he expressed that 'being quadrilateral' is, according to him, the dominant characteristic of a solid. For his second choice he was led by the perception of four right angles. This characteristic was perceived when he felt the solid in bag B again. Putting his hand into bag A again the first solid he met which had this characteristic was the cube which he chose without any further reference to any other shapes. Visual perception on taking the cube out of the bag gave him quick information about the metric characteristics of the cube. His third attempt was successful. It should be noted that our second mechanism listed
above – mechanism of tactile-visual verification of selection – was also used in this process.

The next example is a good illustration of a pupil perceiving the solid as a gestalt and not its separate properties on meeting it for the first time. Jill was a nine year old English girl when we worked her on the tasks in September 2001. Her teacher chose her for the research. Jill showed unusual mathematical culture and perfect insight into the geometrical world when solving all the tasks. She also had a remarkable mathematical vocabulary, which she used with understanding. When she found the identical solid in bag B, (task 1) before she took it out she was challenged to say why she thought she had made the correct choice. The following is an fragment of the transcript of the subsequent dialogue with her. J4 represents the fourth comment by Jill and E5 the fifth by the experimenter.

J4: Because it feels like the first one.
E5: So what do you think was special about it?
J5: It was small, it has the same amount of sides. (She meant faces.)
E6: How many?
J6: (A short pause whilst she checked the held solid.) Six.
E7: So you think it has six sides, do you think you have seen a shape like this one before?
J7: No.

Both used words 'feel' and 'small' indicate that Jill perceived the solid as a gestalt. The second part of J5 was surprising because it showed that she tried to give an analytical description of the solid and the use of the incorrect terminology, 'sides' instead of 'faces', which was an unusual occurrence in all her communication, was evidence of the demanding nature of the transfer from global to analytical descriptions (Pegg, Baker, 1999). The drain of energy, which this transfer caused, was the reason she chose the incorrect word for 'face'. J5 shows unusually sophisticated mathematical thinking for a nine-year old girl. She was aware that the global characteristic of a solid was not the perfect answer to the task, hence she felt the need to define the solid by analytical characteristics. We did not meet any similar case of such thinking in our research. This is a good example of the second type of mechanism of tactile selection.

The analysis of our research did not produce any interesting results related to the third type of tactile selection mechanism.

Jill's use of correct mathematical language and her knowledge of the characteristics of both solid and plane shapes can be seen in the following examples. When she was asked by the experimenter at the end of Task 1 what solid did she think would be created if the faces of the truncated pyramid were extended to a point, she immediately replied 'a square-based pyramid'. In the third task she was asked to say what was different about the solids that she had chosen. Her response was 'They all have at least one face which is a quadrilateral in 2D'. The experimenter made sure that Jill fully understood what she was saying by both 'at least' and 'quadrilateral'.
CONCLUSION

We believe that little research has been carried out and written up this area. Our research has produced tools which we consider are beneficial for investigating cognitive and communicative processes. They could be used to advantage in the normal classroom in two ways, the first being that the methodology of the tasks is very much in the format of constructivist teaching strategies (Noddings, 1990) and so would help the children to learn about solids in a concrete, meaningful and understandable way. The second is that all the tasks, develop the pupil's ability to communicate mathematically which we find is lacking in school text-books. These books get the pupils to construct shapes or solve riders with no opportunity to explain or discuss their work and their understanding of geometrical concepts verbally. In particular we found that the game OWL, which can be modified for all age groups, not only helps the communicative ability of the pupils and develops their mathematical vocabulary it can also be used to quickly diagnose deficiencies in these areas (Jirotková, 2001).

AN INVESTIGATION INTO MY PRACTICE OF TRAINING TEACHERS IN USE OF TEACHING AIDS IN MATHEMATICS TEACHING AND WAYS TO IMPROVE IT

Janet Kaahwa, School of Education, Makerere University

Abstract

In this paper I report the procedure I followed to investigate my practice of training teachers in use of cultural objects as teaching aids in mathematics teaching and also ways I ought to improve this teaching. Two cohorts of student teachers and two practising teachers were involved. So far two cycles of action research have been completed and the results indicate that my practice is and has been open to improvement.

Introduction

One of my former students told me: “I have tried to do those things (referring to teaching mathematics using aids) but it has proved to be lengthy.” “When I finish my present research,” I promised, “I am going to come out to schools and work with the teachers. I want to get a class and teach it to show that these ideas can be put into practice and can work”.

The issue of teachers’ non-use of teaching aids has bothered me over the past ten years. I got more and more concerned each year as I trained teachers in their use and still found no evidence of their use in schools. This was despite the improvements in my training that I tried to make each year.

I have a strong desire to see that all Ugandan children successfully learn mathematics. It is a core subject at primary and lower secondary levels and the grading of certificates at these levels is based upon success in it. I believe that if teaching aids were used adequately by all teachers, students would love and learn mathematics, which would empower them as citizens (D’Ambrosio, 1990). Mwanamoiza (1992) found that students in Ugandan classrooms are treated as passive receivers of knowledge. Many simply cram formulae and methods of solving specific problems in mathematics. The use of aids may encourage other approaches.

The Problem

Despite the training in use of teaching aids in mathematics teaching that Ugandan teachers get in pre-service programs, they hardly use them. This made me question the training they get. Was it adequate? Was it appropriate? If not, how could I improve on the training I was giving them?
How would I train teachers so that they could adequately use teaching aids in mathematics teaching?

**Theoretical framework**

A major theoretical framework underlying this study is constructivism. The view that knowledge is actively constructed and not passively received (Noddings, 1990). The belief that all knowledge is a product of our own cognitive acts (Confrey, 1990), implying that knowledge is constructed in the human mind and that understanding is constructed through experiences.

The learners have a knowledge base /structure on which they compare incoming knowledge. Then either the new knowledge is modified for taking in, or the knowledge base is modified to allow it to fit in. This is to say that the teachers come to training with some knowledge and beliefs about teaching and use of aids (Ball (1990) to which they compare new knowledge. A series of experiences facilitate this knowledge acquisition and the learner ought to be provided with such an environment. (Piaget, 1969 cited by Von Glasers 1990; Noddings 1990; Confrey, 1990). Freedom to express oneself must be part and parcel of this environment (Vygotsky, 1978). In the training that I give teachers I try to give practical, hands on experiences. The knowledge structure is continuously revised using active knowing (Noddings, 1990). In the intervention phase of this study, students were put in groups, in which they worked and were able to talk freely. Vygotsky (1978) and Bruner (1985) explain that some kind of mulling over takes place in the learner’s mind as he/she interacts in the environment. In the intervention phase I attempted to involve students in reflection by requesting them to keep diaries.

Thus the teacher should endeavor to ascertain what knowledge base the learner has and then plan to offer the right environment. A questionnaire and interviews after sessions served this purpose in my study. The teacher’s prompting, questioning etc. which Vygotsky calls scaffolding, is integral to this kind of environment. It should be an environment that is social, that is full of sharing ideas, challenging, questioning and explaining and negotiations of meanings (Jaworski, 1994) between teacher and learners and between learners and learners (the peers according to Vygotsky (1978)).

Sometimes such an environment can be created through bringing experts to the classroom (Davidson & Miller (1998), Lave (1988), Lave and Wenger(1991)). Such an approach would be an eclectic one and in my view profitable to learners. This is what justifies my bringing in of an experienced teacher to teach with student teachers acting as students in cycle 2. Jawoski
(1994) refers to this as socio - constructivist nature of learning. Of course, the teacher knows more than the learners do. So by planning in a purposeful way for them the teacher may be able to offer situations that are profitable to learners. The experiences could be through observing and questioning experts who might be other (more capable) students or the teacher.

In my study I used cultural objects as a sample of teaching aids. I claim like D’Ambrasio, (1990); Gerdes, (1998); Zaslavsky (1994) and others that there exists mathematics in every culture which can be explored through artefacts. While D’Ambrasio refers to it as ethnomathematics or mathematics in specific cultures, I wish to claim that ethnomathematics is mathematics, no different from European mathematics. I agree with Gerdes (1994) that mathematics is preserved in cultural objects. It is ingrained in the cultural activities. Thus aspects of culture can be used to teach mathematics. Using cultural objects in this way allows the learner to work on mathematics as both an unintentional and natural process (Lave 1988) and also through reflective abstraction from purposefully arranged activities (Noddings, 1990).

Vygotsky’s theory of social development through the idea of Zone of proximal Development (ZPD) also suggests an area where culture can be used for learning. Teachers or peers tutor the learner until he/she gains mastery of his/her own actions through activities which allow the learner to make a leap. The context could be the use of cultural objects. The use of such objects allows mathematics to take place within. Cultural settings and activities that go on daily and in which learners participate naturally as members of the communities to which they belong (Lave, 1988).

Methodology

The objectives of the study were to:

(i) Document, (ii) observe and critically analyze, (iii) innovatively explore ways of improving my current practice of training teachers in use of teaching aids particularly cultural objects. I chose them because they are in every home and therefore familiar to teachers and pupils. Being in homes they are affordable and they also offer pupils a good opportunity to explore mathematics at home.

Subjects

I used two categories of teachers; (i) 3rd year mathematics’ student teachers of academic years 2000/2001 and 2001/2002; (ii) two practising mathematics teachers. The study was organized in two action cycles. Cycle 1
was a pilot phase and involved student teachers of academic year 2000/2001 and two teachers while cycle two was an intervention phase and involved student teachers of academic year 2001/2002 and one experienced teacher from cycle 1.

**Instruments**

I used video recordings, classroom observations, interviews (audiotaped) and questionnaires. An action research approach was used and it enabled me to (i) document my current practice, (ii) observe it, (iii) discover problem areas through critical analysis alone and with friends, (iv) imagine a solution, (v) try it out and (vi) evaluate my actions. Two action cycles were possible in the given time. Documentation of remembered action in my usual practice enabled me in cycle 1, to act out systematically and purposefully what I usually do as routine. I taught both sets of teachers on the use of cultural objects as teaching aids in mathematics while being recorded on video. After each session with the pre-service teachers I interviewed five of them asking them what new ideas they had got out of the session concerning cultural objects as a resource for teaching mathematics.

With the two practicing teachers I did a two-hour session. Two weeks later I had another two-hour session with them in which we discussed the activities they had prepared exhibiting the knowledge they had obtained in the first session. Two weeks later they used these to teach while I observed the lessons and taped them on video. Throughout, these teachers were free to consult me at any time for clarification on the things we were doing.

Work with these teachers gave me a comparison between in-service and pre-service training.

Eight months later I observed four student teachers teach during school practice. I interviewed each of them concerning what they had learnt from my sessions with them vis a vis their practice in class. I also asked them how other students viewed my sessions and whether they could they suggest some improvements.

**Analysis of cycle 1**

I watched the videotapes repeatedly noting down my actions and trying to analyze why I did what I did. On separate occasions I watched excerpts of the tapes with five critical others (three individually and two together) and taped their comments which were sometimes prompted by my questions. I transcribed the comments and read through them comparing comments of different viewers with my own observations. I compared the comments from
different sources, (the critical others, the student teachers, the teachers, and my own comments). I triangulated these and came up with some discoveries about my practice, which I termed shortcomings.

This work was supported by my reviews of the literature on culture, teachers, teacher educators and learning theories. These reviews also informed my actions in cycle 2.

Thus, from: (i) observations on video tapes and in the classrooms, (ii) interviews with 10 student teachers and the two teachers, (iii) interviews with critical friends, and (iv) critical literature review, I was able to critically analyze my current practice, establish what it is and identify areas of strengths and weaknesses. I worked out a possible course of action that might improve my practice and tried the ideas out in cycle 2.

**Findings from cycle 1**

The following were the findings:

(i) I talked a lot; i.e. I used the telling mode a lot, although I believe in learners constructing knowledge. The planned activities for the learners to do in the sessions were rather superficial. The time I allowed for each activity was short. (ii) Throughout my presentations I was worried about time and kept mentioning time being short. (iii) Although it was felt that I was clear in my exposition and presentation, the student teachers’ hearts did not appear to have been touched. (iv) None of the student teachers were observed using cultural objects as teaching aids in their teaching. v) Although the student teachers would not agree, they did not seem understand what cultural objects are and how to use them. Neither did they appear to conceptualize the possible benefits of using them. (vi) The literature highlights how prospective teachers come into training with their own views about mathematics, its teaching and learning. In the student teachers could be observed (even in their own words) a strong belief that cultural objects are not easy to obtain and that if teaching aids were used the syllabus would not be covered.

**Conclusions from cycle 1**

Teachers may have knowledge of teaching aids and their use and yet not know how to use them in their classroom teaching. The knowledge they have may only be superficial. That is, it may be of a matter of demonstrating and pointing out to pupils what concept they (the teachers) can see in a teaching aid. They, however, might not know how to engage pupils in related mathematics learning. For example they may not be able to prepare
activities that might engage pupils in constructive mathematics learning based on such objects. One possible explanation might be that the teachers are never convinced of the approaches to teaching that they get during training. Since prospective teachers come to training with their own beliefs about mathematics; those that they form over the years of mathematics learning, the limited time of training, within which they get the exposure to new ideas may not be enough to change their views. The reality of conditions in schools does not appear to help either. Teachers' attitudes are that it is impossible to find time to teach children practically using teaching aids and still manage to complete the prescribed syllabus to enable children to pass examinations.

Lesson observations showed that the in-service teacher taught with more expertise and confidence while using teaching aids than those trained in preservice. This may be due to amount of time on training and/or the experience working in the classroom which might lead to more readiness. It suggests that training teachers at in-service level may be the answer to my question: "How can I train teachers in use of teaching aids?"

**Cycle Two – Intervention**

Basing on the findings from pilot (cycle 1) and literature review, I carried out the following planned activities for cycle 2 as an intervention measure.

(i) To find out the views that teacher trainees came with to my sessions I administered a questionnaire at the beginning of the first session. In it I sought for their views about mathematics, mathematics learning and teaching. I also asked them to evaluate two of the lessons they had taught during the completed school practice; one they judged as their best and another they judged as their worst. Then, in groups, I asked them to discuss one successful lesson and one failure. I provided them with guidelines to follow as they did this. (ii) To create more time for the course, I gave each student teacher a file with all the materials that we would need during the six weekly one-hour sessions that we were to have. I also gave them notebooks in which to write their thoughts, reflections on the sessions and their own learning which was meant to encourage them to spend more time thinking about the work done during sessions. In order to encourage students to find time outside sessions and to impress upon them the importance of groupwork, I asked them to form groups of five to six in which they would work throughout the course. In these groups they were to discuss and complete unfinished work started during sessions. This arrangement also helped make students talk more while I talked less.
(iii) To practically demonstrate use of teaching aids in a mathematics lesson, I asked an experienced teacher from cycle 1 to come and demonstrate to them. (iv) To monitor the progress of their learning I interviewed three to five students after each session. In each interview I asked each of them what new thing they had learnt concerning mathematics teaching and learning, use of teaching aids, lesson organization, and pupil involvement. I also asked them to say something about teaching aids from culture and those from the environment. (v) To keep record of all information, I taped on video all sessions, and all lessons I observed, I taped on audio tapes all interviews with students and teachers, I kept a diary of all my actions and my thoughts on what I was doing. I requested that students hand in all the assignments and the work done during each session including the diaries and files containing all they had done. After the last session I asked them to fill in a course evaluation questionnaire.

**Results from cycle 2**

From preliminary analysis of my diary, students’ documents (diaries, files, assignments) and interviews, my own session observations I found out that:

(i) The majority of students came to my sessions not convinced that teaching aids are available and can be used. After the sessions they appeared to be convinced that there are many materials that can be used especially from the environment reflecting their culture. Students now said that the teacher only needs to be innovative and willing to look for such objects.

(ii) Students got an idea of what teaching aids are and their possible use. They also understood that cultural objects can be used to teach mathematics and were certain they could use them.

(iii) Teachers could not give a clear distinction between objects from any environment and those, which are cultural. This may be a false distinction or one, which needs more time for assimilation.

**Conclusions**

The results of cycle 2 still have to be further investigated. However, the changes in my practice appear to have offered the pre-service teachers the opportunity for constructive learning through active group work, and mulling time (Vygotsky (1978), Bruner (1985)). My instructions offered a form of scaffolding. The experienced teacher demonstrated that teaching aids could be used. My expectations of the student teachers’ out of session work were this time explicit. All this I would claim has improved students understanding of the ideas I tried to pass on.

LEARNING OPPORTUNITIES IN A KINDERGARTEN ABOUT THE CONCEPT OF PROBABILITY

Sonia Kafoussi
University of Aegean, Greece

Abstract
In this paper we describe the students' mathematical learning in a kindergarten during a classroom teaching experiment about the concept of probability. We present and analyze the learning opportunities that were created in the classroom as the children tried to resolve their problems, to reason mathematically and to communicate their thinking to others. The results of the research showed that kindergarten children made considerable progress in their probabilistic thinking, when they accepted the process of the experiment to check their different predictions as well as when they arrived at a consensus about the solution of a problem.

As a consequence of the constructivist epistemology, it is nowadays acceptable that the learning of school mathematics is a process in which students reorganize their mathematical activity to resolve situations that they find personally problematic (Cobb et al., 1991). Learning opportunities can arise for students from their personal engagement with the mathematical activities as well as from their interaction with the other members of the classroom. The teaching of school mathematics can be characterized as a process in which the students and the teacher negotiate their mathematical meanings and interactively constitute the truths about a "taken-as-shared mathematical reality" (Cobb et al., 1992).

This acceptable view has oriented research towards the construction of models that specify the development of children's thinking on concrete topics in mathematics as well as to the investigation of the role that interaction among the members of the classroom can play in cognitive development. However, many questions have to be answered for the organization of mathematical education on subject matter specific knowledge and many researchers suggest that empirical data from real classroom settings are necessary.
Towards this effort, the purpose of this paper is to explore and analyze the learning opportunities that occurred in a kindergarten during a classroom teaching experiment concerning the development of probabilistic thinking. The concept of probability is considered as one of the most difficult in mathematics education, as many researches have shown (Shaughnessy, 1992-Kapadia & Borovcnik, 1991). The research reported in this paper is a part of a broader program that try to: a) investigate the range of the abilities that children can develop in the kindergarten on stochastic concepts, b) analyze the learning opportunities that are created in the classroom taking into consideration the cognitive and social processes involved, c) scrutinize the contexts of the activities that can be fruitful for students.

In the research program, we were based on current research literature about the development of student’s thinking in probability (Jones et al., 1997- Jones et al., 1999) and these findings influenced the organization of the instructional activities given to the pupils.

**Methodology**

Fifteen kindergarten children were participated in the classroom teaching experiment in a typical public school of Athens. The research project was realized in November 2001 and it lasted one month. The children were engaged with mathematical activities related to probability three times per week. Every lesson was lasted half an hour. The program was realized in collaboration with an experienced and well-informed kindergarten teacher. In the course of the program we developed a set of instructional activities on the concept of probability concerning the following themes: sample space, probability of an event, probability comparisons and conditional probability. The instructional activities used in the classroom were developed before and during the progress of the program, according to the evolution of the students’ ideas, so that they could be problematic to the students. Moreover, all the activities were related with the interests and the experiences that children have
at this age. More specifically, the activities were presented through games, small stories in puppet show and dramatic metaphors. A typical lesson could be described in the following way: The teacher introduced the instructional activity to the whole class, the children made their predictions about the concrete problem by explaining their thinking and the teacher recorded the different ideas of the students. Then, the children checked their predictions through the realization of an experiment, they recorded the results and they discussed about the solution of the problem.

The children had not received any previous instruction in probability. Moreover, they had not yet received any instruction in whole numbers. Each child was interviewed for one hour prior to the instructional program, at the end of the program and one month later. The interview included 14 tasks. The children were asked: a) to report the outcomes for a probability situation (for example, what could be happened by throwing a die with different colors), b) to predict the most likely outcome in a random experiment (for example, to predict which color is “the easiest” to be drawn from a box with colored balls), c) to chose the probability situation for the most likely realization of an event and d) to report the outcomes of an experiment, since they had realized one trial. All the lessons were videotaped. The transcripts of the interviews and the lessons provided the data for the analysis of the students’ learning. Analytical descriptive narrative was the method used for our analysis (Erickson, 1986).

Results

Prior to the instructional program, all the children participated in the teaching experiment seemed to interpret the tasks in probability in a subjective manner. However, we could identify some qualitative differences in their thinking. More specifically, the students’ responses could be classified in two general categories.

On the first category, the children gave answers that they were strongly influenced from their favorite color for all the tasks (4 children). Ada was a
representative child for this category. She answered the red color as the only one that could be appeared in all the tasks. So, she reported only one outcome in a one or two stage experiment (e.g. she gave only one ordered pair in a two-stage experiment including the red color) and she insisted that the red color was “the easiest” to come out in all the experiments. Since she had realized one trial in an experiment (with or without replacement) and she was asked to describe the possible outcomes on the next trial, she repeated the color that she has got on the first trial.

On the second category, the children could give all the outcomes for a one-stage experiment. However, they gave only one ordered pair in a two-stage experiment. These children considered that they could not give another combination, because they had only three colors in the bag and so «it is only one that it is left over». That means that it was very difficult for them to understand the context of the task, as they considered that one trial of the experiment was identical with the solution of the problem. They could not imagine that for every trial all the balls could be again inside the bag. Furthermore, these children did not have a consistent way of thinking to answer the tasks for the probability of an event, sometimes they gave a right answer and sometimes they gave a wrong answer. However, in all cases it was very difficult for them to provide an explanation for their answer. In the case that they presented their arguments, they seemed to be influenced by the position of the materials or their favorite color. In the comparison probability tasks, they gave usually the right answer for the probability situation related to spinners and a wrong answer for the one related to boxes with balls. Since they had realized a trial in an experiment, they did not usually mention the color that they picked, but they gave all the other outcomes.

The following episodes were selected for analysis as they represented critical moments in the students’ learning. In these incidents that took place in the classroom, learning opportunities were created as the children tried to resolve their
personal problems or to communicate their thinking to others and to justify their position/solution to a problem.

First episode

The children were engaged in the following activity (This was the second activity about the probability of an event): The grand mother and the grand father of the squirrel would like to make a scarf for him. The grand mother found a bag with balls of wool with different colors (1 blue and 3 green). As the grand mother and the grand father were in complete disagreement about the color of the scarf, they decided to pick a ball at random. The children were asked to predict the color that was "the easiest" to come out. The following dialogue took place between the children:

Anna: The green, because there are 3 green.
Teacher: Is there another opinion?
Socrates: The blue, because it is higher up in the bag.
Teacher: What do you want to say Paul?
Paul: I say the green ...we close our eyes and we pick a ball.
Teacher: Paul said that we close our eyes when we pick a ball. So, we cannot see which it is up. As we are picking a ball, we can mix the balls. (He is doing the movement.)
Socrates: It is the blue one, because the two green are below.
Anna: It is the green, because there are more. Let's do it.
Socrates: Yes!
Teacher: OK! Let's do it.

Anna, Paul and Socrates were three of the children whom their responses at the interview could be classified on the second category. However, in the progress of the program Anna’s responses were based on quantitative judgments, she used the words «more» or «less». It was the first time that she used numbers to justify her answer. On the other hand, Socrates was still influenced by subjective judgments, when he tried to justify his answer. The level of Paul’s thinking about the probability of an event could be characterized as transitional (Jones et al., 1997), between subjective and naive quantitative thinking. In this episode, as he tried to justify his answer, he based on the process that they used to make the experiment, and he used an argument which could upset Socrates’ argument. This argument seemed to be a fruitful contribution for the development of Socrates’ thinking. Although Socrates insisted to his answer, when Anna told him that they could find
the solution to their problem by executing the experiment, he willingly accepted her idea. This was the first time that the children legitimated a way to resolve their disagreement by respecting the results of the experiment. Until now, there were children like Socrates that they insisted to their solutions even though they knew the results of the experiment. After the realization of the experiment, Socrates changed his opinion. In this sense, this incident was functioned as a catalyst for the following lessons.

Second episode

In the following episode, the instructional activity was related with the different ordered pairs that the children could make in a two-stage experiment. The children had to construct Christmas cards with two flowers in order to help the Father Christmas to share them to the children together with his presents. The children had to pick one color from a box with three colors to paint the first flower and they had to put it back. Then they had to pick again one color for the second flower. After painting the flowers, they should discuss how many different cards they had made.

It was the turn of Thomas to pick the two colors. After picking the first color (it was the red one), he picked the second one. This was also red. Thomas told to the teacher with surprise that this could not be happened, because «we have to chose two different colors». The teacher tried to pose Thomas’ thoughts as a topic of discussion with the rest of the class.

Teacher: What are you saying? Thomas said that this is not right.
Anna: Yes, we cannot have the same color.
Ada: But, this color came out.
Teacher: Ada said that we pick the colors at random. So, can we have the same color twice?

Thomas raised his shoulders puzzled. The teacher did not continue the discussion and the children went on with their work. When they painted the cards, the teacher asked them to find the cards that were the same. The children began to put together the same cards, that is, the cards with the same colors. So, they began to
put together the cards with the red and the green color. On the next card, the first flower was green and the second was red.

Teacher: Where will you put this card?
Thomas: Here. *(Together with the other cards)*
Anna: No, this is different. It is firstly the green and then the red.
Socrates: This is wrong. They are not different. They are the same.
Thomas: It’s a little different!
Socrates: Yes, it’s a little different.

Teacher: OK. There are not the same, however they are a little different, so can we put this card alone, not with the others?
Thomas: Yes, here. *(He is showing a place near to the other cards).*
Teacher: Can we make other different cards?
Anna: Yellow, red.
Teacher: OK. We have the red-yellow card and we can make the yellow-red.
Marina: Two green.
Teacher: Very nice.
Thomas: Two blue.
Teacher: Bravo, Thomas.

On the above episode, as the children tried to negotiate their different interpretations about the word « different» in the concrete context, they managed to resolve their conflict and to construct an acceptable characterization of the difference of the cards. In this manner they managed to find all the different ordered pairs in subsequent similar activities. Moreover, the argument that Ada presented, showed that she had accepted the notion of random and seemed to influence implicitly Thomas’ thinking about the possibility to have the same color twice.

*Third Episode*

The third episode is presented in brief. It is connected with the probability of an event, when all the events are equally likely. The children had to pose their own problem to be solved about the probability of an event.

Paul: I want to give a notebook to Kostas.
Children: What color does Kostas like?
Paul: The red. *(He puts in the box, 2 red, 2 green and 2 blue notebooks).*
Teacher: Which color is the easiest to come?
Anna: The red.
Paul: No. It’s easy to come the red and the green and the blue.

Although the teacher had not discussed with the children until this episode probability situations with equally likely events, this problem arose from children’s
attempts to make their own problems in probability. In this way they provide to us the opportunity to discuss with them similar activities like fair and unfair games.

We should note that at the final interview all the children had done a real progress in their probabilistic thinking. The majority could report all the outcomes in a two-stage experiment and use quantitative arguments to justify their answers.

Conclusions

The results of the research showed that kindergarten children made considerable progress in their probabilistic thinking, when they accepted the process of the experiment to check their different predictions as well as when they arrived at a consensus about the solution of a problem. However, more evidence from different cultural kindergarten classroom settings is needed to investigate the critical incidents that influence children’s probabilistic thinking at this age.

The present study deals with a problem solving process in the early grades. Data analysis focuses on pupils’ mathematical behaviour and the teachers’ management of the mathematical knowledge during the problem solving procedure. The analysis reveals two factors that seem to play an important role in the devolution of the problem and consequently in the construction of the pupils’ mathematical knowledge. The former is related with the fact that pupils control the correctness of their outcomes themselves and the second one with the fact that the teacher facilitates the pupils without reducing the mathematical meaning and the cognitive features of the task.

THEORETICAL ISSUES

Current research on teaching and learning mathematics, independently of the perspective taken, accepts the premise that pupils are not passive absorbers of information, but rather have an active part in the acquisition of knowledge. Furthermore, it emphasises the need for mathematics teaching to be much more than a study of ready-made mathematics, which is still so prevalent. Since learners always construct their own knowledge, the critical issue is the nature of the socially and culturally situated constructions (Cobb, 1994). Thus the teachers' task is to challenge pupils by introducing effective mathematical activities, and maintain a classroom culture that encourages and facilitates independent learning.

In this perspective, two are the basic issues, which are of importance for the research in mathematics education: the choice and the formation of the mathematical content and the organization of the mathematical activity within the classroom. In relation to the former, since the common consideration is that mathematical knowledge cannot be reduced to a stock of retrieval facts, but it is constructive and, consequently, is best demonstrated in situations where something new is generated (v. Glasersfeld, 1983), a considerable number of research focuses on the change of the mathematical content in order to teach mathematics as a subject to be created and explored (Cooney, 1988). This framework implies reforms in the classroom organization: a pupil to perform in a correct way on content is not enough but actually contradictory to the consideration of mathematics as a subject to be created and explored. Thus, children should be given opportunities not only to respond to, but also to pose questions, to phrase hypotheses, to explore their ideas, to check and convince others.
about their correctness and to re-consider their mathematical ideas and constructions (Bowers, Cobb & McClain, 1999, Jaworski, 1994).

Thus, a third issue emerges, which concerns the teacher’s role in the management of the classroom as well of the mathematical knowledge. The teacher should adopt such an approach, which will allow children to develop their ideas and actions: to provide them with challenging tasks, to listen to them, to encourage them to express their thoughts, to organize the results of their work (Jaworski, 1994). At the same time, s/he avoids interventions such as providing hints, simplifying the task, giving a signal indicating the expected response. This kind of hints function as external indicators, they are often misinterpreted by the pupils, who adapt them to their existing system of knowledge as this requires less effort (Brousseau, 1977). This is possible to reduce the cognitive value of the task (Henningsen & Stein, 1997) and of the mathematical meaning of concepts and relations (Steinbring, 2001).

For teachers, the shift from familiar instructional practice to a reformed approach is not easily accomplished (Fennema & Nelson, 1997). On the one hand, this is due to the cognitive demands of challenging tasks required for the organization of the new didactical environment. And the difficulties teachers have

"to determine the preparedness of particular students for investigatory work, and the type of support they may require to successfully engage in investigations" (Diezmann, Watters, English, 2001, p. 258).

On the other hand, the relevant difficulty can be attributed to the teachers’ conception of their role with respect to the acquisition of the mathematical knowledge: they attempt to keep control of the pupils’ outcomes and their validity, to maintain the students’ dependence and to keep for themselves the management of mathematical knowledge (Arsac et al., 1992, Jaworski, 1994, Sakonidis et al, 2001).

In this context one of the important issues concerning the management of the mathematics’ classroom is related with the “devolution of mathematical knowledge” (Brousseau, 1997, p.46).

“the teacher must therefore arrange not the communication of knowledge, but the devolution of a good problem. If this devolution takes place, the students enter into the game and if they win learning occurs” (Brousseau, 1997, p.31)

How pupils interpret the mathematical meaning of a problem, and how the teacher reacts to the different meanings, how s/he helps the pupils to reconsider the problem, its mathematical meaning, without “telling” them the solution and without taking on him/her the mathematical knowledge are central issues for the research.

Based on the above considerations, this paper reports on the analysis of a problem solving process in the early grades (5 and 6 years old). It is a case study and the analysis focuses on the teacher's role in the management of the mathematical
knowledge and tries to identify those elements, which led to the successful outcome of the process.

THE STUDY: A PROBLEM SOLVING PROCESS

The data analyzed for this paper come from a problem-solving situation tackled by pupils 5-6 years old. The problem given to the pupils was as follows: The teacher asked the class to divide in groups and each group try to share among its members in equal portions a circular cake. For this purpose, each group was given a cake with a diameter of about 25 cm, made of paper and decorated with non-symmetrical drawings. This problem was chosen because of its certain epistemological characteristics: it includes references to real life situations, it is commensurate with pupils' interests and experiences, it is challenging given that the solution is not obvious, children can apply their basic knowledge, and the material allows children to control in their own the validity of their outcomes.

The pupils decided on their own to form two single gender groups, one consisted only of girls and one consisted only of boys. This resulted in two groups of different number of pupils (4 boys and 5 girls) and of different ages [1], which, as it will be seen later, influenced decisively the problem solving. Four sessions were needed all together for the completion of the task, one session per week.

Sessions were video and audio recorded. After each session, the teacher [3] completed a report with her comments. In the end of the whole problem solving procedure, a discussion was contacted with the researcher.

Data presentation

In the following, the development of the whole problem solving process is briefly presented. (numbers between brackets are referred to the transcript, which reports about the group of boys)

First session

In order to tackle the problem, children cut in a random manner the cake in pieces, each of his/her own. These pieces are of different size and a large piece of cake is left over. The children initially are worried about the left over piece and are not concerned with the unequal size of the pieces (1-3). They compare the pieces they had cut only after the teacher's intervention (4). The inequality of the pieces 'disturbs' the children only when their own piece is smaller than of someone’s else (5,7). A point worth mentioning here is Costas's pointing out to the difference between senior pupil and junior pupil[2]: it is unacceptable a senior pupil to have a larger piece from a junior pupil! (10). During the process of pieces' comparison, children, while in the beginning they used to compare them by just looking at the
pieces, as time went by, they started using another process of comparison, that is, by placing the one piece on the top of the other.

**Second session**

In the second session, the pupils tried to cut the cake using the process they adopted in the previous sessions: they would cut a piece of cake and they would place it the remaining cake to get the next piece, and so on. They chose this technique, because this way, they know beforehand, the pieces will be equal (15). Thus, the problem that children remained to solve was to cut the whole cake. In order to succeed, they cut larger pieces. However, there is still a remaining piece of cake. It has to be noted the children, in an effort to get an acceptable solution, that is, to be seen as having shared the cake in equal pieces, they suggested to the teacher to take the large piece that is left over (17).

**Third session**

In the third session, the children tried to solve the problem, to have no left over, using the same strategy as in the second session, but cutting this time larger pieces. However, they still do not manage to get the right size, to solve the problem. Thus, the problem remains. In order to get rid of it, Antonio puts forward the suggestion he had made in the previous session: the teacher to take the piece of cake that is left over (20). The teacher does not reject the participation in the solution of the problem, that is, to also take a piece. However, she insists that she should be treat as an equal member of the group and take a piece of cake of the same size of the others (21). Alexnadros’ suggestion that the teacher takes his piece (22) is rejected by the other members of the group: although the older to receive a larger piece is acceptable by the pupils, a partner to receive a larger piece is not; the equilibrium of the system is destroyed. Thus, the pupils, although they are disappointed by the difficulty of the task (25-27) and ready to give up, they are finally forced to carry on with it and the problem is left to be tackled in the next session.

**Fourth session**

Accordingly to the teacher’s comments, children expressed great anxiety in relation to whether they would be able to finally solve the problem.

The girls decided to drop Vaso, who is junior, in order to be as many as the boys, that is 4, and solve the problem. This action led to the formation of three groups and to the change of the situation, as one of the three groups had only two members. In this latter case, the problem was similar to the original, but much easier for the pupils, who were familiar with the concept of ‘half’ from their everyday life experiences (34-35). Thus, the change of the situation final led to the solution of the problem, passing through the solution of a simpler problem.
ANALYSIS OF DATA - DISCUSSION

The analysis of the data will focus on two issues: the mathematical behavior of the pupils and the management of the mathematical knowledge by the teacher.

With respect to the first, the following points are of importance: the children adopted the problem, but the attached to it a different meaning from that intended by the teacher. Thus, for example, in the first session, the pupils tried to solve the problem in such a way as to each of them take a piece, in the second session they focused on sharing in equal pieces and from the third session onwards they attempted to consider the problem as a whole. We could say that the problem the children effectively solve during each session is the following: in the 1st session the try to share the cake, in the 2nd to take an equal piece of cake, in the 3rd to solve the problem and to ‘get rid of it’ and in the 4th to solve finally the problem: the problem’s devolution takes place during all 4 sessions. The pupils’ solutions satisfied each time their own interpretation of the problem and it was only through the evaluation of the result, performed after the teacher’s intervention, that the children adopted a new interpretation and attempted to approach differently the problem. The difficulties encountered by the pupils were of epistemological nature and concerned the equality of the pieces and the properties of the circle. With respect to the former, it is possible that the relation of the problem to the everyday situations functions as an obstacle. This is because, as the pupils tried to overcome the difficulty of finding a satisfactory solution, by appealing to real life rules (the youngest takes a smaller piece, the older a larger), which could make their solution acceptable (thus helping them to get rid of the problem). The final agreement that all (junior pupils, senior pupils, teacher) should receive equal pieces constitutes an epistemological advancement towards the mathematical concept of equality. As far as the properties of the circle are concerned, it could be argued that it is a lack of knowledge (Diezmann et al., 2001) and that the pupils learn about these properties (folding like a cross-symmetry) through this problematic situation.

The above analysis of the problem’s devolution is related to the manner in which the teacher manages the mathematical knowledge and the mathematical learning. She intervenes by posing questions concerning whether the cake was cut in equal pieces or whether the piece that was left over is equal to the others (1,4,8,16,19), avoiding to say whether pupils’ outcomes are right or wrong. Thus, her questions focus on the need for the pupils to check their results. This checking is the crucial element, which will allow them to proceed to the solution of the problem, by re-considering their ideas. This way, she facilitates the children’s approach, without indicating what is right or providing hints, or simplifying the problem, but by helping them to stay focused on the problem (to not give up) and to cope with it, its cognitive demands and the mathematical knowledge it involves. In other words, she allows the
devolution (Brousseau, 1997) of the mathematical knowledge. Another important point is when the pupils ‘desperate’ suggest that she takes the larger piece (22). She refuses to do so (if she had accepted, she would have reinforced their conceptions), but she does not refrain from participating in the solution of the problem with the condition of being treated as an equal member of the group. Thus, by ‘rejecting’ the role of the adult who deserves a larger piece and as teacher who does not solve the problems (they are pupils’ tasks), she reinforces her facilitating role, as described earlier.

The simplification of the task (the creation of two groups of 4 pupils and one group of 2 pupils) was initiated by the pupils themselves. This seems to be a special feature of this particular case. However, if this simplification did not occur in the fourth session, the teacher could have intervened by suggesting the formation of groups of 2 children, without reducing the cognitive and mathematical benefit of the task (it was the right moment).

CONCLUDING REMARKS

Summarizing, it could be argued that there are two factors which seem to play a decisive role in the successful solution of challenging tasks: the first is related to the task itself and it is the possibility for control of the outcomes by the pupils' themselves. The second one is related to the management of the knowledge by the teacher: facilitating and supporting the pupils without reducing the cognitive value and the mathematical meaning of the problem. In this way the problem's devolution takes place and thus the related mathematical knowledge is constructed.

Transcript

First session […]

01 Teacher: Has the cake been cut into equal pieces?
02 Dinos: There is some leftover, because there are not many of us.
03 Alex: I should have cut bigger pieces…
04 Teacher: Are all the pieces the same?

05 Both children compare the pieces they have cut visually. Dinos is taking Alex's piece and as he puts it on the other piece of cake, he finds out that his piece is smaller and he gets angry.

06 Dinos: I will take the big one (he means the piece of cake that is left over)
07 All the others strongly disagree with his action
08 Teacher: Has the cake been cut into equal pieces?
09 Costas: I have a smaller piece than Antonio does (Antonio is junior-pupil)

10 Costas reaches this conclusion by comparing the two pieces via putting his piece on top of the other piece of cake. […]

Second session
We are going to cut the cake two by two pieces.

Hmm, how are you going to do that?

I will cut one piece and I will put it on the top of the first.

So, then?

These two pieces will be the same. […]

Is the leftover piece of cake the same as yours?

You are going to eat it Miss, because it is big and you are the older.

Alex should have cut the cake into bigger piece […]

Is this piece of cake in the middle the same size with all the others?

It is big. You should eat it!

I would like to have a piece of cake the same size as yours.

Take my piece, Miss.

So, are you going to be the one who will eat the bigger? Oh, no. I don't agree with this.

So, the cake has not been cut into equal pieces!

It is difficult, Miss!

We are going to try again!

Yes, but not today! […]

We would like to be four of us Miss, like the boys did!

Girls are jealous of us.

Vaso you better cut an other cake with Mrs Evi. (Vaso is a junior pupil and Evi is the other classroom teacher)

I agree, if Vaso agrees too.

I agree.

Well, today we are three groups and we are going to cut three cakes. I am wondering which group will be the one, which will successfully cut the cake into equal pieces. I would love to hear what you are thinking about […]

You are only two. So you are going to have half cake. This is how my mother does when the chocolate bar is too big.

It is so easy! You will cut it in the middle.[…]

I will fold it, as my mother does when I need a paper to draw.

Dinos is folding the paper and cuts it […]

In the early grade, which usually lasts 2 years, enroll pupils of 5 to 6 years old. Children of the first year are called junior pupils, whereas children of the second year senior pupils.

After this first problem was solved, four more sessions followed, where pupils engaged in sharing cakes of other shapes: square, rectangle, triangle (isosceles and equilateral).
3. There were two teachers in the classroom, exchanging roles, according to the content of the teaching.

EXPLOITING CLASSROOM CONNECTIVITY BY AGGREGATING STUDENT CONSTRUCTIONS TO CREATE NEW LEARNING OPPORTUNITIES

James J. Kaput Stephen J. Hegedus
University of Massachusetts-Dartmouth

Abstract: We examine new activity structures that involve aggregating personal mathematical constructions built on hand-held devices such as graphing calculators on larger computers in publicly shared displays. Among the many possible applications of classroom connectivity, we focus on situations engineered to require students to coordinate mathematical ideas and representations within systematically varying families of functions.

INTRODUCTION: THE CONTEXT AND GOALS FOR THE STUDY

Data, Subjects, Course-Context, and Technology

The context for the study is the same as reported in (Hegedus & Kaput, this PME). In particular, video, field notes and student work in a course for academically weak university freshmen were analyzed. The 12 students reported on here, averaging 19 years of age, were mathematically similar to 14-16 year olds. The three 1-hour sessions from which the observations were made followed those reported on in the accompanying paper, and occurred slightly past the midway point of a 15 class SimCalc exploratory teaching experiment. Students sat at tables in groups of 3-5 in a crowded space, where each used a TI-83Plus graphing calculator running MathWorlds software. Calculators could be connected, by 2m wire, to a hub that could serve up to 4 wires “quadrapus”-style, where different calculators might be interchanged to use a single wire if needed. The hub, in turn, could wirelessly send to and receive data from an external server. This was a prototype version of the TI-Navigator™ system. At the front of the class, in control of the teacher and his assistant, was a computer with display that could upload and aggregate (as described below) student work from the server while running a computer version of MathWorlds. The actual mechanics of the prototype system are ignored for the purposes of this description since they are subject to change as the system evolves.

Goals of the Study

Our aim was to understand the affordances of this level of classroom connectivity, both in terms of the new kinds of activity structures it could support as well as the teaching and learning opportunities it might support, both planned and spontaneous.
Essential Goals of the SimCalc Project

The SimCalc Project, underway for almost a decade as of this writing, seeks to democratize access, beginning at as early an age as possible, to the core ideas of the mathematics of change and variation, especially the ideas underlying calculus (Kaput, 1994; Kaput & Roschelle, 1997; Kaput, Roschelle & Stroup, 2000). The essential means for the effort are a combination of representational and curricular strategies beginning with two foundational representational strategies that change the representational infrastructure embodying the ideas, from algebraic to visual:

(1) To use interactive simulations hot-linked to new forms of visually editable graphs and visualization tools, and

(2) To build the fundamental relationships between rates and accumulations (what is normally referred to as the "Fundamental Theorem of Calculus") into both the software and associated curriculum.

Much of the student work using these representational strategies takes the form of coordinating multiple descriptions of the physical or simulation phenomena involved. For example, relating to #1, students must connect time-based coordinate graphs of position or velocity functions to screen animations driven by those functions, e.g., understanding that where a velocity graph is flat, the object must be moving at constant velocity, and when a position graph is flat, the object must be stationary. Relating to #2, they must learn to coordinate velocity and position descriptions of the same motions (or rate-accumulation relationships for other change-phenomena), e.g., understanding that a horizontal velocity graph corresponds to a straight-line position function, and vice-versa.

Further, students must also coordinate multiple representations of the same functions, e.g., algebraic formulas and coordinate graphs. Not only is the coordination among different descriptions and representations an essential part of the SimCalc strategy, it is also a more general goal of mathematics education extending well beyond the mathematics of change and variation.

Exploiting Diverse Devices and Classroom Connectivity

Technologically, the SimCalc Project has built software to support the above representational strategies, first for computers, and more recently for hand-holds, particularly the popular TI-83Plus graphing calculator (see www.simcalc.umassd.edu for downloadable software and curriculum materials for each). Most recently, we have begun development and extension of technologies that attempt to exploit the strengths of these different kinds of hardware platforms by using them in combination, particularly where each student has the personal at-handedness of a graphing calculator, and where the teacher has available the processing power and high resolution/color display of a larger computer. Further, we attempt to exploit the
newly available classroom connectivity as sketched above. Other work exploiting classroom connectivity and diverse hardware platforms is underway by Stroup and Wilensky (Wilensky & Stroup, 2000) and Resnick and Collela (Collela, 1998), where the focus is also on integrating individual student constructions into larger classroom structures, especially participatory simulations, where each student plays the role of an agent in a larger system with emergent behavior.

The Set-Up: Unique Two-Digit Student Identifiers to Support Aggregation

We used the same three levels of activity-organization as described in Hegedus and Kaput (this PME). Individual, small-group (students sharing a hub, so we refer to these as “hub-groups”), and whole-class. Each student in the class has a unique 2-digit identifier rather arbitrarily defined as follows. The first digit is determined by their hub-group number (which ranged from 1 to 3 for these sessions), and the second digit is determined by simply counting-off in each hub-group beginning with 1. The 3 respective hub-groups had 5, 3 and 4 members for these sessions, so the identifiers ranged from 11 to 34 and were fixed across the three sessions because the students stayed in the same groups, with the same count-off numbers.

The Two-Prior Aggregation Activities

In Hegedus and Kaput (this PME), we described two initial aggregation activities using the 2-digit identifiers to create parametrically varying families of linear position functions where the variation depends directly on the students’ identifiers, which in turn means that the variation depends on the students themselves. The Staggered Start, Staggered Finish activity involved a simulated “race” with a \( Y=2X \) target position function controlling the motion of one screen object (“A”), where each students created, in \( Y=mX+b \) form, a linear function controlling a second screen object (“B”) where their second object \( B \) started at their count-off number but traveled at the same rate as \( A \). Thus they finish at the same distance apart as they were when they started. Within a hub-group each student’s function was different from each other student’s function, varying in the \( Y \)-intercept, so each was parallel to \( A \)’s \( Y=2X \) function. Each student then sent their position function for \( B \) to the teacher where it was aggregated with all the other students’ position functions. While each student’s object \( B \) was represented as a dot in the aggregated collection of objects, there were only 5 different (parallel) position functions because there were only 5 count-off numbers. Part of the whole-class discussion involved identifying each student’s dot and function-graph, where as many as three students’ position graphs overlapped.

The next aggregation activity was a more challenging variation, the Staggered Start, Simultaneous Finish activity, where each student started at 3 times their count-off number and was to finish in a tie with \( A \). After aggregation in this case, the motion showed a series of dots starting in staggered positions and traveling at constant velocities which depended on how far they needed to travel in the given 6 seconds. And the slopes of their respective Position functions likewise varied depending on
the starting positions (Y-intercepts) since all the graphs "focus" in to intersect at the common (6, 12) endpoint, reflecting that the race must end in a tie.

Of special interest in this paper is how we are able to exploit further the students' personal connection with their constructions in the aggregated publicly displayed set of student constructions in order to serve developing the two kinds of critically important coordination skills described above.

AGGREGATION-BASED ACTIVITY STRUCTURES: WHERE ARE YOU?

New Student Coordination Activities: Where Are You?—Example 1

These activities move to a higher level of complexity by involving both the student’s count-off number and their hub-group number in their individual mathematical constructions. Each activity was designed to put the student in the position of needing to coordinate important information about their mathematical construction in order to identify either their motion-object, their function, or a closely related function in the aggregated set in the classroom display – to “find yourself.” The first case involves coordinating position graph information with motion information.

Example 1: Make a \(Y = mx + b\) Position function formula for a 5-second motion for B, where your starting point is your count-off number and your slope is your group number. Then send it up and we will examine where you are.

Figure 1: Initial Positions Equal to Count-off Numbers at Time = 0 Sec

In Figure 1, is what the students saw when the functions were first aggregated. In particular, note that we deliberately did not show their function graphs, which they had already seen on their calculators, and, in fact could—and did—refer to as the discussion proceeded. In response to the teacher’s question “Where are you,” there followed an animated 30 minute discussion that occurred in 3 stages, the latter two of which were based on revealing, respectively, additional information when a consensus was formed that the information was needed: (a) initial position as shown in Figure 1, (b) approximate velocities and ending points, and (c) exact velocities as shown by the “Marks” in Figure 2. Also revealed in stage (b) was the fact that one student had created a 6-second motion and that one student had entered an incorrect slope (2, which should have been 3). Space limitations prevent inclusion of the transcript of the extremely rich classroom discussion (a full account is in progress), although a few observations are central to understanding the activity design and how the students responded.

In stage (a) students recognized those dots that might represent them but decided that they could not exactly identify themselves, except to know that their companions on
the “starting-line” all shared their count-off number. The one exception was Clive, who was the lone member of the class with count-off number equal to 5. He appears in the bottom position, and, when he identified himself, seemed to stimulate and consolidate the consensus that more information was needed by the remainder of the class. Interestingly, Clive had been among the quietest students in the class and barely spoke publicly during the first 6 weeks of the course. By the end of the 3rd class where he was the only student with 5 as a count-off number, he was acknowledged as “famous” by another student and frequently contributed to classroom discussions.

In stage (b), as the class came to recognize that some groups would be faster than others and hence would yield greater total distances traveled, they were able to make progress in identifying themselves, although the errors mentioned above added sufficient uncertainty, as did the fact that the starting positions disappear when the animation is run. The need for specific identification forced a move from qualitative analyses (e.g., “He went the farthest so is probably in Group 3”) to quantitative analysis.

An important visualization feature built into MathWorlds is to have the moving objects “drop marks” (location-traces) for specified time intervals as they move, with the default being 1 second. The students had come to use this feature regularly when the velocity of an object was in question. Hence they called for marks to be dropped. This resulted in Figure 2, which shows the positions of each object at 1-second intervals from the initial position to the ending position.

Since the velocities are constant in this case, we can now read off the respective velocities of each object and coordinate it with the starting position to uniquely identify the identity of each dot.

**Reflections on Example 1: Using Personal Identity to Coordinate Linear Function & Motion Information, Especially X-Coefficient & Rate-of-Change**

Example 1 indicates how, by selectively hiding certain information, in this case the coordinate graphs for the algebraically defined linear functions, and revealing additional information about the associated motion in a pedagogically functional way, students’ personal identities act to motivate and focus attention on key features of a display. Exactly the kinds of cognitive things we want to happen in traditional motion-representation coordination activities at the heart of SimCalc representation strategy #1 identified above (e.g., identify the motion that goes with this formula, or make a formula that matches this motion) can occur very naturally when the activity is of the *Where Are You?* type. Far less obvious in this sketchy, abbreviated and
statistically account is the high level of personal engagement of the students, and, more importantly, how that engagement helped structure the coordination process.

Example 2: Coordinating Velocity & Position Descriptions of Motion—Part 1

Example 2: Make a 2-step velocity function, each step 3 seconds long, where your velocity for the 1st segment is your Group # and your velocity for the 2nd segment is your Count-off # in the group. Everyone starts at 0. Send it up and we will look at the position functions and examine where you are.

Figure 3: Branching Position Graphs – Group # = First Velocity

MathWorlds on the calculator (as on the computer) enables students to make step-wise varying graphs directly by systematically adding and manipulating segments. We displayed the dots and position graphs for the whole class and then asked "Where Are You?" The goal here was to coordinate velocity and position descriptions of a motion—using the ideas that velocity is slope of position graphs and that area under velocity graph segments gives the position-change during those segments. In this case the geometry of the configuration comes to play an interesting role relative to the motion.

Note that Figure 3 is a cleaned-up version of the initial one that appeared—one student sent up a constant velocity graph steeper than the rest and was discovered to be in error. The set of position graphs consist of a 3-branched tree from the origin, one branch for each of the 3 groups, each of which then branches for each of the counting numbers in the group, which varied from 3 to 5. The discussion leading to the identification of individuals was extraordinarily rich, and filled with excitement as the students gradually recognized the two separate roles for their two numbers in the shape of the graphs and the resulting motions. Interestingly, as can be seen from Figure 3, all members of a group travel together, side-by-side, for the first 3 seconds, at which time they diverge to travel at their different count-off number velocities, a fact noted by the students.

Note that Clive, the only "5" was an outlier, and went the fastest at the end of the trip, tied for the longest distance, etc. One student observed that those people with straight graphs and constant motions were those whose count-off number equalled their group number. They also kept their velocity graphs available for reference in the coordination and used the motion information to anchor the two descriptions, exactly as we use it in our traditional SimCalc activities, most of which take the form of matching activities (e.g., make a position function for B to match A's motion exactly, where A's motion is given by the given velocity graph).

Example 3: Coordinating Velocity & Position Descriptions of Motion—Part 2.
Here, members of a group split apart at the outset, where student with the same count-off number were side-by-side. This version involved a very different configuration of graphs and motions appearing—see Figure 4—except, of course, for those students whose Group # = their Count-off #. Of interest is how group identity was vocalized in this case, as each group “broke apart” in the 1st 3 seconds and never came together, despite the fact that they all traveled at the same velocity for the last 3 seconds. It appears that these kinds of activities also provide a prime context for purposeful and logical problem solving, because both their and their classmates’ identities are involved. In this case, there was someone unaccounted for and that person was identified by elimination that involved coordination between the slope-information on the position graphs and the velocity information.

Example 3: Make a 2-step velocity function, each step 3 seconds long, where your velocity for the 1st segment is your Count-off # and your velocity for the 2nd segment is your Group #. Everyone starts at 0. Send it up and we will look at the position functions and examine where you are.

Figure 4: Position Graphs With Count-off #’s as 1st Slope.

Example 4: Velocity Graphs Provide No Position Information.

In this case, we included the example to drive home the point, which had arisen previously, that velocity information tells us “how fast” but not “where.” This shows up quite dramatically where we showed what appears to be a single velocity graph (they all overlapped—See Figure 5) and asked “Where are you?” We temporarily hid the dots, which would have given away the position information. Of course, it is still inconclusive in this case even when coupled with the motion shown—where all the dots move at the same velocity, and end in the same configuration in which they started.

Example 4: Make a 2-part position function, where you start at the sum of your count-off and group numbers, and each part is 3 seconds long. The slope of the first segment should be 1 and the slope of the second should be 2. Send it up and we will look at the velocity functions and examine where you are.

Figure 5: Velocity Functions for 12 Students—all overlapping
REFLECTIONS ON THE EXAMPLES: USING TECHNOLOGICAL CONNECTIVITY TO GENERATE PERSONAL CONNECTIVITY

These early examples only scratch the surface of what we believe to be possible in exploiting new classroom connectivity for educational purposes by tapping into personal identity as a resource for focusing attention and generating engagement in complex mathematical activity. Many more examples are being examined, and the reader could surely generate more. For example, we are currently studying the use of CBR-based data, where groups separately create motions based on their own physical motion, which are then aggregated in a class to form dances and marches and then re-animated on the computer screen. Again, the kind of thinking needed to plan out a dance that, of course, is executed simultaneously, but produced serially, is exactly the kind that we would want to produce by traditional means.

As pointed out by Donald (2001), humans accomplish extraordinarily complex tasks of management of their mental resources and communication in everyday social contexts using the cultural tools of language and, as needed, other representational tools. Most mathematical activity ignores these resources despite the unanimity of recognition of the power of classroom talk and norms that support inquiry and purposeful discussion. The kinds of aggregation activity structures described above deliberately build systematic mathematical variation, personal identity and ownership into a functional classroom role by making them an intrinsic part of the activity structure itself at one or another levels of group organization. Future work will continue to explore and map out this extremely rich opportunity space.

REFERENCES

This paper presents findings from a qualitative study regarding adults’ recalled definitions of function, and their attempts to draw simple linear functions. The subjects in this research were 24 men and women between the ages of 30 to 45, all engaged in successful careers. Findings support the principal conclusion of Bahrick and Hall (1991), who claimed that retaining of high school mathematical material strongly depends on the length of acquisition period and the amount of practice. Also, some of the findings exemplify Bartlett’s theory (1932) concerning reconstruction vs. reproduction in the mechanism of recalling.

Introduction

Consider the phrase “curricular consensus”; sounds like an oxymoron, does it not? So many different views exist about what should be taught in schools, that it seems a great achievement if an agreement can be reached within a single school. Nevertheless, we might find a consensus in the shared implicit expectation of all curricula, which is – as we dare to assume – that graduates should be knowledgeable to a certain degree about the contents they have learned. Such an expectation evokes a cardinal question: What do adults remember from their past studies? This intriguing question was scarcely addressed by research until two decades ago, much to the explicit disappointment of cognitive psychologists specializing in memory research (Neisser, 1978, Bahrick, 1979). Since 1980, some progress has been made in this area (see a review by Semb et al., 1993), but the number of relevant researches is still relatively low, probably due to unresolved methodological problems. In regard to mathematics, a unique work is that of Bahrick and Hall (1991), a large-scale quantitative study designed to identify variables that affect losses in recall of high school algebra and geometry contents. A major finding of this work was:

“When the acquisition period extends over several years, during which the original content is relearned and used in additional mathematics courses, the performance level at the end of the training is retained for more than 50 years, even for participants who report no significant additional rehearsal during this long period. In contrast, those whose acquisition period is limited to a single year perform at near-chance levels...” (p.30).

The performance of Bahrick and Hall’s research participants (about 1700 in number) was measured by psychometric means (that is, correct/incorrect answers); indeed, a statistical study of such a large scale does not usually involve cognitive analysis of
answers to open-ended questions. Since cognitive analysis could potentially reveal phenomena that remain unnoticed by psychometric analysis (Karsenty & Vinner, 1996), it seems that a qualitative study, scrutinizing adults’ attempts to recall mathematical material, could add to the general picture in the issue of maintenance of high school mathematical contents. In this article we chose to present attempts to recall the definition of function and graphical representations of linear functions.

Theoretical background

Mechanisms of recalling. The cognitive aspect of recalling contents has long been an attractive subject for researchers (mostly referring to contents acquired in research laboratories). The well-acknowledged classical work of Bartlett (1932) laid the foundations of this field. Bartlett suggested that recalling is a mechanism of reconstruction rather than reproduction. In other words, when requested to repeat a story heard or an event experienced, people are likely to produce an interpreted version, though they may be unaware of doing so. Thus, some details might be omitted, others emphasized or even added. In this article we present examples of attempts to recall the graphical representation of a linear function, in a way that suggests that a similar mechanism of reconstruction takes place. Moreover, we intend to show that such reconstructions, idiosyncratic as they might be, sometimes follow a certain inner logic that is recruited in the absence of accessible relevant details.

The concept to be recalled: What is a function? Math educators and researchers have debated on proper ways of introducing the concept of function, one of the most difficult and complicated concepts that secondary school mathematics students encounter (Buck, 1970). One of the core questions in that matter concerns the kind of definition that should be used. Roughly speaking, we can divide definitions into two groups, based on the historical development of the notion of function (see Kleiner, 1989). The first group is what we might call “old definitions” – definitions in the spirit of 18th century mathematicians Euler and Lagrange. For them, a function was “an analytic expression representing the relation between two variables with its graph having no corners” (Malik, 1980, p. 490). The second group of definitions can be referred to as “modern”. In these definitions the key word is correspondence, as in the Dirichlet-Bourbaki definition. This major change in the definition of function was reflected in most of the mathematical secondary school curricula all over the world. Examination of ten 20th century Israeli textbooks, dating from 1923 to 1995, reveal a shift from “old” definitions to “modern” ones, around the end of the sixties and the beginning of the seventies (Karsenty, 2001). The question of whether this curricular shift contributes to a better understanding of functions, stands at the heart of the debate mentioned above. Malik (1980) criticizes the use of modern definition of function in courses intended for average students:

"The necessity of teaching the modern definition of function at school level is not at all obvious and most of the instructors feel that pedagogical considerations were ignored while designing the course content and the mode of presentation" (p.490)
Vinner and Dreyfus (1989) doubt the appropriateness of a modern definition for certain courses, and suggest that an intensive example-based introduction should precede and accompany the formal definition. Markovits et al. (1986) suggest ways to overcome some obstacles and enable a successful use of the modern definition.

In light of these opinions, it was interesting to look into the following question in regard to our research subjects. Considering the fact that they had attended high schools around the decade of change (see methodology section below), what kind of definitions will they use when requested to define a function in an open-ended manner? Some results follow the methodology description.

**Methodology**

The data and analyses reported here are part of a study, whose aim was to investigate cognitive and affective characteristics of adults' recollections in regard to their mathematical experience and knowledge (Karsenty, 2001). The study was defined as a “collective case study” (Stake, 1994), and focused on adults with considerably high level of education. The subjects’ selection procedure was described in detail in a previous article (Karsenty & Vinner, 2000), and will be repeated here briefly.

12 men and 12 women were selected for the study from an upper-middle class community whose residents came from all over the country. At the time of the interviewing process the subjects were between the ages of 30 to 45, and their high school graduation year ranged from 1968 to 1984. All of them were graduates of college or university, but they varied in the level of math they had taken in high school\(^1\) and the type of their current profession\(^2\). Each participant attended an individual session, devoted mainly to an interview, which was semi-structured and lasted about 2 hours\(^3\). The first part of it intended to explore personal affective components of learning mathematics (see Karsenty & Vinner, 2000, for some findings). In the second part of the interview, subjects were asked to “think aloud” about fourteen mathematical tasks involving basic concepts and procedures. The interview was intentionally held in a moderately-intervening manner. Thus, when a subject persisted that he or she “doesn’t remember anything”, small hints were suggested as triggers for eliciting any kind of respond associated with the question at hand. All interviews were recorded and transcribed.

In the next section we present results in regard to two interview tasks, introduced to the research participants as follows:

**What is a function?**

**Can you sketch a graphical description of the function \(y=2x\)?**\(^4\)

---

1 In Israel mathematics is a compulsory subject throughout high school, and can be studied in three levels, herein referred to as high level, medium level and low level.

2 Professions were categorized by The Standard Classification of Occupations, a scale of 10 categories published by the Israeli Central Bureau of Statistics.

3 Subjects also filled two questionnaires, findings from which will be published elsewhere.

4 In some cases the given function was \(y=x\) or \(y=x+1\) or \(y=2x+1\).
Results and Discussion

I. Responses to the interview question "what is a function" were grouped into six categories, which will be described and illustrated here in short. The categories are partly adapted from Vinner and Dreyfus (1989).

Category A. The subject's response includes, as a dominant component, one of the following expressions: "relation", "dependence", "influence", in regard to variables or number values.
Example:
"A function is, I think, a relation or a connection between two variables"
(Nurit (female), 38, psychologist, studied math in a high level track)

Category B. The subject's response includes, as a dominant component, one of the following words: "equation", "formula", "operation".
Examples:
"A function is an equation. An equation that describes some kind of a line"
(Gadi (male), 41, architect, studied math in a medium level track)

"A function is... using a... a general formula, and then you can plug in different numbers to reach certain goals. That is, it's some kind of a general formula that afterwards you can use each time with variables that are appropriate in a certain situation"
(Irit (female), 33, senior banker, studied math in a medium level track)

Category C. The dominant aspect in the subject's response is visual; the notion of function is mainly identified with a graphical representation.
Example:
"Ah... What is a function? A function is that thing with the... inside the graph, which has all kinds of shapes, and it looks differently according to its elements. [...] I remember that there are all kinds of functions [draws 3 different sketches of graphs]. Some are like this, some are like this, it depends on how the x relates to the y."
(Amira (female), 31, museum director, studied math in a medium level track)

Category D. The subject recalls the concept of function mainly in a context of exercises that he or she used to work on.
Example:
"I recall some story of substituting points, of a formula that you check. There's a question or instruction to plug in points and then every point to put on a graph [...] I remember the requirement, say in an exercise, of the peak point, something like that, and the lowest point, such things I remember. Or questions that dealt with the relation between the y-axis and the x-axis. Below zero, above zero, such things I recall, very vaguely. It's been some 20 years ago, you know. If you ask me what happens with this and what is it used for, I won't be able to tell you"
Eli (male), 40, principal of a post-secondary institution, studied math in a low track)
**Category E.** The subject can only elicit blurry associations related to the process of sketching graphs.

Example:

"I remember that function was... we used to set up the... we used to set up on the graph there, on the x-axis and the y-axis, points... what was it? x-axis, y-axis, the points, and construct the function accordingly"

(Arie (male), 38, insurance representative, studied math in a low level track)

**Category F.** The subject can neither define, nor exemplify, or even elicit associations to the word 'function'. It seems like the concept has been "deleted".

The distribution of subjects within the six categories is shown in table 1. Several observations can be made in regard to the data presented. First, it should be noted that none of the 24 subjects has defined a function in a way that could be regarded as modern. Generally it can be said that half of the subjects remembered the concept of function and defined it mostly in the spirit of old definitions (relation, dependence, equation, formula, operation, or via smooth graphs). The fact that the modern definition was not preserved in subjects' memory might suggest that it was not well assimilated, in spite of the favorable learning circumstances mentioned before (i.e., when the modern definition became popular in textbooks). It could be claimed, however, that this state of affairs is due to teachers' dissatisfaction with the use of the modern definition, as noted by Malik (1980) (see also Cha & Wilson's report (1999) concerning the inclination of prospective math teachers to define functions as equations or machines rather than by way of sets). One might suspect that, as a result of such dissatisfaction, the modern definition of function has played a lesser role in the implemented curriculum than it did in the intended curriculum.

Second, a connection can be noticed between high school math level tracks and the category distribution: Most of the subjects who participated in a high level track were classified to categories A-B, expressing familiarity with the concept of function. All

Table 1. Distribution of subjects within the six categories of function definition (N=24).
medium-level graduates were classified to categories B-D. Most of the low-level graduates (8 of 12) were classified to categories D-F, which can be characterized by vague recollections, if any at all, about the definition of function. This finding is in accordance with the general conclusion of Bahrick and Hall (1991) in regard to lifetime maintenance of mathematical material, which is basically that the rate of loss is most affected by variables concerned with the amount and distribution of practice. Finally, attention should be drawn to the other half of the subjects, those assigned to categories D-F. Our general impression was that for them, the concept of function was absent from what might be referred to as an "available concept pool". Using Vinner's (1983) terms, it can be said that the cell of "concept definition" became devoid; any associations, if elicited at all, were based on random pieces from the "concept image" cell. This finding is noteworthy, considering the fact that these people are educated adults who are well positioned in modern society. One can only conjecture on the extent of loss, in regard to this important concept, among the wider population of high school graduates.

II. Subjects' attempts to draw graphs for simple linear functions were classified into seven categories. We will not describe these categories here, due to space limitations. Instead, we present three examples of drawings made by subjects. However, we would like to point out that of the 24 adults participating in the study, only 7 could sketch, without intervening clues, a graph that was correct in its general idea.

Example 1. Figure 1 presents a drawing of the function $y=x$, made by Dov (male, 37, government official, studied math in a low-level track).

![Figure 1. Drawing of the function $y=x$, made by Dov.](image)

As can be seen, Dov does not recall the Cartesian system. In the absence of this frame of reference, he tackles the task in an idiosyncratic way. In other words, since Dov's knowledge of linear graphs is inaccessible, and thus can not be reproduced, Dov reconstructs the idea of $y=x$ based on his present interpretation. Apparently, $y=x$ is seen as an equality between quantities, and the two identical line segments illustrate this understanding. Two other subjects gave quantity illustrations; one described $y=x$ as two identical circles, the other described $y=2x$ as two small circles and a bigger circle.

Example 2. Figure 2 presents drawings of the functions $y=x$ and $y=2x$, made by Tamar (female, 42, high school humanities teacher, studied math in a low-level track).
Tamar recalls the axis system, but not the Cartesian representation of points. Like Dov, she reconstructs the idea of linear graphs on the basis of her current common sense. While drawing y=x she says: "Well, anyway, there's got to be something equal here". Thus, she allocates equal segments of one unit on both axis. She then joins the two endpoints by a line. This last action might be ascribed to vague residues of the notion of function, elicited earlier by Tamar: When requested to define a function, she said - "There is a horizontal axis and a vertical axis, and there are points. You join the points and you get a function". Note that Tamar persists with the same logic when drawing y=2x. This time the segment allocated on the x-axis is twice as long as the one allocated on the y-axis, thus reflecting a common proportional misconception. Similar descriptions of linear functions were given by two other subjects.

Example 3. Figure 3 presents a drawing of the function y=3x+2 made by Judy (female, 35, lawyer, studied math in a medium-level track). It is the second graph drawn by Judy. She first drew a correct graph of the function y=x+1, by calculating values of several points and joining them with a straight line. However, while doing so, she remarked: "It's a straight graph because it's very simple, it only has 1 added, and no multiplication". This remark led the interviewer to ask her to draw y=3x-1-2. This time, although Judy correctly calculates five point values, she joins the points with a curved line, as can be seen in Figure 3. She claims that due to the multiplication of x by 3, "what happens is that it's going to be higher and higher".

Again, we can see that a mechanism of reconstruction of knowledge takes place, even when the basic ideas of function graphical representation can be recalled. As a final comment we would like to emphasize, that the examples given above are merely illustrations of interesting phenomena of recalling mathematical material, yet to be explored.

FROM CONTROLLING TO COMMUNICATING: INNOVATION IN BOTSWANA'S TEACHER PREPARATION PROGRAMME ON INTEGRATION OF ASSESSMENT AND INSTRUCTION

Sesutho Koketso Kesianye
The University of Leeds and Tonota College of Education

This paper reports on an analysis of part of a wider study to investigate innovative approaches in the preparation of mathematics preservice teachers in the integration of assessment and instruction (IAI). Student-teachers’ teaching practice was analysed to reveal the effects, if any, of IAI training that emphasised communication over control. The reported case studies show that training student-teachers in this way facilitated their application of IAI, and led to increased reflexive use of information from pupil responses in their teaching, compared to that observed with previous cohorts of students.

Introduction

The integration of assessment and instruction (IAI) refers to teaching and assessment being intertwined, to assessment being used formatively. Torrance and Pryor (1998) suggest that IAI occurs when assessment is intended to generate information about children’s knowledge and understanding while at the same time contributing to the process of creating that understanding. In mathematics teaching, the main aim of IAI, as Chambers (1993) explains, is to access students’ mathematical thinking, and reflect on how to use that knowledge as the basis for instructional decisions for both individual students and the class as a whole. Feedback from such assessments should inform the student of what he or she can do to improve or move further in his or her learning, as suggested by Black and Wiliam (1998). IAI in this study made limited use of techniques of assessment that rely on written work such as tests. More focus was placed on assessment techniques that may be used hand-in-hand with on-going teaching, such as oral questioning and observations of students on task.

The wider study

The wider study from which this report is taken is an action-research project on my own practice as a mathematics teacher educator. It was formulated in the context of the purpose of equipping student-teachers with the necessary tools for their teaching career. It was conducted at Tonota College of Education (TCE) in Botswana, which trains teachers for a Diploma in Secondary Education qualification (DSE). A class of 21 student-teachers training to teach mathematics was involved in the study. The practical element of the study was undertaken over a period of six months covering college-taught sessions and Teaching Practice in placement schools.

In my previous work with student-teachers, I had observed a general failure in their application of IAI during Teaching Practice, despite them receiving several lectures about its techniques and methods, and its importance in the teaching and learning of
mathematics. The students of previous cohorts could not assess students' mathematical thinking effectively or use the knowledge to make appropriate instructional decisions. Invariably, their teaching was characterised by “telling” students rather than engaging them in the negotiation of meanings or construction of knowledge. This observation was also made by educators from the University of Botswana (UB), which validates the DSE programme, and questions were raised about the nature of teaching at the college, which is dominated by the lecture method. The UB, through Hopkin (1999) recommended that:

The College (TCE) should explore the use and development of co-operative teaching in their training programme.

In recognition of this problem, I focused my investigation on how my methods of training affected student-teachers’ learning. In other words, the study addresses what Russell (1997) calls the ‘pedagogical turn’. I also investigated the ‘content turn’ by training student-teachers in IAI. However, as indicated by Webb (1993), IAI is not easy and requires teachers to be prepared for its application. As suggested by Heid et al (1999), mathematics teachers do not automatically attempt to determine students’ understandings. They need to be empowered to act in that sense, for example by learning to listen with student understanding in mind, rather than as part of a method to control student responses.

In order to make a deliberate difference I designed a new teaching programme to illuminate aspects of IAI that I wanted student-teachers to use. It involved (i) oral questioning (ii) responding to students’ responses and (iii) practical ideas that a teacher can draw from to facilitate his or her use of the proposed approach. This was designed to enable student-teachers to reduce control over the students’ responses and allow the students to communicate their mathematical thinking.

As this study was a practitioner-based research seeking to improve practice, I employed action research methods that allowed me to monitor and modify the training as it unfolded. Therefore, it is likely that my influence on student-teachers’ applications of IAI was not constrained by the research process, in that I had the freedom and experience to assist professionally. However, the fact that I was learning at the same as the students may have influenced them.

Data collection and analysis procedures

A lesson observation instrument was used to collect data on student teachers' implementation of IAI, focusing on their planning, on their questioning and other strategies for identifying and eliciting students' mathematical thinking, on their feedback to students, and on their self-evaluation. The lesson observation instrument was supplemented by other data sources such as detailed notes of class incidents, particularly the exact questions and responses exchanged by the student-teacher and their students, and student-teachers’ self-reports. The analysis of data focused on the characteristics of student-teachers’ application in comparison to each other and in
reference to the aspects of the IAI approach covered during training. The overall objective of the analysis was to establish whether training student-teachers in IAI in the way I adopted enabled them to apply it during Teaching Practice.

Results

Three case studies are reported in this paper. They have been chosen to illustrate the range of degree of application of IAI in the cohort studied.

Elvis

Elvis’s lesson planning explicitly made use of information obtained from previous classroom assessment, a point repeatedly emphasised during training. For example, in one of his lesson plans, under the introduction section he wrote:

<table>
<thead>
<tr>
<th>Time</th>
<th>Content</th>
</tr>
</thead>
<tbody>
<tr>
<td>10 min</td>
<td><strong>Introduction</strong></td>
</tr>
<tr>
<td></td>
<td>General comments on marked exercise from last lesson (errors detected)</td>
</tr>
<tr>
<td></td>
<td>5\frac{1}{4} not 5\frac{1}{4}</td>
</tr>
<tr>
<td></td>
<td>make reasonable statements after solving word problems i.e (encoding)</td>
</tr>
<tr>
<td></td>
<td>add: 2\frac{3}{5} + 4\frac{1}{2}</td>
</tr>
<tr>
<td></td>
<td>If 6 (2 + 4) is done</td>
</tr>
<tr>
<td></td>
<td>Therefore 6 + (\frac{3}{5} + \frac{1}{2})</td>
</tr>
</tbody>
</table>

In his lessons, Elvis evidently elicited alternative problem solving strategies by advising students to make realistic decisions on the strategies they preferred to use. He commented that the strategy chosen should be what the individual student understood rather than that it was used by the teacher or other students. He posed questions that informed students clearly that there were alternative strategies that may be used. This is illustrated in the following dialogue:

T: How do we go about simplifying this? (Pointing to 2.4 : 2.7 on the board)
   (Students suggest changing the numbers into fractions and the problem is worked through on the board.)
T: Is there another way of doing it besides changing it to fractions?
S: Multiply by ten and simplify
T: Why did you decide to multiply by ten?

This line of questioning required students to feel free to express themselves. Nevertheless, Elvis found it hard to promote the student-to-student interaction that he wanted so that students would communicate their thinking and share their strategies. His recognition of the importance of this revealed his understanding of students as well as that of the demands of IAI. Indeed the issue of giving students opportunities
to express their understanding is recognised by Black and Wiliam (1998, p11) to be essential in the design of teaching for formative assessment to aid learning. I assisted him in planning and implementing activities that allowed students to interact with each other in one of the lessons. We agreed that he could ask me to intervene during the lesson and I could participate in ways demanded by the situation. After receiving this moral and practical support he regained his confidence in posing questions that required students to communicate their thinking. Without this extension of the training into the Teaching Practice period, Elvis may not have been able to sustain his initial application of IAI due to a failure to get students to express their understanding.

As a result of it he became increasingly able to ask questions that illustrated or revealed certain aspects of the mathematical concepts, and this provided students with an opportunity to learn in the process. In one lesson, students were asked what they would do to simplify a ratio. The response was that they would divide by the LCF and the teacher decided to illustrate that the LCF of any two numbers is 1 by using factors of 10 and 20. He then asked them what they could say about 1 and 10 from the lists of factors. The fact that 1 is the LCF of the two numbers was illustrated and they were asked which of the two would they use to simplify a given ratio. This exchange was giving students an opportunity to learn about the difference between LCF and HCF as well as for them to realise that 1 would be the LCF of any two or more whole numbers, which is usually not considered when teaching the topic.

Elvis often provided students with feedback that supported their knowledge and also extended it in a challenging manner. This was done by asking students to account for their solutions, for example by questions such as:

* Why do you multiply 4 by 500? Say it out, I'm not saying you are wrong. *

The student is supported by being told that questioning them does not mean that they are wrong, but is intended to extend their knowledge.

* What about if this was 10m and 2kg? Can we compare them? *

Here, Elvis wanted students to realise that in ratios the quantities must have the same units. He then moved on to m and km and to conversion of units to express the quantities in ratio form. This type of questioning, to provide challenges to students’ knowledge in the process of giving them feedback on what they already knew, was explicitly encouraged during training.

Elvis also reflected on how to improve his practice. Motivating students to feel free to communicate their thinking was identified as an area for improvement in his teaching. He pointed out that making connections between topics explicitly was also found to enhance such communication for his students. He suggested that some topics might be easy to understand, thus making it possible for students to say something on them spontaneously. By the end of the last lesson that I observed he engaged comfortably in an extended exchange with one student. However, he
continued to experience problems with making decisions about when to persist in the extended exchanges with individual students. This was a reminder to me that there can be no recipe that would work for everyone, as observed by Wiliam (2000, p22).

Tina

In Tina’s case, lesson planning was significantly different from other student-teachers’ planning and this seemed to have an effect on how the lessons progressed. Her initial lesson plans reflected a shallow consideration of content coverage and insufficient student involvement in the development of the concepts. This was evidenced by her failure to recognise alternative solutions raised by students. In one of her self-evaluation statements, she wrote:

"Most of the students were responding well except in the last part where I was unable to use some of their wrong answers well as they gave unexpected answer but some were correct e.g. They gave 18 x 2 while I expected 9 x 4. I could have asked them to expand 18 to get 9 x 2 then have 3 x 3 x 2 x 2."

Either Tina had not considered various ways of expressing 36 as a product of its factors in her preparation, or she had a shallow understanding of the subject-matter. I had no reason to believe that the latter was the more likely explanation since she was one of the two student-teachers in the class with the highest 'O' Level grade. Whatever the reason, it resulted in a restriction of the use of students’ responses in developing the mathematical concepts and thus assessment was not effectively integrated with instruction according to its interpretation in this study.

However, through processes infused in the training program to assist student-teachers to apply and sustain initial application of IAI, like self-evaluations, class observations, practical assistance and conversations after lessons, Tina managed to make progress towards flexibility in both content and use of students’ mathematical thinking. In particular, discussions of students’ responses that focused on why they may have responded that way made her view ideas from different perspectives. These reflections enabled her to learn to view the situation from the students’ perspective; the kind of reflection that Wood (2001) suggested to be essential for pedagogical reasoning. Her line of questioning gradually changed from the more controlling, 'what' type of questions to include more 'why' and reasoning type questions. In the last lesson that I observed, I noted an exchange between Tina and a student that reflected this change of questioning, as follows:

T: What do you think you are going to get?
S: Negative two.
T: How did you get that? You have to try a step-by-step approach.

I viewed this type of questioning as encouraging students to think and communicate their thinking rather than controlling their responses.

Tina also observed changes in students’ motivation as a result of allowing them to express their thinking orally and this encouraged her to pose questions that enabled
everyone to say something. In one of the lessons, she based the development of the concepts on students’ responses to the question “What have you observed?” Although she struggled to provide useful feedback to the students, it was clear that she wanted to make use of their responses to enhance their understanding. She viewed this as important, as reflected in her Teaching Practice report where she stated:

“As the lessons went on some lessons were conducted by questioning asking questions and the lessons are now interesting as they are well motivated. Also pupils are able to answer orally asked questions than written ones.”

The fact that Tina recognised how such assessments affected students’ motivation and that she could use the situation to benefit the students made her pay more attention to how to sustain the situation.

It seemed that Tina’s difficulties in applying IAI were rooted in inadequate lesson preparation during the initial stages. It appeared as though the emphasis on lesson planning during training was not done effectively for her to understand its importance. Though she persistently experienced difficulties with providing appropriate feedback, there were signs of improvement arising from the continuation of training through my active support during Teaching Practice.

**Bowie**

The most developed application of IAI in terms of lesson planning and the level of performance during the lesson was shown by Bowie. Lesson plans were detailed in terms of content, students’ activities and the teacher’s activities. It was evident that questioning was given consideration during planning just as had been recommended during training. The questions that he was to draw from were often stated in his lesson plans. For example:

“Some questions to be asked by the teacher: 1) What can you see in your reading that is common? 2) What do you think is the use of the decimal point?”

From the first meeting Bowie exposed students to group work and to communicating their thinking to the rest of the class. He seemed to have internalised the assumption of active involvement by the students that IAI is based upon. The deliberate emphasis on the notion of learning from each other, including himself in that he was ready to learn from the students, can be associated with socio-cognitive theories of learning, that include ideas of ‘learning from learners’. He achieved this purpose through posing questions such as “Can somebody explain what he said to me?” A working atmosphere in which students became free and keen to express themselves was established. In Bowie’s lessons, students were observed posing questions and volunteering explanations to the class, unlike in other classes. This did not happen by chance, but because he created room for it through deliberate tactics to involve students, such as posing questions back to students, appropriate waiting time, and being honest about things he was not sure about, thus giving students confidence that
he could actually learn from them. Throughout his trials of these tactics, his reflections drew heavily from the training. In our conversations after his lessons, he often related students’ experiences to his college experiences, particularly the struggles encountered in group work and benefits gained from discussions with other student-teachers. It is presumably this experience or the practical exposure provided by the training program that enabled him to try out ideas to motivate students to reveal their mathematical thinking freely. How he was taught during training seems to have had an influence on his teaching.

Good questioning skills was one of Bowie’s strengths in the application of IAI. He used the type of questions recommended during training that were perceived to enable students of different abilities to come up with something to say, such as:

“What similarities can you observe? What is common among these readings?”

Students’ responses were commonly used to ask further questions that in some cases supported the acquired knowledge and sometimes led students towards the mathematical concept being developed. This can be seen in the question:

“The three is a fraction of a centimetre. Should we write mm or cm (written on the board) now that we have three over ten (\(\frac{3}{10}\))?”

Bowie’s questions and the dialogue that followed bear similarities to that which Black and Wiliam (1998, p12) recommended, in stating that:

The dialogue between pupils and a teacher should be thoughtful, reflective, focused to evoke and explore understanding, and conducted so that all pupils have an opportunity to think and to express their ideas.

Bowie employed a variety of assessment techniques such as observations to identify students’ strategies that he then used in further instructional decisions. The observations of students’ strategies served a meaningful purpose of exposing them to alternative strategies. They were not merely to check who was correct. In one lesson, the following strategies were identified through observations of students’ work and were put up on the board for a class discussion:

(a) \[12 \times 10\hspace{1cm}(b) \hspace{1cm}12 \times 10\hspace{1cm}(c) \hspace{1cm}12 \times 10\]

\[
\begin{array}{c}
H \hspace{0.5cm} T \hspace{0.5cm} U \\
1 \hspace{0.5cm} 2 \\
\end{array}
\]

\[
\begin{array}{c}
x 10 \\
00 \\
\end{array}
\]

\[
\begin{array}{c}
1 \hspace{0.5cm} 2 \hspace{0.5cm} 0 \\
\end{array}
\]

1 place to R

This exposure to alternative strategies was followed by questions that reinforced knowledge already acquired by the majority of the students, if not all;

“What observation have you made when you multiply by 10?”

Another demanded thinking from a different perspective;
"What happens to the digits when the decimal point moves to the left?"

The latter demonstrates how students' knowledge can be challenged by way of providing feedback in the form of further questioning without necessarily posing difficult questions. Bowie also used questions such as "What else is missing?" to stimulate students to think of more, and from different perspectives. To me this was a sign of his perceptions of students: that he saw them as capable of thinking beyond their current thinking, as people who are capable of thinking for themselves instead of being there to be 'filled' with knowledge.

Conclusion

The case studies reported in this paper show how moving from controlling to communicating was achieved by empowering student-teachers during a preservice training programme. Previous cohorts did not progress to communicating because they did not have the advantage of the training methods I devised for this programme. The case studies also emphasise how individual student-teachers' learning differences play a significant part in their progress, and illustrate the value of training programmes having a means of incorporating further training for some student-teachers within Teaching Practice. In the study being reported, this was achieved by making supervision of student-teachers' first Teaching Practice formative, rather than to serve the purpose of grading currently practised at TCE.

THE ACCURACY OF MATHEMATICAL DIAGRAMS IN CURRICULUM MATERIALS

Gillian C. Kidman

The Centre for Mathematics and Science Education, QUT, Brisbane, Australia

In this paper, two diagrams are analysed, for accuracy, using a set of principles generated from a review of the research literature from the fields of mathematics education, cognitive science, computer-aided learning, computer graphic design and semiotics. The diagrams are typical of those found in an Integrated Learning Systems (ILSs) evaluated in Queensland schools and a student workbook. Using this set of principles, it is explained why many of the diagrams contained within these curriculum materials do not facilitate the construction of mathematical knowledge.

BACKGROUND

The general aim of this pilot study is to investigate the accuracy of mathematical and scientific diagrams available in curriculum materials. The focus of this paper is on the mathematical components of the study. The study is timely in four ways. First, it focuses on mathematics and science education that are disciplines crucial for economic developments for Australia. Secondly, it integrates science and mathematics. Making connections across the curriculum has been recognised as an important learning outcome (International Society for Technology in Education, 1999; National Council of Teachers of Mathematics [NCTM], 1989; National Research Council, 1996). Third, it concentrates on diagrams, important in our iconic world. Finally, it considers an area with scant literature concerning diagrams in curriculum materials. No other studies have investigated science and mathematics coupled with an accuracy analysis of diagrams contained in curriculum materials.

Mukherjee and Edmonds (1994) made the observation that diagrams in many Integrated Learning Systems (ILS’s) often seem to have been developed in a vacuum by individuals or teams that have no background in graphic design or visual literacy. Diagrams therefore have the potential to be erroneous and misleading.

Curriculum materials. Most curriculum materials suffer from a lack of coherence and focus (Schmidt, McKnight & Raizen, 1997). They do little to promote critical thinking about mathematics (Risner, Skeel & Nicholson, 1992). Many teachers’ lack of confidence and knowledge in relation to mathematics teaching is a world-wide problem with most attempts to remedy the problem achieving limited success (Peacock, 2001). As a consequence, teachers throughout the world rely on diagrams in both print and electronic based curriculum materials to provide the knowledge, and techniques of mathematical ideas to their students, and so such diagrams greatly influence the content of lessons. The only way to gain information relating to the suitability of instructional material is through an evaluation of the instructional materials available. However, teachers have neither the confidence nor competence to make these decisions in mathematics (Peacock, 2001).
Teachers may not realise that diagrammatic errors are present in some curriculum materials (Kidman, 2000). They reason that if several materials use a similar diagram to teach the same concept in exactly the same way, how could all those materials and diagrams be wrong? (Beaty, 1996). While publishers and other curriculum material developers are eager to claim that their materials have content accuracy, few schools and individual teachers are able to devote the time and resources necessary to judge the accuracy of scientific diagrammatic content themselves.

**Relations between diagram and text.** Diagrams are frequently used in mathematics curriculum materials at every academic level. Most texts have several diagrams on each page (Iding, 2000). Diagrams are included for two purposes: that of instruction and that of decorative purposes. High quality diagrams enhance instruction by encoding new information not referred to in the text, thus compensating for text deficiencies, and also by verifying each clause in the text, to develop an initial representation (Hegarty & Just, 1989). Hunter, Crismore and Pearson (1987, p. 122) identified five possible relations a diagram has in relation to the text it accompanies:

1. **Embellish** - provides completely new information not discussed in the text.
2. **Reinforce** - repeats all information presented in the text.
3. **Elaborate** - partly repeats and partly adds to information presented in text.
4. **Summarize** - provides a broad overview of text, much like an advance organizer.
5. **Compare** - provides information intended to be compared with a previous graphic.

This categorization, and the one that follows, are particularly appropriate for investigating the accuracy of mathematical diagrams because they focus on the relationship between textual and diagrammatic information and on the typical diagram types that are reasonably representative in mathematics curriculum.

**Role of diagrams.** A review of the research literature indicates that diagrams can play at least 4 different but interrelated roles in learning and instruction:

1. **Identification** - Diagrams that point out or identify parts of things (Cook & Mayer, 1988, Charles & Nason, 2001). For example, most students are familiar with geometry diagrams of the circle upon which the names of the diameter, radius and circumference are labelled (Iding, 2000; Kidman, 2000; Lowe, 1993).
2. **Comparison** - Diagrams that compare one kind of thing to another (Lemke, 1999; Hunter, Crismore & Pearson, 1987; Winn, 1989). For example, two different kinds of time-pieces, analogue and digital, might appear next to each other.
3. **Sequence** - Diagrams that point out stages in a chain of events (Cook & Mayer, 1988; Hunter, Crismore & Pearson, 1987). Typical examples would be diagrams of a sporting race showing the ordinal finish.
4. **Combination** - Possibly the most frequently occurring type of diagram, particularly in scientific texts, is one that combines two or more of the above...
functions (Cook & Mayer, 1988; Hunter, Crismore & Pearson, 1987; Iding, 2000; Lowe, 1993; Winn, 1989). For example, a diagram of a scaled map can provide more than one view, for example, an additional cross-section or enlarged view (i.e., comparison). Aspects of the map can be labelled (i.e., identification) and the pathway to follow can be indicated via the use of arrows (i.e., sequence).

**Accuracy of diagrams.** Diagrams contained in curriculum material, with the purpose of instruction rather than decoration, need to be evaluated as to how well they address instructional criteria. Instructional criteria can be arranged in seven broad principles (see below), and are consistent with effective mathematics learning and teaching found in the National Council of Teachers of Mathematics current standards (NCTM, 2000).

2. Diagrams should introduce terms and procedures; represent ideas accurately, and demonstrate/model procedures (Gentner, 1982; Kidman & Nason, 2000).
3. Diagrams should provide conceptual links within the representation, and allow the learner to abstract and understand the important notion underlying the diagram (Fish & Scrivener, 1990; Kidman & Nason, 2000).
4. Diagrams should reduce the working memory demands of the problem solving process (Fish & Scrivener, 1990; Kidman & Nason, 2000).
5. Diagrams should allow for exploration of ideas and understandings not possible from natural language (Lemke, 1999; Kidman, 2001; Kidman & Nason, 2000).
6. Diagrams should contain elements of natural language facilitating links between scientific and mathematical expressions and natural language (Lemke, 1999).
7. Diagrams should allow the learner to interpret underlying scientific and mathematical notions, and allow the learner to participate in an expressive learning activity (Gordin, Edelson, & Pea, 1996; Kidman & Nason, 2000).

**DATA ANALYSIS**
Data comprised the diagrams. The relations between the diagram and the text, and role of the diagram were considered. The analysis of accuracy of a diagram was informed by a set of seven principles (above) for analysing diagrams within mathematical curriculum materials (Kidman & Nason, 2000).

**RESULTS AND DISCUSSION**
Two examples are presented for discussion. One example is drawn from an Integrated Learning System (ILS) (Computer Curriculum Corporation, 1996) (a collection of electronic worksheets, divided into a range of strands (e.g., fractions)). 550 instructional diagrams were sampled from the ILS and evaluated. 220 of these diagrams were found to be deficient in at least five of the seven principles. A second example is drawn from a Year 5 student workbook (Boswell, 1998). Of the 501 instructional diagrams found in the workbook, 38 were found to be deficient in at
least five of the seven principles. Both the ILS and workbook series are found in many classrooms throughout Queensland, Australia.

In order to illustrate the nature of the diagrams found in the ILS and workbook, a detailed analysis of the two diagrams is now provided. The deficiencies identified in the ILS example are typical of those found throughout the 220 diagrams (e.g., font problems, unclear purposes and layouts, forced formatting and poor links between natural language and visual representations) as is the case for the workbook.

The diagram presented in Figure 1 comes from the repertoire of exercises contained in the ‘Fraction’ strand of the ILS. The relation between the diagram and text in Figure 1 is that of elaboration. The diagram partially repeats text information in the form of the triangle having a base (b) and height (h), and partly adds the information that height is perpendicular height. The role of Diagram 1 is one of identification as it identifies where the base and height are to be found on the triangle. The intended skill of this exercise is the multiplication of fractions (see upper left hand corner of Fig. 1: fr840 = Fractions, Year 8, 40 percent of the way through Year 8).

The diagram presented in Figure 2 comes from the exercises contained in the ‘Number’ strand of the workbook. The relation between the diagram and text in Figure 2 is that of embellishment. The diagram provides completely new information not covered in the text. The role of Diagram 2 is one of identification as it identifies the spatial relationships between five cities. The intended skill of the exercise associated with Figure 2 is subtraction “from four-digit numbers, with regrouping” (Boswell, 1998, p. 93). The text accompanying Figure 2 is “Here is a chart showing some airports and their distances from one another. Use this information to write three subtraction problems” (Boswell, 1998, p. 93). To the right of the diagram is a highly structured area for the student to write the three problems.

**Figure 1.** ILS Example

**Figure 2.** Workbook Example
The analysis of the diagrams in Figures 1 and 2 are presented in Table 1. Both of the diagrams analysed in this paper are clear and relatively uncluttered. However, neither of the two diagrams facilitates meaning-making.

Table 1 Analysis of Figures 1 & 2

<table>
<thead>
<tr>

</thead>
<tbody>
<tr>
<td>1</td>
<td>Low</td>
<td>The font and the layout of both diagrams are clear to read. A major problem found in both diagrams making understanding difficult is that neither diagram is drawn to scale. Understanding of the diagram in Figure 1 is hindered by the text leading the reader to believe the exercise is on area measurement and not on fraction concepts. Understanding of the diagram in Figure 2 is hindered as the reader may be led to believe that a distance of 6912 km is the same as 752 km on the chart.</td>
</tr>
<tr>
<td>2</td>
<td>Low</td>
<td>The diagram in Figure 1 does not relate the area of the triangle to the notion of the unit (i.e., a 1x1 square), so it does not enable students to focus on deep structural knowledge. It does not encourage the use of intuitive knowledge about fractions. The diagram in Figure 2 does not relate the notion of the different distances between cities and geographical locations, so it does not enable students to focus on deep structural knowledge. It also does not encourage the use of intuitive knowledge about subtraction with regrouping. Neither diagram encourages spatial awareness.</td>
</tr>
<tr>
<td>3</td>
<td>Low</td>
<td>An important notion in Figure 1 that needs to be abstracted from the diagram is that 1/2 x 2/5 x 1/5 is equivalent to 1/25 because if two fifths is halved, then a fifth is generated; and if a fifth of a fifth is then found, then a twenty fifth is generated. Because the diagram does not relate the area of the triangle to this, the “Correct” answer is not conceptually linked back to diagram. An important notion in Figure 2 that needs to be abstracted from the diagram is that in subtraction algorithms, the bottom number needs to be subtracted from the top number, even when at first sight it cannot be done. Because the diagram does not relate this notion, the “Correct” answers written by the child are not conceptually linked back to diagram. An adequate environment for learners to abstract and understand this notion is not provided in either diagram.</td>
</tr>
<tr>
<td>4</td>
<td>Low (Fig 1)</td>
<td>Students are unable to add notes to the diagram in Figure 1. Unless they are instructed to make notes on paper much information has to be memorised potentially overloading the working memory capacity. Students are able to add notes to the diagram in Figure 2, and a highly structured area is supplied for the student’s working. Very little information has to be memorised, freeing up the working memory capacity.</td>

</thead>
<tbody>
<tr>
<td></td>
<td>The diagrams allow for some interpretation but because of the lack of compliance with the majority of the above Principles, only low levels of interpretation can occur. The diagrams cannot be used for expressive learning activity.</td>
<td></td>
</tr>
</tbody>
</table>

For example, neither diagram:

1. highlights the relationships between the problem information or prior knowledge and skills;
2. enables the reader to focus beyond the surface level aspects of the task, and
3. provide students with the means to construct a deeper appreciation of the concepts beyond that which can be achieved through the semantics of natural language.

Because of these limitations, it is highly unlikely that either of the visual representations would do much to facilitate the construction of deep-level, principled knowledge about fractions or numeration.

However, the effects of these limitations may be more serious than this. The covert geometry curriculum presented in both these diagrams is not given the attention it deserves. The barriers to the development of spatial intuition created by these two diagrams are of concern due to the lack of attention to scale. The development of spatial awareness is informal. "It is the use of space, shape and form at an intuitive, personal and unstructured level such as interpreting a map" (Booker, Bond, Briggs, & Davey, 1997, p. 270). Geometry allows many ideas to be pictured and thus, facilitates problem-solving, therefore placing geometry in a unique position in relation to other branches of mathematics.

Both diagrams unnecessarily lack an attention to scale. In Figure 1, the base of the triangle ought to be twice that of the height. This is not even approximated on the diagram. Figure 2 is a map supposedly showing airports. It actually shows only two airports (Brisbane and Wellington) and three cities (the names of these three cities airports differ to their city names). The map indicates that Wellington is somewhere between Brisbane and Sydney. This is not correct, it is geographically south east of Sydney, in a different country to Sydney! The lack of attention to these details, and many others in Figure 2 are inexcusable. Present curriculum documents like those produced by the National Council of Teachers of Mathematics (2000) call for integrated links between mathematical topics and concepts. This is clearly not being done in the diagrams assessed in this and other studies (Kidman, 2000; Kidman & Nason, 2000).
CONCLUSION
The findings from this study and the previous studies by Kidman and Nason indicate that instructional diagrams are not facilitating mean-making. The studies have shown that a significant proportion of diagrams are not facilitating the construction of mathematical knowledge. This study has shown that while the diagrams may be attractive, and possibly attract and maintain a student’s attention it is highly unlikely that either of the diagrams would do much to facilitate the construction of deep-level, principled knowledge about fractions or numeration. The lack of attention to scale in both diagrams is a problem for the development of spatial awareness.

The National Council of Teachers of Mathematics (2000) has called for a coherent curriculum where mathematical ideas are linked and built on one another. It argued that this would facilitate understanding, deepen knowledge and expand application. It is evident that this coherence is not present in these diagrams.

REFERENCES

The literature is rich in studies on the conceptual difficulties with the notion of limit of a sequence of numbers and infinite sum of numbers. In this study we analyzed the students’ perceptions of the infinite sum of functions. Two different approaches were used: analytical and algebraic. In the first, the infinite sum is represented as a process and in the second, as an object. Mathematica software permits multiple representations of the same concept. The students used animation to focus on the "process itself" and not on the divergent process of adding terms to the sequence. Symbolic manipulations were utilized to create the illusion of an infinite number of calculations performed at once. The infinite sum as an object appeared clearer. However, not all the conceptual difficulties were resolved.

Students' conceptual difficulties in learning the notion of infinite sum are well documented. A number of double strands are observed when students try to understand the concept of infinite sum: the infinite sum as a process or as an object, the intuition of the infinite process as a potentially infinite process or as an actual infinite sum, and the reading of the equality \( S = a_0 + a_1 + \ldots + a_n + \ldots \) from left to right or from right to left, which is cognitively different.

Herein, we describe a study that examined the effect of introducing the concept of infinite sum of functions using two different approaches in which those double strands are present. The research was conducted in the context of an experimental course on Approximation theory that was given to eleventh grade high school students. The concept of infinite sum was introduced by developing a function in infinite series. In this way an infinite decimal is obtained by substituting a particular value of \( x \). Mathematica software was used. In particular, we utilized the software’s ability to support multiple representations of the same mathematical concept.

Multiple representations were applied in two interpretations:

In the first, two different mathematical approaches were used, analytical and algebraic, the first representing the infinite sum as a process, a potentially infinite process, and the second as an object, an actual infinite sum. In the second interpretation, each of these two approaches to the infinite sum was investigated by multiple attributes of the Computer Algebra System: symbolic computation, graphics, and animation.

The use of animation in teaching the limit concept is discussed in Kidron et al. (2001). Animation gives the illusion of completing an ongoing process.
This article describes some efforts to partially overcome the difficulties that were pointed out by Núñez (1994). Núñez explained some difficulties concerning the concept of infinite sum by the fact that two types of iterations, of perhaps a different nature, are involved simultaneously: the process itself and the divergent process of adding terms to the sequence (an increasing number of steps).

We utilized Mathematica’s capabilities in a way that reduced the two-dimensional analysis, which stems from the two types of iterations, to a one-dimensional analysis. In the analytical approach, in which the infinite sum is represented as a potentially infinite process, the use of animation might help in focusing on the process itself and in differentiating it from the divergent process of adding terms to the sequence. In the algebraic approach, in which the actual infinite sum is represented as an object, the software creates the illusion of symbolic manipulation taking place on the actual infinity of terms. The illusion that the infinite calculations are performed at once might facilitate the transition from symbolic manipulation to a symbolic object.

Our study examined to what extent the interrelationship between the two approaches and the different attributes of the Computer Algebra System helped the students to perceive the infinite sum as a limit of the infinite process. We also investigated the readiness of the students to grasp the formal definition of infinite sum.

CONCEPTUAL DIFFICULTIES WITH INFINITE SUMS

The “finitist” character of our intellectual schemes might cause difficulties when we deal with the notion of Infinite Sum. Fischbein et al. (1979) observed that the natural concept of Infinity is in fact the concept of “Potential Infinity”, which is simply a process that goes on without end, like counting without stopping. Lakoff & Núñez (2000) suggested that metaphorical thought might be necessary to conceptualize another infinity concept: the “Actual Infinity”.

The intuition of infinity might become an obstacle to learning the formal definition of the concepts related to infinity (Cornu, 1991). Vinner & Hershkowitz (1980) introduced the terms “concept image” and “concept definition”. The term “concept image” describes the total cognitive structure that is associated with the concept which includes all the mental pictures and associated properties and processes. The term “concept definition” is defined as a form of words used to specify that concept (Tall & Vinner, 1981). The concept definition of Infinite Sum is not necessarily linked to the concept image. There may be a gap between the mathematical definition of the concept and the way one perceives it.

Symbolic notation is another source of conceptual difficulty. The symbol \( \lim_{n \to \infty} \sum_{k=1}^{n} a_k \) represents both the process of \( n \) tending to infinity and the concept of limit. It is a procept (Gray & Tall, 1994). Another source of cognitive complexity is embedded in the symbolic notation “=” in \( S = a_0 + a_1 + \ldots + a_n + \ldots \). An understanding of what “=” means requires a cognitive analysis of the mathematical ideas involved (Tall, 2000).
STUDENTS’ PERCEPTIONS OF INFINITE DECIMALS IN PREVIOUS STUDIES

The following perceptions of infinite decimals were observed:

* Infinite sums exist only in theory (Kidron, 1984). The infinite decimal is perceived as one of its finite approximations (Kidron & Vinner, 1983). The infinite decimal is perceived as a process not as a product (Kidron & Vinner, 1983; Monaghan, 1986).

The students also expressed a generic concept of measuring infinity: $1 + 1/2 + 1/4 + 1/8 + ...$ is stated to be $s = 2 - 1/\infty$ because “there is no end to the sum of segments” (Fischbein et al., 1979). In Kidron (1984), the students in comparing 0.9 and 1, claimed that 0.01 is a legitimate number that is equal to 1 - 0.9. The existence of a conflict in comparing 0.9 and 1 and the path dependence of the decisions are mentioned by Tall (1976).

The following perceptions of infinite decimals were observed in some computer environments: Monaghan et al. (1994) pointed out difficulties that result from attempts to use the computer for learning the concept of limits. Nevertheless, the limit sum as an object appeared clearer. Sacristan (2001) presented some results demonstrating that in exploring different types of representations, including visual ones, the students gradually understand how a process can continue infinitely and not grow to be infinite. Tall (2000) indicated that reading the equality $a_0 + a_1 + ... + a_n + ... = S$ from left to right or from right to left can relate to ideas that are cognitively different. For example, most of the students regarded $0.1 + 0.01 + 0.001 + ... = 1/9$ to be false but $1/9 = 0.1 + 0.01 + 0.001 + ...$ to be true. The students were interviewed and as a possible explanation, Tall suggested that when reading from left to right, the first statement seems to represent a potentially infinite process that can never be completed, whereas the second shows how 1/9 can be divided out to get as many terms as are required. Tall also noted that the students were reluctant to accept a formal definition of infinite sum that does not agree with their personal experience.

THE TEACHING EXPERIMENT

High school students learning at the highest level (grade 11, N = 63) participated in the research. The laboratory consisted of 20 PCs, each equipped with Mathematica software. The author taught the students six hours a week; two of the six hours in the PC lab were devoted to topics in Approximation theory.

The concept of infinite sum was introduced from two different points of view. The algebraic approach represents the polynomials with “an infinite number of terms” as an object. The analytical approach describes the process of the different polynomials approaching a given function. We pointed out the importance of interacting with each of the different representations. Moreover, we emphasized the importance of establishing links between the different types of representations. The algebraic approach is Euler’s intuitive idea of expressing non polynomial functions as “infinite polynomials”; it relates to the concept of Infinity as Actual
Euler's approach is from left to right: you start from a given function \( f(x) = \frac{P(x)}{Q(x)} \) and you seek a "polynomial with an infinite number of terms" such that \( f(x) = \frac{P(x)}{Q(x)} = a_0 + a_1x + a_2x^2 + \ldots \). The students used Mathematica to follow the original text of Euler (translated into English in Euler, 1988). Following Euler's instructions, the students carried out the "continued division procedure": they assumed that there is an infinite series such that \( \frac{P(x)}{Q(x)} = a_0 + a_1x + a_2x^2 + \ldots \) and then calculated the coefficients \( a_0, a_1, a_2, \ldots \) that satisfy the equality by multiplying both sides of the equality by \( Q(x) \) and comparing the coefficients as Euler did.

Using the analytical approach the students plotted two functions, \( f(x) \) and \( g(x) \), whose formulas were different but whose plots were similar, near \( x = 0 \). The notion of the order of contact was introduced. The two curves, \( y = f(x) \) and \( y = g(x) \), have an order of contact \( n \) at \( x = 0 \) if: \( f(0) = g(0) \), \( f'(0) = g'(0) \), \( f''(0) = g''(0) \), \( \ldots \), \( f^{(n)}(0) = g^{(n)}(0) \). As an application, the students were asked to find the polynomials of degree 2, 3, 4, \ldots that have the highest possible order of contact with a given function at \( x = 0 \). Mathematica helped the students solve the relevant system of equations. Using the analytical approach, the students calculated polynomials with a finite number of terms, the Taylor polynomials, which approach a given function. Acting with this representation, they observed that when the degree \( n \) of the approximating polynomial \( P_n(x) = a_0 + a_1x + a_2x^2 + \ldots + a_nx^n \) increases, the approximation is better. The students made graphical representations of their results. By means of animation (Kidron, 2000, example 1) they were asked to "encapsulate" the process into an object (Dubinsky, 1991). The animation permitted them to see the dynamic process in one picture. Animating the approximating polynomials \( a_0 + a_1x, \ a_0 + a_1x + a_2x^2, \ldots, a_0 + a_1x + a_2x^2 + \ldots + a_nx^n \) approaching the given function \( f(x) \), may help in identifying the equality \( a_0 + a_1x + a_2x^2 + \ldots + a_nx^n + \ldots = f(x) \). In both representations the students performed algebraic manipulations of the two sides of the equality in order to find the unknowns \( a_0, a_1, a_2, \ldots \) which are the coefficients of the Taylor series.

**DATA ANALYSIS AND RESEARCH METHODOLOGY**

Each year, one class (grade 11) participated in the experimental course throughout the academic year. The course was given three times. All together, 3 grade 11 classes participated in the experiment. We noted the students' questions and remarks during the sessions, and collected the Mathematica files of their examples. We gave the students a questionnaire that was designed to elicit their conceptions of infinite sum. The same questionnaire was given each year. In the second and third years, a full session was dedicated to the formal definition of the infinite sum of functions as the limit of an infinite sequence of partial sums. We present here a class discussion and some findings from the questionnaire in different years.

**The class discussion**  When we replace a given function \( f(x) \) by its Taylor polynomial \( P_n(x) = a_0 + a_1x + a_2x^2 + \ldots + a_nx^n \), we just leave off the "infinite tail". Some students had problems with this "infinite tail".
Dina: How could we speak about a graph that describes the error $|f(x) - P_n(x)|$? This difference is the “infinite tail”: $a_{n+1}x^{n+1} + a_{n+2}x^{n+2} + ...$

How could this difference be well defined?

A similar reaction is shown in the following class discussion. The teacher proved Taylor’s theorem at $x = 0$. In one step of the proof, in order to calculate the derivative of a certain term, she mentioned that the error term $d = f(x_0) - (a_0 + a_1x_0 + a_2x_0^2 + ... + a_nx_0^n)$ is a constant.

Julia: Why is $d$ a constant?

Teacher: $d$ is the difference between two constants when we approximate $f(x)$ with a polynomial with a given exponent $n$ at a given point.

Julia: But $d$ is the “infinite tail”... how could it be a constant?

Tomer: We compute the error for a given $n$.

Julia: But $d = a_{n+1}x_0^{n+1} + a_{n+2}x_0^{n+2} + ...$ so how could it be that $d$ is a constant?

Tomer: $d = a_{n+1}x_0^{n+1} + a_{n+2}x_0^{n+2} + ...$ is an infinite sum that is equal to a given number.

Ron: Yes! For example, you have $1/2 + 1/4 + 1/8 + 1/16 + 1/32 + ...$ which equals 1.

Julia: Will it not be bigger than 1 when we continue to add terms?

Dan: In the example $1/2 + 1/4 + 1/8 + 1/16 + 1/32 + ...$ the infinite sum is a defined number but there are other examples in which the infinite sum is not a given number. It tends to $\infty$!

Adi: So, how could we know if $d = a_{n+1}x_0^{n+1} + a_{n+2}x_0^{n+2} + ...$ is an infinite sum which is equal to a given number?

Yifat: In the last lab we have seen animations showing that when $n \to \infty$, the expression $f(x) - (a_0 + a_1x + a_2x^2 + ... + a_nx^n)$ tends to 0. Therefore the expression $d = a_{n+1}x_0^{n+1} + a_{n+2}x_0^{n+2} + ...$ is a given number and not an expression which tends to $\infty$.

The questionnaire  We report on responses to three of the questions.

**Question 1** deals with the meaning of the statement:

$$1/(1-x) = 1 + x + x^2 + x^3 + ... + x^n + ...$$ for $-1 < x < 1$.

We observed three categories of perceptions of the infinite sum of functions:

I The infinite number of terms is perceived as a very large but finite number of terms: **the infinite sum is perceived as a finite approximation**.

II The infinite sum is perceived as a process and not as a product; it is perceived as an ongoing process that passes through an infinite number of terms: $1, 1 + x, 1 + x + x^2, 1 + x + x^2 + x^3, ...$.

III The infinite sum is perceived as a limit, as the product of the infinite process.

Table 1: Distribution of the categories of perceptions in question 1

Question 2  Complete:  \[ 1+1/2+1/4+1/8+\ldots+1/2^k+\ldots = \]

Our aim was to check the students’ perception of the infinite sum of numbers as a limit.

\[
\begin{array}{c|c|c|c}
 & \text{First year} & \text{Second year} & \text{Third year} \\
\hline
1+1/2+1/4+1/8+\ldots+1/2^k+\ldots=2 & 50\% & 57\% & 61\% \\
\end{array}
\]

Table 2: Distribution of answers to question 2

In the first year, no one linked question 2 to the expansion of \(1/(1-x)\) in the power series in question 1. In the second year, 33\% of the 57\% linked question 2 to the expansion \(1/(1-x) = 1+x+x^2+x^3+\ldots\) (in the third year, 36\% of the 61\%). These students indicated that they could look at the process from the opposite side, from right to left, \(1+x+x^2+x^3+\ldots=1/(1-x)\) and then substitute \(x=\frac{1}{2}\). This ability did not eliminate the students’ difficulties in perceiving the infinite process as an object:

Daniel:  As a consequence of the expression \(1/(1-x) = 1+x+x^2+x^3+\ldots\), \(1+1/2+1/4+1/8+\ldots+1/2^k+\ldots\) is supposed to be equal to 2 if \(K = \infty\), but since there is no such thing ‘infinite’ the expansion tends to 2.

Question 3  Find:  \(\lim_{n \to \infty} (9/10 + 9/10^2 + \ldots + 9/10^n)\).  Is 0.\(\hat{9}\) equal to 1 or less than 1?  Justify your answer.

\[
\begin{array}{c|c|c|c}
 & \text{First year} & \text{Second year} & \text{Third year} \\
\hline
\lim_{n \to \infty} (9/10 + 9/10^2 + \ldots + 9/10^n) = 1 & 14\% & 27\% & 32\% \\
\lim_{n \to \infty} (9/10 + 9/10^2 + \ldots + 9/10^n) = 1 & 57\% & 41\% & 21\% \\
\lim_{n \to \infty} (9/10 + 9/10^2 + \ldots + 9/10^n) \to 1 & 29\% & 32\% & 47\% \\
\end{array}
\]

Table 3: Distribution of answers to question 3

Some perceptions already seen in previous studies reappear:

Orit:  The limit tends to 1, but will not reach it since infinite exists only in theory

Aviv:  0.999\ldots is less than 1 because it always lacks 0.000\ldots01 (an infinite number of 0) in order to be 1.

The legitimate 0.01 re-emerges!
DISCUSSION AND CONCLUSIONS

The class discussion indicates that a conflict exists. The teacher presented the error term as the difference of two constants \( d = f(x_0) - (a_0 + a_1x_0 + a_2x_0^2 + \ldots + a_nx_0^n) \). Julia looked at the representation of \( d \) as an infinite sum \( d = a_{n+1}x_0^{n+1} + \ldots \). She realized that the difference between two constants is a constant and yet she was not ready to accept the infinite tail as a constant. Julia looked at the infinite sum as an unending process. In the class discussion, the dynamic images produced by animation were present in the students’ minds even when the computer was turned off. The animation enabled them to concentrate on the process itself (the error term tends to zero) and to differentiate it from the divergent process of adding terms to the sequence. It helped the students understand that an infinite sum is not necessarily an expression that tends to \( \infty \), and that it could be equal to a given number.

One of the purposes of the study was to investigate the students’ ability to perceive the infinite sum as a limit, as an object. In our research we encountered some perceptions of the infinite sum that were observed in previous studies. However, there was also an indication that some students were beginning to see the infinite sum as an object (43% of all the students expressed their perception of the infinite sum of functions as a limit; 56% of all the students wrote \( 1+1/2+1/4+1/8+\ldots+1/2^k+\ldots = 2 \)). A possible explanation for this is that the students, looking at the same concept from different approaches, developed a more balanced view of the infinite sum as process and concept. We quote also Euler’s reason for applying an algebraic approach to subjects that are usually discussed in analysis: in order that the transition from finite analysis to analysis of the infinite might be rendered easier. We also wanted to investigate the students’ ability to grasp the formal definition of an infinite sum. The percentages of answers where students perceived the notion of the infinite sum as a limit, as an object, were slightly higher in the second and third years (these students were given the formal definition of an infinite sum). It seemed that the influence of providing the formal definition was minor. However, this impression changed examining the students’ explanations to their answer \( 1+1/2+1/4+\ldots+1/2^k+\ldots = 2 \). Some of the students who received the formal definition were able to link between this question and the first question, where \( 1/(1-x) = 1+x+x^2+x^3+\ldots+x^k+\ldots \) for \(-1 < x < 1\). In order to do so, they had to look at the equality from the other side (from right to left) and to replace \( 1/2 \). Yet, Daniel’s answer to question 2 illustrates the fact that the flexibility to read the equality from both sides does not eliminate the conceptual difficulties in the transition from finite analysis to analysis of the Infinite.

FACILITATING STUDENT LEARNING THROUGH MATH JOURNALS

Hari P. Koirala
Eastern Connecticut State University

Abstract. In the last two decades, mathematics teachers have shown a great deal of interest in how students learn mathematics through journal writing. I have also used journals in my mathematics classes for the last five years. Based on the analysis of more than 1800 journal entries written by approximately 200 students in the last five years, I conclude that journal writing have potential to aid in student mathematical learning even though teachers need a large amount of time to examine student journals and provide feedback. Math journals not only help instructors in understanding students' feelings, likes, and dislikes about classes but also help students to demonstrate their mathematical thinking processes and understanding.

Introduction and Theoretical Framework

The National Council of Teachers of Mathematics (NCTM, 1989, 2000) and the American Mathematical Association of Two Year Colleges (AMATYC, 1995) emphasize that students should be able to communicate mathematically, both in written and oral forms, using mathematical vocabulary and notations. NCTM (2000) argues that "reflection and communication are intertwined processes in mathematics learning" (p. 61) and writing in mathematics provides opportunity for students to express their thinking. Teachers also benefit from student writing by getting access to student thinking, which can be used to improve instruction. Following these recommendations, many teachers have used journals as a regular feature of their school and college mathematics classrooms and report that journal writing helps students reflect and learn math concepts (Burns & Silbey, 2001; Chapman, 1996; Dougherty, 1996; McIntosh & Draper, 2001; Pugalee, DiBiase, & Wood, 1999).

The use of journal writing in a mathematics classroom is not only being supported from the experience of classroom teachers but also from research. Qualitative researchers working from a constructivist framework often use journals to inquire and understand participants' mode of thinking (Kroll & LaBoskey, 1996; Mewborn, 1999; Miller, 1992; Pugalee, 2001). Because the construction of knowledge is a continuous process, it must be regularly communicated and reflected. Mewborn uses journals as tools for reflection. Miller points out to the benefits that teachers get from reading students' writing. Pugalee claims that writing is a necessary part of metacognitive thinking, which helps in constructing mathematical knowledge. The present study focused on the role of journals in mathematics content course designed for prospective elementary school teachers. The main purpose of the study was to
explore the ways in which math journals influence the teaching of mathematics to prospective teachers. Consistent with previous studies, this study claims that math journals help preservice teachers in their learning of mathematics as they express their thinking and get feedback from the instructor. Furthermore the instructor of the course consistently valued student math journals as they provided helpful hints on how to modify and improve classroom instruction.

Research Methods

The setting for this study was the course "Number Systems," which is a required mathematics content course for prospective elementary school teachers at a North Eastern university in the United States. Most of the students in this course intend to become future elementary school teachers. The main goal of the course has been to encourage students to embrace the challenge of learning mathematics through inquiry and exploration. In the past five years of my teaching, the course has taken a problem-solving approach in which students were required to monitor their thinking process while solving mathematical problems. Students monitor their thinking through math journals, which is a necessary component of this course. So far more than 200 students have participated in journal writing.

In the first two years of teaching, the course required all students (approximately 100 students) to write weekly journals, 1 to 3 pages long. Each student wrote a total of twelve entries for the course during the semester, totaling approximately 1200 journal entries. Because of the large volume of journals in those two years, the frequency of journal writing was reduced to bi-weekly in the last three years, which generated approximately 600 journal entries. All 1800 entries were carefully analyzed in this study.

The students wrote journals in a variety of forms. In some entries they simply reflected on their excitement or frustration regarding their learning of a particular mathematics concept that was discussed in the classroom. For example, they might describe a new mathematics concept they learned that week or reflect on the confusion caused by a new concept. For other entries, the instructor provided them with specific questions or scenarios for response. For example, in one of the entries students were asked to respond to the following scenario developed by this researcher:

Senator X, an expert mathematician, proposes a new number system to be adopted in the United States. She said that the new system will have only two numerals 0 and 1. According to her these two numerals can be used to represent any numbers of the present Hindu-Arabic numeration system. "If we can do all the work with two numerals, why bother using the Hindu-Arabic system with ten numerals", argued senator X. Other senators, however, are totally confused with the senator X's proposal. Senator X further argued that adults are confused with the new system
because they have used the Hindu-Arabic system for a lifetime. "But look at the future of the millions of children who will learn only two numerals to represent all numbers," she contended.

The Senate is now interested in getting responses from public. Write a letter to the Senate describing your position on whether or not the new system should be adopted in the US. Remember that most of the senators have difficulty understanding this system and you should clearly describe what the system is and the advantages and disadvantages of the new system over the Hindu-Arabic system. Please provide examples to demonstrate your understanding of the new system in your letter.

Additionally some selected students were interviewed about their experience in journal writing. All the students interviewed valued the role of journals in their mathematical learning. Because of the space limitation, only the analysis of journals is provided in this paper.

Data Analysis

The researcher/instructor read all the responses from student journals and responded to them during teaching. In addition to reading and providing feedback to students, the researcher also coded, analyzed, and categorized each journal using qualitative data analysis methods, in particular, the constant comparative method (Guba & Lincoln, 1989) and the interactive model (Huberman & Miles, 1994). The researcher also made an overall reflection about student journals at the end of each semester.

Two kinds of questions were considered in the analysis. First, what were students' responses in a particular week's journal? For example, what were various responses provided by students to the entry related to Senator X's proposal of the binary system of numeration? Second, how did journals helped students for their growth of mathematical understanding? These questions led the analysis mainly in two categories: Journals that only described students' attitudes and feelings and the journals that demonstrated student mathematical thinking. Because the constant comparative method of data analysis was used students' responses were checked for consistency and patterns.

Results and Discussion

In response to open topics related to course materials, more than 80 percent of the students simply chose to express their beliefs about mathematics. Although they were asked to demonstrate their mathematical understanding in their journals no such understanding was noted. They made statements like "I liked the last week's class because it was fun" or "I did not understand what you were trying to do in the last class." Moreover, the journals were rather brief and did not demonstrate any in-depth reflection from students. I continuously encouraged them to express their thinking.
and problem-solving methods in their journals. Sometimes, I asked them to read specific materials and at other times I asked them to reflect on particular concepts that we discussed in class. These responses encouraged them to think at a deeper level. As the course progressed, the students developed sufficient confidence to express their concerns, difficulties, frustrations, and excitement in their journals. They also began to identify mathematics concepts in their journals. Some of the examples from students are provided below.

I wish to begin this journal by reflecting on my frustration that I have experienced during this first week of class. The two words “Problem Solving” frighten me, as I have never been successful at solving any math problems (word problems) ever.

I was frustrated this week when we started discussing the binary system of numeration. I liked the Dienes blocks and Unifix blocks [cubes] that we were using and I understood the Base-10 number system (probably because I’ve been using it for years!), but the binary system was confusing to me when we were using the Unifix blocks. I wasn’t sure what you meant by “trade” this one for that one.

This week in math we did more fun things. The first thing we did was the chart to find your age. ... When we first did this I didn’t understand how you were getting the answer. I thought that you were looking at every number in each of the columns but then I found out that you add all the numbers together from the top row to get the answer. ... I tried it on some of my friends and they enjoyed the game also.

While the information obtained from students' general entries were helpful to address their problems and concerns, it was difficult to explore their mathematical thinking. Students' mathematical thinking was more evident on specific journal entries, such as those in the senator X’s proposal even though there was still a significant proportion of students (about 25%) who provided very general response to this scenario. A student who was struggling to understand the materials in the course responded to the journal as follows:

Having only two numerals, 0 and 1 would lead to much confusion. As an example telephone numbers, bank accounts, social security numbers etc., would be impossible to distinguish for all citizens in the United States.

This response does not provide good evidence that the student understood the binary system of numeration. It is so general that anyone can state this without actually understanding the system. Some other students, however, wrote what they understood. For example, one student responded like this.

This is how the senator feels this new system should work. .000000001 would represent 1. After all the zero’s are represented by 1, the next 1 will be represented on the other side of the decimal point. This is what the system would like:
The student knew that the binary system of numeration has only two numerals 0 and 1, but did not know how these numerals can be combined to write numbers. The student was simply adding the digits to represent the base-10 numbers. But what was important in the journal was that the student clearly communicated what she understood about the system.

There were some students who clearly demonstrated their understanding. For example, one student responded to the proposal as follows:

Ladies and gentleman of the Senate, this new system of numbers is very disturbing to me. Let us say we want to call someone. Their phone number is currently 555-2233. To fit this new system we will have to change the number to 101 101 101-10 10 11. What kind of phone number is that? Are you really going to remember that kind of a number? It's hard enough to remember a 7-digit code not including the area code. It would be impossible to remember that number.... How old are you? Not 33 anymore. Now the person would be 100001 years old. I am sorry but there is no need to have an age that looks like that. Imagine trying to write that on job applications. If you live at 5 Main street, you now live at 101 Main street. Whoever lives at 101 Main street now lives at 1100101 Main street. Does anyone want to write that for an address? ... Ever buy a computer? The one I am using costs about 1899.00 dollars. In the new system it would be approximately $11101101011. How can we change all of our monetary units to match this system?

This student clearly understood how to convert the base-10 numbers to the base-2 and wrote the journal in a powerful way. The journal was particularly powerful because all the examples chosen are from real life contexts and there are no mathematical errors in the journal. There were other journals in which students demonstrated an excellent understanding of the binary system. For example, let us look at an excerpt from one student below.

Senator X proposes changing our current numeration system (Hindu-Arabic), which is base 10 to a Base 2 system, in which the only numerals used would be 0 and 1. Let me first identify some properties of this Binary System.
1. Remember that all values can be represented, but numbers other than 0 and 1 do not exist as symbols.

2. Hence, the first 10 numbers in the Binary System that Senator X proposes would be represented as: 0, 1, 10, 11, 100, 101, 110, 111, 1000, 1101.

3. For your understanding let's use our (Base 10) number 27 as an example. Instead of a two digit number to represent the value of 27, the binary representation would be 11011! Imagine the length of the number used to represent larger values!

This student demonstrated that she understood not only how to convert the base-10 numbers to the base-2 but also how to perform operations such as addition and subtraction in the new system. The journals that were more specific like the above ones allowed the instructor to explore students' understanding of mathematical concepts required for the course. Moreover, students themselves found that journals were powerful tools for them to express their concerns. As one student commented, "I like the journals because they give me time to think and reflect about what I learned and ask questions as they come up, and not have to wait until class-time." Another student noted:

I've never really liked math before, but I did in this class. I feel like I had a chance to go back to basics, and find out why everything works the way it does. All through my schooling in mathematics, teachers have said, do this, do this, do this, and never really given a reason, how we know why things really work. Now we know why things really work. I really loved all of the specific journals we did. They really made us think.

The case was similar when students had to reflect on why minus times minus is plus. Many students really had a hard time providing a logical explanation. They knew the rules but they did not know how the rules worked. Following are some typical responses:

I must be honest about this journal entry. I've never encountered this question. My teachers always told me the facts, such as positive plus positive equals positive or negative times negative equals positive, but never why. I was told to memorize the equations but never understood why. "That's just the way it is;" that's what I was told.

For this week's journal our assignment is to explain why a negative multiplied by a negative equals a positive number. I had a very hard time finding a way to explain why two negatives multiplied together equal a positive because I never questioned why this was true.

It is very strange how we are taught things in school and we just think that this is how something is done without even asking why. I'm sure this occurs in many other
subjects besides math and I think maybe we should ask more questions, and be more
critical and make people explain what they mean.

The above responses made it clear to me that many of our students who intend to be
elementary school teachers in future never had the opportunity to learn mathematics
in a meaningful way. They were taught to accept rules without asking why those
rules worked. The responses from students provided me with an opportunity to
discuss the importance of understanding mathematics conceptually.

**Conclusions and Implications**

The use of journals in this course helped the instructor improve his teaching of
mathematics in two ways. First math journals were effective in soliciting students'
mathematical thinking, both cognitive and affective. In this case, math journals were
serving as tools for thinking. Second, the instructor was able to understand students'
mathematical thinking and was able to respond to their concerns. As a result of this
interaction, students' mathematical understanding was improved.

Despite the roles journals played in students' mathematical growth of
understanding, it was clear that only journals entries such as senator X's proposal
solicited student's specific mathematical thinking. The non-specific entries provided
information about students' beliefs and attitudes, which were also helpful for the
course. Because of these positive atmosphere created by journals, the author of this
paper believes that journals are important tools for student growth of mathematical
understanding despite the fact that the use of journals demands substantial amount of
time on the part of the instructor.

The findings of this study are similar to those found by Miller (1992) and Pugalle
(2001) that journal writing is useful in mathematics class to improve instruction and
student learning. In spite of substantial amount of time I spent in examining student
journals, I find that they are powerful means of communication and reflection. It is
refreshing that many students who hesitate to speak in the class express themselves
well in their journals. This study implies that writing about mathematics improves
student mathematical reasoning. This is an important area that needs further
exploration by researchers who are interested in student thinking.

Another implication of this study is that student responses in journals depend
mostly on the tasks assigned. If the tasks are general such as "write what you think"
the students' responses are also bound to be general, in which it is hard to find
evidence of their mathematical thinking. These general responses are usually
affective, which are related to student feelings and attitudes. Although these affective
domains contribute to teaching, there needs to be some specific mathematics tasks
such as Senator X's proposal to generate specific mathematical thinking from students.
References

The paper proposes a theoretical framework to analyse the understanding of the roles of literal symbols in algebraic tasks basing it on the distinction between free and bound variables. This approach is applied to study the difficulties of advanced high school students with the notion of the parametric representation of a plane. It is shown that algebra courses tend to form a limited understanding of the notion of variable which creates an obstacle for a learner in advanced courses.

INTRODUCTION

The students' difficulties with the mathematical language has been the traditional concern in the introductory algebra courses. Some time ago the issue has also got an attention in the field of advanced mathematical thinking: for example in relation to the teaching of linear algebra. It was shown, for instance, that students do not interpret rightly the formulas of linear algebra and do not have for the latter appropriate set-theoretical meanings (Dorier, Robert, Robinet & Rogalski, 2000). Other researchers had also suggested that studying linear algebra requires from a student a good understanding of the mathematical syntax and use of variables (Sierpinska & Nnadozie, 2001).

There are enough signs, however, that many of the difficulties with understanding the mathematical language originate as early as at school and are not overcome by the students in their passage from school to college (Ursini & Trigueros, 1997). It was repeatedly shown, for example, that an average high school student doesn’t realise the difference between unknown, parameter and functional variable. Some studies had related this obstacle to the historical development of algebra and deficiencies of the dominating structural approach in teaching of elementary algebra (Sfard & Linchevski, 1994), whereas others, to inherently complex propositional nature of algebraic tasks, especially when they contain parameters (Bloedy-Vinner, 1994). At this moment there is a growing agreement that the ‘algebraic sense’ developed by a learner may be to a large extent equated with his or her mastery of the concept of variable. Ursini and Trigueros suggested that a learner must understand the three main uses of variable: as unknown, as a general number, and in functional relationships (Ursini & Trigueros, 1997). Bills showed in a recent study that there are many problem solving situations which require from a student not only to recognise different uses of literal symbols, but to shift attention from one to another meaning of the same symbol in order to succeed with a task (Bills, 2001). The latter, like other studies, used its own, though more extensive than others, list of the roles of literal symbols in the algebraic tasks. This leads to the following methodologically important questions: To what extent do the lists proposed by different studies
correspond to each other? What is their relation to the mathematical status of literal symbols as defined in mathematical logic? And can the research on algebraic thinking draw on it to describe the roles of literal symbols a more unified and simple way?

The author believes in a positive answer to the last question and suggests as a guiding principle the distinction between free and bound variables used in mathematical logic. This theoretical framework is then used to describe the difficulty of advanced high school students with such notion of linear algebra as the parametric representation of a plane. It is shown that their difficulty follows from the limited understanding of the notion of variable. The paper ends with the discussion of the historical and didactical aspects related to the teaching the notion of variable in introductory and advanced algebra courses.

THEORETICAL FRAMEWORK

Whereas there are numerous terms used by researchers for the roles of letters in algebraic expressions, in mathematical logic a literal symbol which doesn’t denote a mathematical constant is either free or bound variable. This useful distinction was introduced in mathematics by Peano and has become the standard approach in any formal analysis of the mathematical language (Taylor, 1999). According to this distinction, the free variable in an expression stands for any one unspecified element of a set, while the bound variable denotes collectively all the elements of a set. The bound variables are used in such mathematical expressions as sums, integrals, limits, equations of curves, etc. An assignment of a certain value to the bound variable is irrelevant procedure, as far as the corresponding mathematical entity is defined by all the possible values of that variable. When variable in an expression is treated as free, it may, on the opposite, be assigned any value, and the resulting expression is treated as a particular case of the initial generic form. The main experiences with free variables in algebra courses are related to their use as generalised numbers and to equations. Finding among the values of a free variable those which satisfy an equation, corresponds to solving the equation in relation to this variable, which is then called unknown. If the equation contains besides the unknown an additional free variable, then the latter is called the parameter for this equation. The parameters may also appear in the formula of a function in addition to the independent variable, which has the status of the bound variable. The status of variable in a certain expression may depend on the goal of a task and may be changed in the course of the task. For example, a parameters of an equation or function may be ‘binded’ when one is interested to consider instead of one equation or function corresponding to an arbitrary value of a parameter, the properties of the entire family of equations or functions corresponding to all the possible values of the parameters. Another important example is the introductory course of linear algebra: binding of variables in an arbitrary linear combination produces a subspace. Many additional examples may be found in the theory of groups and functional analysis. On the school level more often happens ‘unbinding’ of variables: for example, in evaluating functions for certain values of independent variable or in finding certain points on a curve.
METHOD

The reported here study is a part of a larger project evaluating the difficulties of the Israeli 12th grade students with their regular vector geometry course. The sample consisted of 10 classes (N=214) of most advanced students (top 10% of the student population which pass the mathematics matriculation exam on the highest, ‘5 units’, level) chosen from 5 academically high standing schools. The teachers, who volunteered to participate in the study, all had at least the second academic degree and included also the Heads of the mathematics departments of these schools. The purpose of the described below questionnaire was to test the students’ general understanding of the parametric representation of a plane which had been one of the core notions of the course. The teachers were acquainted with the questionnaire in advance and recommended to deliver it in their classes in the most appropriate moment after the notion of the parametric representation would be well mastered by the students. Some of the students were interviewed after they had completed the questionnaires, and it allowed to clarify their written answers and the meanings they hold about the parametric representation. Another way to get a better insight into the students understanding of this notion was to suggest the same questionnaire to the academics from the mathematics and theoretical physics departments and analyse the differences between their and the students’ approaches. Due to the space limitations, the results for only two of the items of the following questionnaire will be presented.

Let \( x = a + tu + sv \) be the parametric representation of a plane. Find out for each of the following two representations whether they may represent the plane identical to that of the given representation. Explain your answers!

1. \( x = a + tu + tv \)
2. \( x = a - tu + sv \)

RESULTS

Though the first two items were not expected to present any difficulty, they revealed a serious misunderstanding by the students of the role of the parameters in the parametric representation of a plane. Only 32% of the students in the sample had answered correctly that the first item didn’t represent the same plane, whereas the rest wrongly claimed that the item could be a representation of the plane identical to that of the given representation. These students treated the expression \( x = a + tu + sv \) as a symbolic name of a plane which is completely specified, if each of the lettered symbols were assigned a certain value. It included the parameters \( t \) and \( s \) which were understood by the students as two certain numbers. The students’ explanations could be divided into three described below categories.

Category ‘Formal’. The students in this category had considered the parametric representation as a formal expression. In order to find out whether two representations correspond to one and the same plane, the students equated them and
solved corresponding equations, treating the letters as unknowns. Thus the common conclusion in this category was that the item may represent the same plane as the given representation, if t equals to s:

'The planes do not coincide, since one of the direction vectors is not identical to that in other representation. The planes will coincide only if t=s'.

'Yes, t and s are given numbers. It may happen to be the case that these s and t will be equal'.

'No, it may represent only the planes for which t=s, but all other planes are not possible to represent by this equation'.

Category 'Geometric'. These students assumed that the parametric representation is a way to express the geometric fact that two intersecting lines, or correspondingly, two vectors applied to a certain point, determine one and only one passing through them plane. For these students the main elements of the parametric representation are vectors u, v and a, since geometrically they are enough to determine a plane. The values of the parameters t and s are not important, because a pair of vectors tu and sv still determine the same plane as vectors u and v. Therefore, the parameter was considered to be a free variable which may be substituted by any letter or number without changing the corresponding plane. The following are the examples of the explanations in this category:

'Yes. It doesn't matter whether s=t or s ≠ t, what matters is that the vectors are the same'.

'Yes, since s and t in the given representation are variables, so that even if we substitute s=t, like it is in this item, the representation will represent the original plane'.

'Yes, it may be, because s is a variable, so it is possible to write instead of s anything, including t'.

Interviews with the students had confirmed that for many of them any two given values of the parameters were considered to be enough to determine a plane. The following is an excerpt from an interview with one of the students Ron after he completed the questionnaire:

I: So you say, that it doesn't matter what the parameters are. Can you describe me the case, of say, t=s=2?.

Ron: OK, we have a direction vector which is in the same direction but twice as long as vector u and another one which is also twice longer than v. But still it is the representation of the same plane.

I: ...How?

Ron: Well, imagine two vectors u and v in space. I can put a plate on them in only one way, so that its position will be quite determined. Now you have vectors 2u and 2v. They still define that same plate: it doesn't matter infinite or not. Do you see?
To provide more evidence that the students saw nothing wrong in the substitution of a parameter by a specific number, an additional item \( x = a + 100u + sv \) was included in the questionnaire delivered in four classes of the sample (N=74). The success with the first item in this sub-sample was 32%: the same as in the whole sample. The success rate with the additional item turned out to be only slightly higher: 42%. Most of the students, who erroneously claimed that the first item could represent the plane identical to that of given representation, answered the same to the additional item: 35 students out of 41. In the category ‘Formal’ this proportion was the highest: 26 out of 28; that is, 93% of the students in this category gave the same answer to the both items.

Category ‘Analgebraic’. The term ‘analgebraic’ was first introduced by Bloedy-Vinner (Bloedy-Vinner, 1994) to describe the students’ behaviours which go against the basic algebraic conventions. The students in this category not only assumed that the parameters \( t \) and \( s \) denote two certain numbers, but that these numbers must be necessarily different, since they are denoted by different letters:

‘No \( t \) is not equal to \( s \).’

‘No, the direction vectors are not the same’. 

‘No, the lengths of the direction vectors have become equal’.

The distribution of the students’ answers to this item according to the described categories is presented in Table 1:

<table>
<thead>
<tr>
<th></th>
<th>‘Formal’</th>
<th>‘Geometric’</th>
<th>‘Analgebraic’</th>
<th>no explanation</th>
</tr>
</thead>
<tbody>

<td>55</td>
<td>40</td>
<td>18</td>
<td>28</td>
</tr>
</tbody>
</table>

Considering the item \( x = a - tu + sv \), most of the students answered, like they did for the previous item, that it represents the same plane as the given representation \( x = a + tu + sv \), which in this case was the right answer. The close analysis of the students’ explanations had shown, however, that many of them were based on the same erroneous assumption that parameters in the parametric representation of a plane are certain fixed numbers. For example, one of the very common answers was: ‘the same plane, because the direction vector \(-tu\) is just opposite to \(tu\)’. This utterance means that for a student \(-tu\) denotes only one, rather than a set of vectors corresponding to all real values of \( t \) and that the letter \( t \) is assumed to denote in different representations one and the same number. Another type of erroneous explanations which accompanied the correct answer to this item was: ‘yes, it is a linear combination of the same direction vectors’. This answer indicates that a student doesn’t understand the difference between a generic linear combination and the parametric representation of a plane which is the set of all linear combinations.
described by this generic form. 

Among those who didn’t answer correctly to this item, most had formally equated the item and the given parametric representation of a plane and, after subtracting the terms $sv$ in the resulting equation, concluded that ‘the item represents the same plane only if $t=0$’. Only few among these students had realised the contradictory nature of this conclusion: ‘Not the same plane. If $t=-t$, then $t=0$, rather than being any real number’. In fact, by equating the representations in order to get the conditions of their equivalence, the students were employing a sound mathematical procedure. However, the performance even of those who knew that the parameter should be any real number, was lacking the understanding that the parameters in different representations vary independently one from another and for that reason can’t be denoted in the resulting equation by the same letters.

DISCUSSION

The study has revealed the students’ serious misunderstanding of the role of the parameters in the parametric representation of a plane. That this misunderstanding is rooted in the students’ one-sided experience with variables, becomes evident if one compares the answers of the students and the experts to the same questionnaire. Most of the students saw the item $x = a + tu + tv$ as a result of the assignment of a particular value to one of the variables of the representation $x = a + tu + sv$. For all the academics, on the other hand, it was obvious that the number of the parameters in the two representations was different. Unlike the students, the academics knew that the parameter in the parametric representation of a plane is a variable which is not characterised by its particular values. The students’ unawareness that there are different types of variables and that the parametric representation requires the bound ones, made them readily accept that $x = a + 100u + sv$ is also the parametric representation of a plane.

The fact that the introductory algebra courses still do not include the issue of different types of variables, has several historical and didactical reasons. First, it should be noted that the distinction between free and bound variables is of relatively recent origin. Almost up to the beginning of the 20th century, the mathematics were quite satisfied with the Euler’s simple distinction between variable and constant quantities and meeting, for example, something of the type $ax+by+c=0$, one knew exactly which is which. It was not until Russell had challenged this tradition and proclaimed on the first pages of his ‘Principles of mathematics’ a new, ‘only variables’ age (Russell, 1903/1964):

‘...But unless we are dealing with one absolutely particular line, say the line from a particular point in London to a particular point in Cambridge, our $a$, $b$, $c$ are not definite numbers, but stand for any numbers, and are thus also variables’.

Russell had, of course, good reasons for this claim. He developed the notion of variable as a set-building device which allowed to deal with a family of equations, rather than with its arbitrary representative; to form functions, functions of functions -
all this by just prescribing for a free variable in a mathematical expression to become a bound one. He had also suggested special symbols to mark bound variables, but this and other similar suggestions had never been universally accepted, so the type of variable is still inferred only from the context. On the other hand, the mathematicians find even some advantage in this notational ambiguity, since it allows to deal with different meanings of the same expression by just imagining that corresponding variable had changed its type. Furthermore, this ability for mental ‘binding’ of variable has become a prerequisite for learning advanced mathematics in which this feature has become widely used.

One of the conspicuous features of the school mathematics curriculum is that though it is permeated with the distinction between bound and free variables and is concerned that the students master it, there is no any attempt to teach it explicitly. Probably the first occasion when the students have to deal with the notion of a bound variable is related to functions. However, as this study shows, this doesn’t necessarily led even the advanced students, who had a year-long introductory calculus course, to master this notion in a way that allowed to them to recognise and apply it in linear algebra. Avoiding the issue of variables also in this latter context, may only multiply the students’ misunderstanding, because the dual use of variables there is quite common. For example, in the expression $tu + sv$ the letters $t$ and $s$ are bound variables, if it is meant as the parametric representation of a plane, but are free variables, if it is intended as a general linear combination of vectors $u$ and $v$. The difference is not well expressed in the ordinary language, as in the both cases one would likely to say that the lettered symbol stands for any number. Indeed, in their explanations that the item $x = a + 100u + sv$ is the parametric representation of the same plane as $x = a + tu + sv$, some students wrote that the parameter may be ‘any’ number, meaning by it any some number; what a teacher or a textbook meant by using the word ‘any’ in relation to the parametric representation, was that the parameter should take on all the real numbers, that is to be the bound, rather than free variable.

The ‘silencing’ of this distinction is the worst possible choice in the case of the parametric representation of a plane, because the textbooks introduce it starting with an arbitrary point on a plane and then describe its possible positions on a plane as all the linear combinations of the basis vectors. This passage remains an impossible mental exercise for a learner who is neither prepared for set-theoretical arguments, nor is proficient in bound variables. This shows the dilemma of the current algebra courses: on the one hand, due to certain didactical tendencies of the last decades the textbooks try not to use the set-theoretical notations, in order not to embarrass the students; on the other hand, they by all means avoid any informal or kinematically coloured expressions, like ‘parameter ranging over all numbers’ or ‘a point moving along a plane’. It is worth to note that the university textbooks seem to have much less constraints in this sense and do not hesitate to explain to a reader that ‘the parameter $t$ runs through all numbers’ (Lang, 1966, p.13).
CONCLUSIONS

The study has described the difficulties experienced by advanced high school students with the notion of the parametric representation of a plane. It is shown that this difficulty followed from their lack of understanding of the difference between free and bound variables in mathematical expressions. This distinction, though basic in mathematics, has not received any attention in the current algebra courses. It is suggested to direct more research and didactical efforts to this issue which may significantly improve the situation.

Promoting students' meaningful learning in two different classroom environments

Marie Kubinová, Jarmila Novotná, Charles University, Prague

Abstract: The paper continues the research presented in (Kubinová, Mareš & Novotná, 2000) and (Kubinová & Novotná, 2001). It reports on an observational study focused on the analysis of concrete situations in two classes taught in different ways by different teachers in the past but taught by one teacher at present. The differences in students' behaviour, teacher's approaches and results achieved by students are diagnosed and illustrated by the topic Functions.

1. Theoretical framework and related research

The teaching experiment dealt with in this paper is a part of a longitudinal research focused on the transition from the traditional transmissive, instructive way of teaching to the constructive one.

In (Kubinová, Mareš & Novotná, 2000), four schemes subject matter – teacher – students were analysed and characterised: IR (instructive teaching method, direct teaching of ready information or learning from text), ID (instructive teaching method, attempt for students' independent transfer of acquired knowledge), CR (constructive teaching method, learning from text), SC (social constructive teaching method). The main consequences of the use of constructive teaching methods are: The subject matter becomes an intermediary which enables the development or modification of students' existing concepts and the creation of new ones; social relations among individual cognising subjects are accepted; the role of the social relationship between students and teacher are accentuated, and the social relations among students are taken into account.

In (Kubinová & Novotná, 2001), the differences in students' behaviour, teacher's approaches and results achieved by students were diagnosed by analysing concrete situations in two classes taught in different ways by different teachers in the past but taught by one teacher at present. It is shown that even if the teacher who wants to implement the change from instructive to constructive teaching, is sufficiently qualified, has long-term experiences with constructive teaching strategies and has no obvious external obstacles for implementing their plans, has to be open-minded and respect students and their prior experience.

The present paper focuses on the development of students' understanding of mathematical concepts when the constructive teaching method SC for 4 years had been applied. The findings are illustrated by the topic Functions which is commonly agreed to be one of the difficult topics of school mathematics.

Function concept

(DeMarois & Tall, 1999) undertakes the complexity of the function concept. The function concept is studied as an organising principle for algebra and beyond. The aspects studied include the function notation and the symbolic, numeric and graphic
representations. The pre-procedural, procedural, process, object, and perceptual levels are studied. It is documented that for many students, the complexity of the function concept is such that the making of direct links between all the different representations is a difficult long-term task.

In (Even, 1990), ideas giving basis for the difficulty that functions represent to students are summarised: the arbitrary nature of functions; the univalence requirement; the function as a unifying, complex concept at one side and their different behavior, representations, notations on the other; alternative ways of approaching functions - point-wise, interval-wise and objects-wise; the richness and accessibility for students of the basic repertoire of functions; the importance of both procedural and conceptual knowledge and the relationship between them.

In the Czech Republic, the function is usually the first concept that students meet at the Basic school and that contains a certain dynamics, movement. This fact markedly influences the process of constructing a notion. A significant progress was reached mainly in that the curriculum of all three valid educational programmes for the Basic school suppose that the stage of preparing the function begins in an implicit form already at the first years of schooling with a more significant use of a variety of inter-disciplinary links and with a systematic stabilisation and refreshing of the mutual connection function – (real) story, notion. The programme authors appreciate that in the didactic interpretation in the concrete schooling, the dynamic nature of the function enables very well among other the use of experimenting, solving problems intuitively, modelling, but also a timely preparation of further concepts.

**Social interactions**

Social situations exist in the school regardless of the significance we give them (Kubinová, 1999). If an opening of the space for effective teaching is to occur, it is necessary to create more natural conditions for teaching, i.e. a situation which enables this to happen. The teachers should

- admit that they are not the only source of information for students, that discussions with other people, TV programmes and Internet access significantly influence students’ knowledge and way of learning,
- understand that each of their students creates their own concepts and these concepts are multileveled with respect to the student’s own concepts as well as to their peer group, and that many of these concepts are not complete, sometimes even not correct but used by them for experiencing the world,
- suppose that students already created a certain concept through various resources, not only during the work in class.¹

Steinbring (2000) has studied social discourse and a reflexive discussion, and shows by analysis of teaching episodes how individual learning strategies and social-interactive constructions of knowledge favour different forms of an epistemological

¹ Similar ideas can be found already in the work of J.A. Komenský (Comenius).
development of new mathematical knowledge. Construction of a new knowledge is not only an individual process, but collective processes make potential development of new knowledge possible.

2. Our research

When studying questions related to using constructive approach to teaching (mathematics) we use variety of methods: longitudinal evaluation of teaching effectiveness by comparison of periodic testing of parallel classes, direct observation of the milieu of the classroom and analysis of teaching strategies, the teachers accounts of their own classroom experience, analysis of audio/video recordings of lessons and of students’ products, as well as the direct teaching at one Basic school. In the school year 2000-2001 we faced a singular opportunity. One of the authors of this paper taught mathematics in two parallel classes of the ninth grade (9.A and 9.E referred to below where students are age 14). In 9.A she taught the class for five years and using constructive teaching strategies (Kubinová & Novotná, 2001). The class as a whole showed very good results in mathematics, in the inquiry most students put mathematics among their favourite subjects. She has never taught the other class (9.E) before. In this class, there was never one teacher teaching longer than during one year. The class was commonly considered as average, two students showed excellent results. Only two students put mathematics on the list of their favourite subjects.

Following the direct observation, interviews with students and teachers who had taught in both classes in the previous school year and the analysis of students’ written products, the input diagnosis of both classes was created. For the purposes of our paper we will focus in the further text on the phenomena related to the creation and fixing of the function concept.

The diagnosing tool evaluating the input analysis was the student project *What do the graphs say* (see Table 1).

**What do the graphs say**
Describe by another way the dependences those graph is on the figure.

![Graph Image](image)

Table 1

At the end of September 2000, pairs of students in both classes elaborated the project individually outside of school (in order to be able to use various sources of information). After that period they showed written materials and presented their results in a mathematics lesson.

Working pairs in 9.A presented divers solutions (often unexpected for us) and were able to defend their results also during the following discussion about the project outputs. In Table 2, all types of 9.A students’ solutions (including the incorrect ones) and some of their statements are summarised. Students’ solutions (I), (P), (T), (S), (U) and (R) represent separated models of dependences, (F) an universal model.
What do the graphs say

<table>
<thead>
<tr>

</thead>
</table>
| **Trip graphs**                             | Time, distance       | - Train (car, student, dog, ...) moves between two places with different velocity or is staying  
| (I)/7                                       |                      | - It is possible to continue the graph (time is running always). |
| **Water in tank**                           | Time, water cubage   | - In the tank there is a certain amount of water, the bleeder is opened, amount of water decreases, after some time it is closed again and then the feed-pipe with another velocity is opened and the amount of water is increasing.  
| (V)/8                                       |                      | - Instead of filling in and out we can take out water from the tank by cans and add some using other cans.  
|                                             |                      | - It is possible to do it as along as the tank is empty (e.g. they forgot to close the bleeder)  
|                                             |                      | - Water may also flood if we let the feed-pipe opened too long. |
| **Changes of temperature**                  | Time, temperature    | - We follow the outside temperature regularly. It stabilise after a while, then descends, then is again stable and then increases.  
| (I)/9                                       |                      | - From a digital thermometer we would not have such a nice line. |
| **Changes of state**                        | Time, amount of heat | - We are cooling boiling water until its temperature starts to descend. When it is at zero, we still cool it until we get ice. After a while we will heat the ice and we get water that will start to heat.  
| (S)/3                                       |                      | - Time when nothing happens cannot be extended as we want. After a certain time the state changes and the temperature starts to change as well. |
| **Savings**                                 | Time, amount of savings | - We have some savings and after a certain time we begin to spend it regularly. Then we stop it for a while and then we start to save again.  
| (U)/2                                       |                      | - Or we have also some money and have to pay interests. After paying them, we do not do anything with our money and then we put them on an account and they give us interests, so out money begins to increase. |
| **Changes of velocity**                     | Time, velocity       | - We are at the motorway in a super-fast car with the same velocity, then we have to brake in order to move with a smaller velocity and at a certain moment we can increase the velocity again. |
1. beginning
2. nothing is happening (bigger value)
3. graph is descending
4. nothing is happening (smaller value)
5. graph is ascending
6. end

For our work with 9.A the following findings were most important:

- Students interpreted the open assignment of the problem in various contexts, even from non-mathematical once. Here we were mainly surprised by the physical interpretations (changes of temperature and above all changes of state depending on time).

- Students were aware of limiting conditions for individual dependence descriptions (e.g. limitations for the range given by the volume of the tank or by the size of the latent heat of the dissolution of ice).

- In the cognitive structure of our students the universal model of a continuous (discrete) function was not created yet. They used a “continuous” line for interpreting discrete actions (measurement of temperature in given intervals, saving money, supplying water in a tank using a can).

- Students reflected the existence of more precise tools for the graphic record of dependences (e.g. digital thermometer).

- Four of eleven working pairs offered, besides the separated models, also the universal one \((F)\), see Table 2.

The situation in 9.E was different. Only three from twelve working pairs accepted the openness of the project assignment and presented separated models \((V)\) (2 pairs) and \((T)\) (3 pairs). One of these three pairs labelled the coordinate axes and presented the universal model \((F)\). Four pairs did not solve the problem anyhow while they did not considered the curve to be a graph of a dependence. (it did not correspond with any of graphs they had in their register, i.e. the graph of linear or quadratic dependence or indirect proportion). The last five pairs modified the task first to a closed one (by a concrete labelling of axes) or simplified it (omitting parts of the graph) and presented the unique solution. In four cases, the dependence description was the dependence of distance on time, in one case of temperature on time.
Using the input diagnoses, teaching strategies based on constructive approaches in both classes were stated for the period of one school year. In 9.E they could not be developed to the whole versatility because students grasped only step-by-step the cooperative ways of working, learned to work with open problems, solve non-standard problems, trust their own decisions etc.

The output diagnoses based on participating observation and analysis of written products showed that having worked with the function concept during one school year 9.A students précised their knowledge to such extent that they
- did not failed when solving standard school problems,
- were able to work with the universal model of a dependence (function), solve non-standard problems, use various representations of the concept when solving school and practical problems,
- used systematically various information sources (also out of school),
- identified at the intuitive level important properties of functions (continuity, discreetness, monotony, extremes, ...)
- classified some classes of functions (linear, quadratic, ...).

In 9.E, the class climate changed significantly towards the cooperative one. 9.E students did not show a significant shift in grasping the function concept during the school year. We identified only the enlargement of the group of separated models and more frequent attempts to solve non-standard problems. There survived the link to the function assignment and creation of graphs of “known” functions following the rules given beforehand. The influence of the preparatory period neglect was significant.

3. Concluding remarks

In (De Corte, 2000) it is stated that: "... we should realise that powerful learning environments ... require drastic changes in the role of the teacher. Instead of being the main, if not the only source of information – as is often still the case in average educational practice – the teacher becomes a ‘privileged’ member of the knowledge-building community, who creates an intellectually stimulating climate, models learning and problem-solving activities, asks provoking questions, provides support to learners through coaching and guidance, and fosters students’ agency over and responsibility for their own learning.” From the evidence above it is clear that the teacher’s role is crucial, he/she has to understand and respect the situation in each individual group of students. It is not possible to transmit the methods and forms of work which were successful with one group of students to another unmodified, however it is possible to use experiences gained with one group of students to organise work in another group.

In (Edwards & Jones, 1999), the grouped categories of students’ views of learning mathematics in collaborative groups were classified. The following were clearly identifiable in our analysis of 9.A and 9.E performances in school mathematics:
benefits of working together, respecting others in the group/sharing knowledge, confidence building and speed/volume of learning. In the class where the interactive teaching strategies were newly introduced (9.E) it influenced the climate in the class first, the influence on the mathematics behaviour and knowledge was significantly milder and occurred later. To change students’ gained norms of acting to a greater extent demands a long period of phased transition from transmissive teaching strategies to constructive ones (in our case, after 8 years of schooling, one school year was not sufficient).

In our experiment the role of peer interactions in the process of cognitive development was important. To profit from them needs a long experience of students in the similar activities, the enlargement of their self-confidence as well as the changes in their attitudes towards the subject. Students urgently need to see clearly mathematics as the subjects having narrow links to other subjects and mainly to the life situations.

In this paper we present an analysis of student responses to a written question involving logical implication and its converse in the context of simple number theory. Our sample consisted of relatively high attaining 13 year old students in randomly selected English schools. Most of the students regarded the statements representing the implication and its converse as essentially the same, and though nearly half were able to make a correct deduction on the basis of one of the statements being true, very few students used deductive reasoning as warrants for their conclusions about the truth of the statements. Students preferred to argue on the basis of empirical evidence, though many were not able to use the evidence in a mathematically appropriate way.

There is a considerable body of research over many years into argumentation in the mathematics classroom and how the processes of explanation, justification and proving can be fostered by teachers in order to develop a culture of mathematical interchange. Yackel (2001) for example took Toulmin’s scheme (Toulmin, 1958) comprising conclusion, data, warrant and backing, as elaborated for mathematics education by Krummheuer (1995), to analyse interactive argumentation. In this paper, we report on student responses to a written question in which students are asked to evaluate the truth of a logical implication and its converse, and to justify their conclusions. Though a written question is far removed from the kind of interaction reported by Yackel, Toulmin’s scheme provides a useful framework for discussing our results.

School students have a propensity to use inductive reasoning to validate conjectures in mathematics (e.g. Bell, 1976; Van Dormolen, 1977; Balacheff, 1988) rather than to prove them deductively. Even when students seem to understand the function of proof in the mathematics classroom (e.g. Hanna, 1989; De Villiers, 1990; Godino & Recio, 1997) and to recognise that proofs must be general, they still frequently fail to employ proof to secure beliefs in the truth of their warrants, preferring instead to rely on more data (e.g Fischbein, 1982; Vinner, 1983; Coe & Ruthven, 1994; Healy & Hoyles, 2000; Rodd, 2000; Simon, 2000). At the same time, there is some evidence from cross-sectional studies of logical thinking, that the use of 'child logic', whereby an implication and its converse are deemed as equivalent, decreases with age (O’Brien et al, 1971). In the 1970s there was considerable research on students’ understanding of logical connectives, and recognition of the importance of domain knowledge (eg, Wason & Shapiro, 1971), but no systematic study of the
development of logical reasoning over time in mathematical contexts, perhaps surprisingly given its importance for success in the subject.

How do students who are not taught explicitly about logical implication come to appreciate its structure from a basis (we surmise) of everyday or inductive reasoning? How do students exploit inductive reasoning (that provides a way of forming and testing conjectures, but not of proving them) to support their claims about the meaning, outcome and truth of \( p \rightarrow q \), but also, in Toulmin’s language, begin to develop more general and explanatory warrants for their conclusions? In this paper, we begin to address these questions through an analysis of students’ responses to a written question, L1, which we describe below.

Question L1 involved logical implication in the context of simple number theory. It involved the concepts odd, even, sum, and product, which would be familiar and meaningful to most of the relatively high attaining students that formed our sample. It was one of nine in a 50-minute written proof survey that was given to about 3000 students in June 2000 when they were approaching the end of Year 8 (age 13 years). A detailed scheme was devised to code the responses to all the questions, based partly on theoretical distinctions and partly on samples of pilot data. The students came from the highest attaining class (or classes) in 63 state funded secondary schools randomly selected within nine geographically diverse English regions. The same classes were also given a baseline mathematics test (using a broad selection of TIMSS items) about a month before taking the proof survey. We report here only on the students who were present on both occasions \((N = 2663)\)°. All the students had followed the statutory National Curriculum in which they are encouraged to engage in informal argumentation about mathematical problems but where the nature of logical implication is not explicitly taught. Our assumption is therefore that analyses of cross-sectional responses will provide a picture of students’ understandings of the deductive process in a mathematical context, after having engaged in classroom experiences of justifying and explaining, either verbally or in writing.

RESULTS AND DISCUSSION

Question L1 was devised to investigate whether students could distinguish between a logical implication (Joe's statement) and its converse (Fred's statement). It was based on a classroom activity suggested by Watson (1995) for highlighting the directional nature of some proofs and the role of counter example. The introduction to the question is shown in Figure 1, below.

The question had four parts. In part a) students were asked "Are Joe's and Fred's statements saying the same thing?". In b) students were told that the product of two whole numbers is 1271 and to suppose that Fred is right. They were then asked to select one of three conclusions, namely that you can be sure that the sum of the two numbers is i. even or ii. odd or that iii. you can't be sure whether the sum is odd or even until you know what the two numbers are. Students were then asked to state
whether c) Joe's and d) Fred's statements were true and, in each case, to explain their answer.

Joe and Fred are thinking about the pair of numbers 3 and 11.

They notice that the SUM \((3 + 11)\) is EVEN.

They notice that the PRODUCT \((3 \times 11)\) is ODD.

Joe says: If the SUM of two whole numbers is EVEN, their PRODUCT is ODD.

Fred says: If the PRODUCT of two whole numbers is ODD, their SUM is EVEN.

Figure 1: Introduction to Question L1

In part a) 13 percent of students correctly stated from the outset that Joe's and Fred's statements are not saying the same thing, with a further 15 percent changing their answer from Yes to No at some stage. The vast majority of students, 71 percent, stated that they were saying the same thing.

In b), the large and rather obscure number 1271 was chosen to discourage students from trying to find the actual numbers (31 and 41) whose product this is. The aim of the item was to see whether students could play the mathematical game of supposing a statement is true, whether it is or not, and then making a correct deduction on this basis. Nearly half the students in the sample (47 percent) chose the correct option (that the sum must be even) with another 47 percent choosing the empirical option (you can't be sure until you know what the numbers are).

In c), 36 percent of students correctly stated that Joe's statement (Sum-even \(\rightarrow\) Product-odd) is false and supported this with one or more appropriate counter example, as in this response: "No. Because if you do 2+4=6 (even) then 2×4=8 (even) so they are both even". Of this 36 percent, most (28 percent of the total sample) gave specific counter examples (usually just one, as in the above response), but some students (8 percent of the total sample) described the counter examples in general terms (namely, that both the initial numbers are even). A general explanation of this sort represents a shift from just looking at data to looking at structure: it goes beyond showing that the statement is false, though this is all that the item requires, by giving some insight into why it is false, and so provides some insight into the warrants students held to support their conclusion.

In d), 24 percent of students correctly stated that Fred's statement (Product-odd \(\rightarrow\) Sum-even) is true and supported this with appropriate examples, as in this response: "Yes. 3×3=9. Product = odd. 3+3=6. Sum = even". Another 9 percent of students supported their correct evaluation of Fred's statement with a general explanation, of the sort "If the product is odd, then the numbers must be odd, so the sum is even". 
In contrast to c), a general explanation is needed to answer d) satisfactorily as empirical examples can not show conclusively that Fred's statement is true.

The response frequencies for the four parts of question L1 are summarised in Tables 1 - 4, below.

Table 4: Distribution of responses to L1d (Fred: Product-odd \rightarrow Sum-even) (N = 2663)

One striking feature of the frequencies in Tables 1 - 4 is that the proportion of students who seem to use general, deductive reasoning is far higher in part b) (47 percent) than in parts c) and d) (8 percent and 9 percent respectively). This difference might be partly due to the greater complexity of items c) and d) compared to b), although the fact that our multilevel statistical analysis showed a correct response to b) to be a significant predictor of overall proof score suggests that some appreciation of the structural nature of logical implication influences approach and success to questions involving deduction. However, it also suggests that many students who use an empirical rather than a more general, deductive approach in c) and d), do so out of choice or habit rather than necessity. Of course, the point has been made that a satisfactory mathematical explanation in c) does not require a deductive approach, though it does in d).

It is also striking that the corresponding frequencies in c) and d) are very similar. Care must be taken in interpreting this, however. It does not necessarily mean that
the two items are similarly demanding. Indeed a good case can be made for expecting the frequencies in the last two columns of Table 4 to be substantially higher than the corresponding frequencies in Table 3b. That this is not the case could be due to the order of presentation of the two items, in that many students when they reach d) will be influenced by their response to c), given the widely held belief that Joe's and Fred's statements are essentially the same. In particular, this is likely to increase the number of students who say No in d), as roughly 1 1/2 times as many students say No in c) as say Yes.

If the raw frequencies in c) and d) can not easily be compared, the relative frequencies are still of interest. In particular, it is notable that the students who give a correct deductive reason in d) are greatly outnumbered (by nearly 3 : 1) by those who give a correct (as far as it goes) empirical reason. This fits with the findings of other studies (e.g. Bell, 1976; Van Dormolen, 1977; Balacheff, 1988) and supports the observation made earlier that students in our sample are for more likely to favour an empirical, data-driven approach to evaluating a mathematical statement than to consider mathematical structure and to argue deductively. However, it is of interest too that the corresponding ratio in c) is similar (just over 3 : 1), bearing in mind that a general, deductive reason is not necessary here.

An examination of individual students' scripts indicates that most students' explanations in parts c) and d) start with one or more empirical example. Usually, the explanation stays at this level, though occasionally, as the frequencies discussed earlier indicate, the empirical examples are followed by a more general statement which is an empirical generalisation of the examples or, as seems to be the case below, for which the examples serve as illustrations:

```
  d) (Fred: Product-odd → Sum-even)

9 = 3 × 3  3 + 3 = 6  21 = 3 × 7  3 + 7 = 10
I believe that it is correct as only an odd times an odd can equal an odd and if you add together the
  two odds you always get an even.
```

Students who provide appropriate empirical examples (in support of a correct conclusion) commonly only provide one empirical example, or, where they provide several, the examples are often quite similar. This suggests that rather than starting with fairly random examples with which to explore Joe's or Fred's statement, the example is carefully chosen after 'inspecting' the statement in some way. Interestingly, too, the example chosen is often quite special, for example consisting of a pair of small numbers, often identical, such as 4 and 4 in c) or 5 and 5 in d). Such numbers would seem to be the antithesis of numbers that would provide a 'crucial experiment' (Balacheff, 1988), and nor would they seem well suited for a generic example; however, one should not discount the possibility that some students thought of the numbers in one of these two ways.

There seemed to be a tendency for students who generated a lot of data to go wrong, by making incorrect conclusions from the data, perhaps because they were
overwhelmed by the data or perhaps because they lacked a clear idea of the nature of the data and how it could be used to validate a claim. We have tried to describe some of the warrants students seemed to use to explain why the data they presented supported (or not) their conclusions. This analysis suggests that students may not only fail to distinguish logical implication from its converse, but also fail to appreciate how data can properly be used to support a conclusion as to whether “p → q” is true or not. For example, some students would take “p → q” to be true if they found data to support it, even if they had other data that would serve as a counter example, as in the response below. This could arise because the counter example was ignored or in the belief that 'a statement is true if it is sometimes true' (perhaps by analogy with 'a statement is false if it is sometimes false').

c) (Joe: Sum-even → Product-odd)

<table>
<thead>
<tr>
<th>Yes.</th>
<th>No. Certain numbers added together will become ODD for example: 7+2=9. The product of those two numbers is also now even: 7x2=14.</th>
</tr>
</thead>
<tbody>
<tr>
<td>4+8=12.</td>
<td></td>
</tr>
<tr>
<td>2+4=6</td>
<td></td>
</tr>
<tr>
<td>1+15=16</td>
<td></td>
</tr>
<tr>
<td>3+15=18</td>
<td></td>
</tr>
<tr>
<td>4×8=32.</td>
<td></td>
</tr>
<tr>
<td>2×4=8</td>
<td></td>
</tr>
<tr>
<td>1×15=15</td>
<td></td>
</tr>
<tr>
<td>3×15=45</td>
<td></td>
</tr>
</tbody>
</table>

Other students deemed “p → q” to be false if data could be found that falsified both propositions in the given statement, as illustrated below, suggesting that the statement was being seen as a conjunction rather than an implication.

c) (Joe: Sum-even → Product-odd)

Interestingly, the student who gave the above response switched, in answer to part d), to seeing Fred's statement in the conventional way, as is shown below. Such inconsistency was not uncommon, which has led us to wonder how far a student’s expression of a warrant for their conclusions (either in writing or verbally during an interactive episode) can be assumed to be based on the appreciation that if a warrant is to be mathematical, it must be applied consistently (even if it might not be correct from the teacher’s point of view!).

d) (Fred: Product-odd → Sum-even)

| Yes. If the product of the numbers is known to be odd the sum will be even: |
|------|--------------------------------------------------------------------------------|
| 7×3=21 | 7+3=10 5×5=25 5+5=10 9×5=45 9+5=14 |

Some students were at what we tentatively suggest might be a transitional level. Typically, they initially answered Yes to a) but changed this to No, presumably after reflecting on their answers to c) and d). Interestingly, those who changed their answer to No had a somewhat higher mean score on the other numerical/algebraic items in the survey and a higher baseline test score than those who stuck with No from the outset and than those who answered Yes (mean score of 6.7, 6.0 and 5.8 respectively for algebra and 16.6, 15.7 and 15.0 for baseline, compared with means of 6.0, out of a possible 13, and 15.3, out of a possible 22, in algebra and baseline for the sample as a whole). These students could cope with the suspension of disbelief and the deduction required in b) and were able to answer c) and d)
competently using empirical data, and perhaps using large numbers as a crucial experiment to test their conclusion in d) more thoroughly, as in the response below:

<table>
<thead>
<tr>
<th>d) (Fred: Product-odd $\rightarrow$ Sum-even)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Yes. Fred said the product of two whole numbers is odd, their sum is even. So:-</td>
</tr>
<tr>
<td>3x5=15 (odd) $\checkmark$ 3+5=8 (even) $\checkmark$</td>
</tr>
<tr>
<td>I tried 5 and 7, 9 and 17, and lots more, they all worked. Fred is right!</td>
</tr>
</tbody>
</table>

Students are more likely to adopt a general, deductive approach if they reflect carefully on the data they have generated or, indeed, if they reflect on the structure of a mathematical task before generating data. This is not something that is particularly emphasised in the English National Curriculum – perhaps even the opposite is the case, with students commonly being encouraged to formulate and test conjectures by first generating lots of data. It will be interesting to see, therefore, how the different types of warrant that students call upon to justify their conclusions, together with the consistency of their use, change over time, and to what extent the use of deductive reasoning to justify conclusions increases in our sample as the students get older.

**ACKNOWLEDGEMENT**

We gratefully acknowledge the support of the Economic and Social Research Council (ESRC), Project number R000237777.

* Virtually the same question was given to the same sample of students one year later in 2001.

*b Consider, for example, someone who works on an empirical basis and whose first step is to find a pair of numbers that fits the first proposition in the statement under consideration. In d) (Fred's statement), the numbers will both be odd and so will of necessity fit the second proposition, thereby supporting the correct conclusion that Fred's statement is true. On the other hand, in c) (Joe's statement) the numbers that fit the first proposition will both be even or both be odd, so they might (both even) or might not (both odd) support the correct conclusion that Joe's statement is false.

*c Our analysis of responses to the survey administered in 2001 will assist in this interpretation as we will be able to describe the trajectory of student responses over time.

From the Lotto Game to Subtracting Two-Digit Numbers in First-Graders.

Bilha Kutscher, Liora Linchevski, Tammy Eisenman. The Hebrew University of Jerusalem.

The purpose of this study was to design a context for the subtraction of two-digit numbers that would survive the transfer into the classroom situation, make sense to the children and thus have the power to elicit their outside-school intuition and would lead to the invention of an efficient computational method. A modified version of the Lotto Game was found to be such a context. All the first-graders who participated in this study invented and used the “Overshoot-and-Come-Back” method in the context of the game. Moreover, this method was used by the children also when later presented with abstract subtraction expressions where the unit digits of the subtrahend were larger than the unit digits of the minuend.

Background

It has been found that grade 2 and 3 students who use their own invented-strategies to solve multidigit subtraction make significantly fewer errors than students who were taught to use the standard subtraction algorithm (Carpenter et al, 1998). Moreover children who use invented-strategies develop knowledge of base-ten number concepts earlier (Hiebert & Carpenter, 1992) and gain higher levels of understanding (Hiebert & Wearne, 1996) than students who were taught from the beginning to use the standard algorithm. First grade students, however, usually do not demonstrate ability to invent algorithms for subtraction of two-digit numbers, although they are able to for addition (Carpenter et al, 1998) even though they had been previously provided with opportunities to solve both addition and subtraction word problems that involved two-digit numbers and solved them meaningfully.

Typically, pupils who are encouraged to develop computational strategies learn in mathematics classrooms that are characterized by instructional designs that afford the construction of mathematical knowledge via solution of context problems (word-problem situations). Well-chosen context problems provide the students with opportunities to develop specific-situation solution strategies. When these informal strategies do develop, they can then be modeled. These models can then be generalized to develop into entities that may become models for mathematical reasoning (Gravemeijer & Doorman, 1999).

Study

Following the above-reported results that indicate that invented strategies develop students’ understanding and result in more correct solutions, it would seem disadvantageous to teach first-grade students algorithms for two-digit subtraction
expressions. However, since situations that involve subtraction of two-digit numbers are meaningful to them (and they are able to solve them albeit in primitive basic methods like one-digit back counting or modeling with unit counters) it seems challenging and advantageous to look for situations that are likely to provide new affordances for fostering higher invented strategies (Schwarz & Linchevski, 2002). For instance, children have been party to situations where they paid for an item out of a given amount of money they had in their possession. For example, a child might have 64 cents in his or her pocket – 6 dimes and 4 one-cent coins – and buy candy for 28 cents. Thus, if it were possible to “import” such a situation into the classroom in a context that would evoke in the children their outside-school intuition (situated intuition), an invented computational strategy might emerge and then be developed into more formal mathematical thinking.

Two questions arise:
1) Is it possible to design a context also in the classroom that would afford the development of an invented computational strategy for the subtraction of two-digit numbers in first graders?
2) If so: a) What strategies would be invented for this context?
   b) Could the model of this situation become a model for abstract subtraction problems?

Our hypothesis was that
a) A “buying-selling” situation could be a context for the developing of invented strategies for the subtraction of two-digit numbers.

b) Since invented subtraction strategies generally start with the larger unit (Hiebert & Wearne, 1996; Fuson et al. 1997), we expected two possible invented strategies: i) Decompose-Tens-and-Ones; ii) Overshoot-and-Come-Back. For example, in strategy i) the children would first pay 2 tens out of the 6 tens, change another ten to 10 ones and then pay 8 ones out of the 14 ones leaving 6 ones. Answer: 36. In strategy ii) the children would pay the 28 with 3 tens, get 2 ones back, so they are left with 34 + 2. Answer: 36. This strategy we coined the “Change” method (sometimes referred to as “Compensation” or “Overshoot-and-Come-Back”).

Students who would develop strategy (i) could be guided to model it mathematically as, for example: 60-20=40, 10(out of the 40)+4=14, 14-8=6, 30+6=36. Students who
would invent strategy (ii) could be guided to model it mathematically as, for example: 64-30=34, 30-28=2, 34+2=36.

**Study Design:** The study involved two sets of teaching episodes in heterogeneous groups in a cooperative learning environment (Linchevski & Kutscher, 1998). The children were first-graders who had not yet received any instruction in subtracting two-digit numbers, although they were acquainted with addition and subtraction of one-digit numbers. One of the researchers was both teacher and interviewer. All the meetings were videotaped to allow further analysis. The sequence of episodes was designed a) to elicit out-of-school spontaneous strategies for the subtraction of two-digit numbers, b) to allow the shift of the spontaneous strategies from intuitive meanings to mathematical meanings expressed in mathematical sentences (Linchevski & Williams, 1999).

**Research population:** An average, suburban first-grade class was chosen for our research population. Students who participated in the study were those who on a pretest were able to a) read/identify two-digit numbers b) decide which of two given two-digit numbers is the larger c) understand that a two-digit number like 27 is 20 plus 7. The two top students of the class were excluded. 20 students participated in our research.

**Teaching episodes:** During the first set of teaching episodes a “buying-selling” game – a modification of the well-known children Lotto Game - was played by the groups. Each of the participants was given a different lotto-board that had 9 picture squares drawn on it. For each lotto-board there were 9 square picture-cards identical to the ones drawn on the board that the players had to accumulate in order to cover the pictures on their lotto-board and thus win. We modified the game by writing prices of two-digit numbers on the pictures; their values were between 11 to 45. Each child started off with the same amount of money – 77 IS - 7 strips with division lines, each strip representing a 10 IS note and 7 squares representing the ones. Each child had an empty 200-number-board on which he or she could store and arrange their money. There was also a communal bank of money where there were ample tens and units that the students could change from tens to units and vice versa, so that they could apply any strategy they wished. The cards were distributed equally among the children. If a player did not have a picture-card for his or her lotto-board they had to buy it from another player in the group according to the “price” of the picture-card. This “buying” process laid the base for the subtraction.
During the second set of episodes the children reflected on concrete cases that they experienced during their game and were offered ways of translating the intuitive strategies they used during the game to mathematical sentences. The translation was done in four stages:

a) A verbal formulation of the solving strategy in shared spoken-language terms for concrete cases from their game. The verbal formulation was based on the shared verbal communication they had developed during the game.

b) (i) A written account of the solving process for concrete cases using the verbal formulation.
   (ii) Solving expressions written in verbal formulation of hypothetical cases that could occur in a game.

c) (i) A written representation in mathematical symbols for concrete cases.
   (ii) Solving expressions written in mathematical symbols of hypothetical cases that could occur in a game

d) Solving written abstract subtraction expressions.

Results

First set of teaching episodes: The lotto game.

When the children were faced with the problem of having to pay money for a picture-card, having enough money on the board, but not enough ones, all the children who participated in this study used the "change" method to solve their problem.

The process of the invention of the "change" strategy: 1) Identification of the problem

2) Solution of the problem.

1) Two patterns of identification were recognized:

a) Identification of the problem after trying to pay the exact amount:

Y wishes to buy a flag. Its price is 17. She takes off 1 ten-strip while she counts the units. She takes off money of value 16. There are no more units on the board. She immediately takes off another ten-strip – the buds of the "change" strategy.

b) Identification of the problem before paying by comparing the number of units on the board to the number of units that need to be paid.

K wants to buy a car. Its price is 29. "I don’t have”.
Interviewer: What do you mean when you say 'I don't have'? T (another player in this group): That he doesn't have the number.
Interviewer: But you have even more (than you need).
T: That we don't have like these; and he points at the units.

2) The solution - a joint learning effort: Report and Analysis.

The following is representative of how the groups constructed cooperatively their strategy:

B is interested in buying a sofa. Its price is 47. He removes 4 ten-strips and says “I don’t have”. Interviewer: Does anyone have an idea?
A: To give one like this. And she points at one of B’s ten-strips.
B removes 1 ten-strip from his 200-board.
Interviewer (to V, the owner of the sofa-card): What will you do?
V: I’ll give change.
Interviewer: How much change? You were supposed to get 47 and you got 50.
V and A announce a few numbers: 2, 5, 7. And A shouts: “Three!” This answer is approved by all.

Every member of this group was involved in the construction of the solution. B identified the problem, A suggested the need to “overshoot”, V the need to “come back” and A found the amount you “come back” with.

As reported earlier, all children adopted the “change” method in the game. But none found it necessary to find, after a transaction, the amount of money left on his or her 200-board: the answer to the multidigit subtraction problem. Their behavior corresponded to the situation that elicited their spontaneous strategy: in a buying-selling situation one does not usually calculate the amount left in the wallet – unless there is some concern that the amount will not suffice. Thus the children’s disregard of the amount left on their 200-board is not surprising. The teacher would call their attention both to the initial amount on the 200-board and to the amount left after each transaction in the second set of teaching episodes, when the transactions would be translated to mathematical subtraction- expressions.

When encountering the problem of not having enough units to pay, in no instance did the pupils suggest that the buyer exchange a ten-strip for ten ones albeit the ‘bank’ was on the table. The decomposition of tens strategy did surface once, when the seller did not have enough change:

V is interested in buying a flute. Its price is 16. She removes 2 ten-strips and gives B. B doesn’t have change of 4 ones on her board.
Interviewer: Does anyone have an idea? V doesn’t have 6 units and B doesn’t have 4 units to give her change?
A: *We’ll change this* (points to a ten-strip on B’s board) *to small ones.* B removes a ten-strip, puts it in the ‘bank’ and takes 10 unit squares and sticks them on his board on the row that was vacated when he removed the ten-strip. Only then does he give V 4 square-units.

The preceding vignette allows us to observe the powerful effect of situated-intuition. Why is it that here “decomposition-of tens-and-units” was the spontaneous reaction and that in all the other instances only the “change” strategy was evoked? It might be that in ‘real’ life experiences, it is usually the responsibility of the cashier to change the “big” money into smaller denominations in order to be able to give change to the buyer. Furthermore, just as was observed in B’s behavior, in real life when the seller changes money into smaller denominations he places it in the till and only then gives the buyer his or her change. Thus, when both the “buyer” and the “seller” did not have the necessary units to complete the transaction, the solution that was offered in the game, mirrored a real-life problem-solving strategy. However, this decompose-tens strategy although understood and approved by the group was not used by the students later on.

**Second set of teaching episodes:** Translation of spontaneous strategies from intuitive meanings to mathematical meanings expressed in mathematical sentences:

This teaching episode had 3 parts:

*Part 1)* The children played a shortened version of lotto in the presence of the interviewer who documented their transactions using their shared language. This time the game ran very smoothly: all children applied the change method to complete their transactions. At the game’s completion the interviewer reconstructed with the children the game’s transactions and translated them first into (i) shared verbal formulation they developed and then (ii) into written spoken-language. The translation was from the viewpoint of the buyer as this was the language the children had used during the game. The transaction of money from the buyer was coined “I gave”. The transaction of money to the buyer was coined “I received”. Reference to the amount of money left on the 200-board was coined “I am left with”. The reconstruction was done in 3 stages: a) The interviewer recalled a transaction from the game: “B had 68 and she had to give 38.” b) Each child reconstructed this by first sticking 68-worth of strips and/or squares on the board, then “gave” 38 and reported the money that “I am left with”. c) The children documented the transaction using a combination of numbers and spoken-language stickers. This was done first with “simple” transactions such as 56-32 that was translated to:

```
3 - 254
```

PME26 2002
A "complex" transaction (needing change) such as "There were 74 and one had to give 38" was reconstructed and executed via the 200-board and translated in 2 stages:

a) verbal spoken language: "I had 74, I gave 40, I received 2, I am left with 36",
b) written spoken-language (the expressions "I gave", "I received", "I am left with" were written on stickers to facilitate the first-graders' 'writing'): 74-38= ;

The children seemed to be able to reconstruct the transaction and follow the corresponding steps in writing quite easily. But despite the fact that they counted the strips and/or squares left on the board, when the interviewer summarized: "There were 74, I gave 38, how many are left?" the children could not answer the question immediately. This difficulty repeated itself a few times in each group. Some children re-counted the strips and/or squares on the 200-board, some recalled the end result on their board and some re-looked at what was written on the paper.

Part 2: Each child was given "Work-Sheet1" with written abstract subtraction problems such as "63 I gave 26= " Some children disregarded the equal sign completely, verbalizing the expressions in shared spoken-language as "I had 63, I gave 26" and put a sticker "I am left with" next to the "= " sign: 63 I gave 26 I am left with 27. It seems that they perceived the equal sign as a "start-working" instruction. For these children the mathematical expression seemed to be part and parcel of the game situation. The children learned to document each part of the process in written spoken-language in the same steps as is reported in Part 1.

There were some children who developed dependence on "reconstruction" as a model for documenting the solution. They would solve the entire problem with strips and/or squares, then verbalize these steps and only then use stickers to write all the steps of the solution.

Part 3: The spoken-language expressions "I gave", "I received", "I am left with" were replaced by corresponding mathematical symbols -, +, =. Thereafter the interviewer reconstructed with the children two transactions from the lotto game they had previously played, using the strips and/or squares to calculate the result. Following each game move, she translated it with the children into mathematical sentences using only mathematical
symbols, in the same steps as had been previously made with the spoken-language stickers. Each child was then given Work-Sheet2; they were asked to solve written abstract subtraction expressions such as “57-13=” and “42-36=” All the children solved these problems correctly using their strips and/or squares. However, they found the documenting process to be a burden as it broke their line of thought. Thus most children preferred to write only the numerical answer to the problem. Two children did document, but with the aid of stickers. One child documented using only mathematical symbols.

Discussion

The results of this study suggest that first grade students are able to solve two-digit subtraction problems. We infer that the reason our first-graders were able to invent quite a sophisticated computational method for the subtraction of two-digit numbers, despite the fact that children of this age and mathematical experience, are generally not at the appropriate stage of number-concept development, is because of the specific context-design and documenting device. The buying-selling situation - embodied in a modified game of lotto - survived the transfer into the classroom context, made sense to the children and thus had the power to elicit the outside-school intuition. This led to the invention of a computational method - “overshoot-and-come-back” - for subtraction problems where the unit digits of the subtrahend were larger than the unit digits of the minuend. Moreover this computational method was used by the children also when later presented with abstract subtraction expressions.

The purpose of this study was to provide construct-related evidence of a model measuring problem-solving skills based on Marshall's schema theory (ST) using responses from 712 4th and 5th grade Cypriot students to a battery of tests on PS. The Extended Logistic Model of Rasch was used and a scale was created for the battery of tests and analysed for reliability, fit to the model, meaning and validity. It was also analysed separately for each of the two types of knowledge proposed by Marshall in order to examine the appropriateness of ST in building a model of measuring PS skills. The analysis reveals that the battery of tests has satisfactory psychometric properties and supports the conceptual design of the proposed model. The findings are discussed with reference to intended uses of the assessment of PS skills and suggestions for further research are drawn.

INTRODUCTION

Problem solving (PS) is a central issue in mathematics education theory, as it can be documented by recently published literature on curriculum and assessment in Mathematics (see e.g., NCTM, 2000). In this context, Marshall (1995) developed a comprehensive proposal for teaching and assessing PS, which is grounded on schema theory (ST) and the acquisition of basic schemas by the learners. Mayer (1992) points out that "a schema is an organised structure consisting of certain elements and relations which are related to a situation and it can be used for understanding incoming information" (p. 228). ST was based on the assumption that the external representations used to describe the structure of a problem (i.e. diagrams) can serve in constructing a mental model which can be retrieved and used in solving analogous problems of the same structure (Goldin, 1998). Thus, ST aims to help students systematise PS experiences by providing them with simple diagrams for solving problems of additive and multiplicative structure.

Previous research on PS (Schmidt & Weiser, 1995) revealed that the crucial element in solving a problem lies in its structure and not on characteristics such as its context, content, or the number or type of the operations needed for solving the problem. Consequently, attention should be paid to the construction of the mental schema, which mirrors the structure of the problem. Diagrams or appropriate physical schemata can serve as vehicles for developing a solution plan (Marshall, 1995), since they provide access to similar structure problems that have been encountered in the past, and the means for reformulating or simplifying a problem. It is also recognised that retrieving the appropriate schema facilitates the design of a solution strategy, which is the most important part in the whole endeavour. Nesher and Hershkovitz
(1994) argue that schemas constitute the bridge between the verbal formulation of a problem and its mathematical structure. Schemas are, therefore, of primary importance with respect to cognitive processes involved in PS, since they facilitate the comprehension of the semantic relations in given text and serve as generalised frames for action in given situations (Philippou & Christou, 1999). In brief, schemas help students construct deeper understanding of problems, clarify their thinking and justify their ideas.

Marshall (1995) proposed five distinct problem situations: change, group, compare, restate and vary. The former three situations can be used to solve additive structure problems, while the last two situations are mainly used for solving multiplicative structure problems. For each situation, Marshall (1995) proposed an appropriate diagram, which is expected to help students recognise the problem situation and solve the problem. In this process, students are expected to proceed through four stages, each representing a different type of knowledge: identification knowledge, elaboration knowledge, planning knowledge and execution knowledge. The first stage refers to specific characteristics, features, and facts that help students recognise the schema; identifying the main elements of a problem can be considered as the most important part for schema activation, since it is this understanding that contributes to the initial recognition of a situation. The second stage refers to working out rules and limitations having to do with the use of the schema; at this stage the students recognise the details that are distinct to each schema, and consequently choose or construct the correct schema to solve the problem. The planning knowledge refers to ways through which students make decisions about the schema that is appropriate for the solution of a problem. Finally, the last type of knowledge includes a set of procedures, rules, or algorithms that can be applied to reach sub-goals and the final goal.

To the best of our knowledge and belief, no systematic attempt has so far been made to verify the sequence of these four stages, or to investigate whether these stages, representing different types of knowledge, may help us form a developmental model measuring PS skills based on ST. We consider the development of a model as highly important, since it may help teachers design activities that will enable students to progressively develop the required abilities to solve routine problems.

In this context, the main purpose of this study was to collect empirical data in order to examine the validity of a model measuring pupils' skills in PS. The developed model refers to additive structure problems of three situations, namely: change, group and compare, with regard to the former two types of knowledge that a student is expected to acquire (identification and elaboration knowledge) in order to be able to use appropriate schema(s) to solve a problem. Hence, another purpose of this study was to reconfirm the two aforementioned types of knowledge proposed by Marshall which could be helpful for using ST in teaching and assessing PS.
THE DEVELOPMENT OF THE BATTERY OF TESTS ON PS

To answer our research questions, a battery of tests on PS was constructed guided by existing research and theory on assessment of PS skills in Mathematics and by taking into account ST. Further, we sought a developmental ordering of tasks on a continuum of difficulty, which is an essential concept derived from research on developmental assessments for measuring proficiency in cognitive abilities and content areas (Hambleton, 1995). A final key requirement in designing the tests was its alignment with the mathematics curriculum that was operative in the country where the study was conducted.

The specification table of the tests (Table 1) included eight levels of PS skills which belong to the first two types of knowledge proposed by Marshall (1995); the former four levels referred to the identification knowledge of schemas and the remaining four to the elaboration knowledge.

Table 1: Specification table of the tests on PS based on ST

The eight levels were mainly based on tasks proposed by Marshall (1995) for assessing the acquisition of each type of schema-knowledge. Specifically, the first two levels included tasks examining the verbal and diagrammatical identification of the schema needed for solving a problem (i.e. students were requested to identify the structure or the appropriate diagram which could be used to solve a given problem). The third level included tasks examining students’ ability to select problems that could be solved using a given diagram, while the fourth level referred to their ability in posing a question to produce a problem of a certain structure. The four remaining levels included tasks such as filling the data in a given diagram to represent the structure of the problem (5th level), placing the unknown quantity in the correct position of a diagram (6th level), and posing a problem given either the context of the problem (i.e., a given diagram including words and numbers) or solely numbers (7th and 8th level, respectively). The specification table guided the construction of a battery of tests with 178 items, representing the eight aforementioned levels. Each level included tasks of all three problem-situations (change, group and compare situation).
METHODS

The items in the final version of the battery of tests were content validated by three experienced primary teachers and two university tutors of Mathematics Education. The "judges" of the tests were asked to mark-up, make marginal notes or comments on or even rewrite the items. Based on their comments, minor amendments were made particularly where some terms used were considered as unfamiliar to primary pupils. The final version of the tests (available on request) was administered to all 4th grade (314) and 5th grade (398) pupils from 21 primary schools selected by stratified sampling (336 of the subjects were boys and 376 were girls).

The Extended Logistic Model of Rasch (Rasch, 1980) was used and the data were analysed by using the computer program Quest (Adams & Khoo, 1996). The data were initially analysed with the whole sample (n=712) for all items together; it was found that all items fit the model. The analysis was repeated with each of the four groups (grade 4, grade 5, boys and girls) of the sample, to investigate whether the battery of tests is used consistently by each group of the sample. By taking into account the item difficulties derived from the analysis of the whole sample, we used the procedure for detecting pattern clustering in measurement designs developed by Marcoulides & Drezner (1999) in order to examine whether levels of PS skills similar to those described in the specification table could be identified. Moreover, separate analysis of the two sub-scales, which refer to the first two types of knowledge mentioned by Marshall, was conducted to analyse the meaning of the general scale and the trait it measures.

FINDINGS

Figure 1 illustrates the scale for the 178 test items with item difficulties and the whole group of pupils' measures calibrated on the same scale. Both figure 1 and the item fit map for the 178 items fitting the model reveal that all the items of the tests have a good fit to the measurement model. Moreover, pupils scores range from -3.44 to 3.58 logits and the item difficulties range from -3.66 to 3.62 logits. This implies that the 178 items of the test are well targeted against the pupils' measures.

Table 2 provides a summary of the scale statistics for the whole sample and for each of the four groups of the sample. We can observe that for the whole sample and for each group the indices of cases and item separation are higher than 0.85 indicating that the separability of the scale is satisfactory (Wright, 1985). We can also see that the infit mean squares and the outfit mean squares are 1 and that the values of the infit t-scores and the outfit t-scores are approximately zero. And since the mean squares are within 30% of the expected values, calculated according to the model, it can be claimed that there is a good fit to the model. Moreover, the analyses of each of the four groups separately revealed that almost all items (176 out of 178) have difficulties, which could be considered invariant among boys and girls, within the measurement error (0.15 logit). The difficulties of 171 out of 178 items are invariant between the two age groups but 7 items vary markedly across the two age groups. Thus, an
important aspect of creating a scale (sample-free item difficulties) has not been completely achieved.

**Figure 1: Scale for the battery of tests on PS (N=712, L=178)**

The Rasch model was also helpful in analysing the conceptual design of the battery of tests. The indices of cases and item separation of each sub-scale (representing the two
types of schema-knowledge) for the whole group and for each of the four groups of the sample are higher than 0.85 indicating that the separability of each sub-scale is satisfactory. Moreover, the infit mean squares and the outfit mean squares for the whole sample and for the four groups are one and the relevant values of the infit t-scores and the outfit t-scores are approximately zero. Thus, both sub-scales have satisfactory psychometric properties.

Separability* (reliability) represents the proportion of observed variance considered to be true.

Table 2: Statistics relating to the scale for the whole sample and the four groups

Comparing the difficulties of the items of the two sub-scales, we can observe that the measurement model places a significant number of the items concerning identification knowledge at the easiest part of the scale and a significant number of items on elaboration knowledge at the harder part of the scale. In order to examine further this finding, the procedure for detecting pattern clustering in measurement designs developed by Marcoulides & Drezner (1999) was used. The cumulative D for the seventh cluster solution is 86% and the eighth gap adds only 2%. Moreover, all the gaps after the seventh gap are very small and this indicates that the 178 items are separable into seventh clusters. Thus, seven levels of PS skills based on ST can be identified. These levels are similar to the levels mentioned at the specification table of the test. More specifically, pupils who are at the first level (i.e. below -2.60 logits) are able to recognise verbally problems. The second level (-2.47 up to -1.78) refers to the diagrammatical recognition of problems. Pupils who are at the third level (-1.54 up to -0.85) are able to select a problem which reflects a given diagram. After the third level, there is a relatively big area where none item is included. This implies that there is a gap between the third and the fourth level (-0.24 up to 0.36) which refers to pupils’ ability to pose questions from a mathematical situation. This gap can be attributed to the fact that although the skills of the first four levels refer to the first type of knowledge mentioned by Marshall (1995) pupils have to make an important
progress in order to be able to pose questions. At the fifth level (0.45 up to 1.20), pupils are able to fill the data in a given diagram to represent the structure of a relevant problem and at the sixth level (1.50 up to 2.16) they are able to place the unknown quantity in the correct position of a diagram. Then there is a relatively big gap between the sixth and the seventh level (2.80 up to 3.62), which refers to pupils’ ability to pose a problem based on a given diagram including either words and/or numbers.

**DISCUSSION**

The findings of this study provide support to the conceptual design of the proposed model of measuring PS skills. The underlying trait, that is pupils’ abilities to use appropriate schemas to solve routine problems, seems to be an overarching concept comprised of the two types of knowledge mentioned by Marshall and upon which the specification of the test was based. It would theoretically be expected that primary pupils would find it easier to develop skills concerning the identification knowledge rather than the elaboration knowledge. The findings of this study provide further support to this argument. Moreover, the procedure for detecting pattern clustering in measurement designs developed by Marcoulides & Drezner (1999) was found useful in supporting the theoretical background upon which the construction of the battery of tests was based. The seven levels of PS skills, which were identified, were similar to those described in the specification table of the test. However, this technique did not identify two different levels in relation to the problem posing skills concerning the elaboration knowledge, as it was expected. Moreover, a gap among the levels of each sub-scale was identified which revealed that problem posing skills are more difficult to be achieved than any other skill concerning each type of knowledge. This finding provides support to the assertion that problem-posing tasks are more complex and difficult for students than PS tasks (Silver, 1994; English, 1997).

The battery of tests on PS skills based on ST and its Rasch scale may help teachers decide how to identify and meet pupils’ learning needs in relation to the seven levels of PS thinking and how to use their teaching time and their resources. An important implication of the identification stage is that it works as the first in sequence, facilitating pupils to make decisions, improve their abilities and move to the next stage (i.e. elaboration knowledge). Teachers should also be aware of the fact that the aforementioned two stages consisting of seven levels of thinking follow a linear sequential hierarchy. However, some pupils could be at the same level even though their abilities may differ. There is no clear distinction between consecutive levels, except between the levels concerning problem posing skills and those which are lower than them.

It goes without saying that further research is needed regarding the levels of PS skills based on ST. Specifically, further studies could explore whether the developmental model which emerged from this study and the seven levels, which were identified, may also derive from a study measuring pupils skills in solving problems of
multiplicative structure. Furthermore, pupils' skills in solving two or three step-problems should be examined. Finally, there is a need to expand the model of measuring PS skills in order to refer to the next two types of knowledge (i.e. planning knowledge and execution knowledge). The findings of these studies may contribute in building a comprehensive model for PS skills based on ST.

THE ROLE OF INSCRIPTIONAL PRACTICES IN THE DEVELOPMENT OF MATHEMATICAL IDEAS IN A FIFTH GRADE CLASSROOM

Teruni Lamberg
Vanderbilt University

James Middleton
Arizona State University

The purpose of this report is to examine the role of classroom practices that emerged within a fifth grade classroom teaching experiment that helped coordinate and support student understanding of the Quotient construct through the invention, modification, and interpretation of inscriptions. Two types of inscriptions supported classroom discourse about quotients: Introduced inscriptions (those drawings and written marks offered to the class by the teacher or text materials as culturally appropriate forms of representing and communicating); and Ad-hoc inscriptions (those marks developed in situ by the students to convey their thinking). Through the use of public depictions of thinking, the classroom coordinated its practices by modifying Introduced forms to fit immediate demands of problem solving, and adopted the ad-hoc contributions of students to form a collective inscription retaining surface features and underlying meanings of both.

Theoretical Framework

The acts of doing mathematics and making sense of mathematical ideas takes place within the microecology (Lemke, 1997) of the classroom. They are reflected in the products created and used within the classroom microculture (Cobb et al. 1997).

Most research in the domain of rational numbers has been conducted from an individual psychological perspective, whereas most classroom instruction is done in a social system. The analysis conducted in this paper attempts to account for the developments that occurred in a fifth grade classroom during mathematics instruction over a five week period. Our reasons for conducting the analysis was motivated by understanding how students co-constructed a unified understanding of the quotient construct and also the mediational means through which knowledge was constructed within the microculture of the classroom. Therefore, the practices and the products that were created and used as representations of mathematical ideas within the context of the classroom were examined. The emergent perspective takes into account that mathematical learning is a process of active social construction and a process of enculturation (Cobb et al, 1997).
A representation is an idea, experience, or object symbolized in another form. Because mental operations take place inside the mind, it is difficult to see or understand another individual's thoughts without some sort of mediational process (Davis, Hunting, & Pearn, 1993). Therefore, individuals need to explicate their thinking using external forms of representations such as through inscriptions (e.g., concrete objects, pictures, and symbols (Roth & McGinn, 1998). These external signifiers (Whitson, 1997) serve as cultural models through which communities of individuals can coordinate thinking (Ball, 1993; Brown, Collins & Duguid, 1989, Greenu, 1991, Kaput 1994).

Representations not only serve as tools for thinking but also for communicating thinking. When a base meaning has been negotiated for a particular inscription, then this taken as shared meaning serves as a “boundary object” to coordinate activities and divergent viewpoints of several individuals, thereby facilitating the flow of resources (such as information, practices and materials) among the variety of individuals in a social setting (Roth & McGinn, 1998).

This means that as students think about a particular concept, they use various forms of inscriptions to record pertinent aspects of their thinking, and then use the set of inscriptions themselves as proxies for operating on the concept. Much of modern mathematics is dependent upon the systematization of inscriptions. In particular, when solving algebraic equations it is necessary to manipulate inscriptions and then retranslate the inscriptions back into conceptual forms is necessary (Kaput, 1999). New ideas are generated when new patterns of inscriptions signify different features of a concept than previously encountered (Ball, 1993).

Method

A five-week whole class teaching experiment was conducted in a fifth grade classroom in an urban school district in the Southwestern United States. Nineteen students and the classroom teacher participated in the study. An instructional unit based on Toluk's (1999) model of students' development of Quotient understanding was developed by the researchers and utilized as part of the instructional sequences. An Anchored Instruction (CTGV reference here) video was also developed as part of the instructional unit. The teaching experiment consisted of the following phases: classroom observation, clinical interview, teaching, analysis and hypothesis testing.

During the classroom observation process, whole group development and individual development were examined. The purpose of the classroom
observation phase was to establish the physical, social, and cultural context of the classroom as a contextual referent within which lesson activities and thinking took place. The clinical interviews of the teacher and selected students provided additional information on the cultural context of the classroom. The teaching phase consisted of the actual implementation of the instructional unit in the classroom over a period of four weeks. These lessons were videotaped. The researcher collaborated with the participating teacher informally to modify and discuss the progression of lessons immediately preceding and following each teaching episode. The researcher also served as a recorder of information by making field notes during the teaching phase.

During the analysis and hypothesis testing phases, the researcher analyzed the data collected from the classroom observations and student work. Student work was analyzed and coded. The videotapes were transcribed. The classroom discourse was analyzed in relation to the activity of creating and translating inscriptions to make meaning of the quotient construct. The hypothetical learning trajectory of the whole class was examined. The teacher and the researcher formally met once a week to discuss the findings and make modifications to the instructional unit based on the findings. The researcher identified the "essential mistakes" students made during the lessons from the analyzed data and used it as a basis for discussion with the teacher. The teacher thought about the essential mistakes students made, and reflected on how she could help her students to overcome them. These reflective sessions resulted in the teacher modifying her teaching practices and the researcher modifying the instructional unit.

Both whole group interactions and a focus group of 4 individual students were videotaped. Digital images of all marks made in students' notebooks were recorded. In the analysis, the creation and modification of inscriptions were used as a focus for examining the connections between students' individual knowledge construction, their contribution to the knowledge of the collective, and the ways in which the practices of the collective constrained those of the individual students. For example, students' written marks in their notebooks often were different than those depicted during whole group discussion. When a student chose to annotate or alter a mark at the board, we cited this as evidence of individual contributions to the collective inscription. The relationship between individual conceptual development and collective development was made by comparing these marks and how they changed over time. For example, when students' annotations in their individual notebooks changed following a whole group discussion, we cited this as evidence of the collective
practices constraining those of the individual. In recording the changes in inscriptions and the discourse that accompanied these changes, we were able to abstract a learning trajectory for the whole class, and note the individual inscriptions and thinking in the hypothetical learning trajectories of the individuals within the class. Normative inscriptive practices for creating and translating inscriptions within were noted during the teaching episodes as students engaged in whole-group discussion on a flip chart (all pages of the flip chart were displayed on the board throughout the 5-week teaching experiment).

Results

Students engaged in the practices of creating and translating inscriptions to make mathematical sense of the relationship between fractions and division with regard to the quotient construct. The whole-class learning trajectory emerged out of these practices. First the emergent collective learning trajectory will be briefly described, and then the inscriptive practices through which this learning trajectory emerged will be explained. Discussion will center on how these inscriptive practices became part of the classroom norms.

The learning trajectory established in the classroom corresponded to key uses of drawings and written marks. These changes roughly followed three Phases: In Phase I, students pictorially represented and solved fair sharing problems. They partitioned the unit into equal sized pieces and distributed them into groups to make equal shares. Initially students represented the answer as a whole number indicating the "number of pieces that made up each share. Then when asked "how much" the number of pieces represented in relation to the whole, students were able to symbolize the answer as a fraction. In Phase II, students focused on understanding that a fair-sharing problem represented a division relationship between two extensive quantities. They began to realize that this division relationship could be symbolized using the conventional notation of the fraction bar or a division symbol (÷, /).

In Phase III, students began to symbolically represent the fair-sharing problem and solution and started to think about the relationship between the division problem and solution in terms of quantities. Prior to this phase, students had been solving the fair-sharing problems using pictorial representations and then symbolizing the answers. Students first represented the answer of the fair-sharing problem as a fraction or a whole number and fraction on the right side of the number sentence. Then they proceeded to figure out how to symbolically represent the left side of the number sentence containing the division relationship between the quantities of the fair-sharing
problem. Therefore, students treated symbolizing the number sentence as a two-step process where they first symbolized the answer and then the division relationship. They thought about each side of the equation as quantities, but they did not focus on the relationship between the fair-sharing problem and answer as a number sentence.

Focusing Attention to the Immediate Problem Context

Students and teacher generated inscriptions on chart paper during whole group discussion to make thoughts and ideas explicit. The whole class focused their attention on the representational context of the person creating an inscription as he or she drew pictures, symbols, or wrote words. The person usually explained what the inscription represented and verbally recounted a running narrative of what he or she was producing. Simultaneously that person used gestures such as pointing and engaged in the act of writing or drawing on the chart paper to draw the whole class’ attention to the particular thought or idea being communicated.

The act of creating an inscription and providing an explanation coordinated the group’s attention to the immediate problem context. Therefore, the act of creating the inscription and the whole class’s focus on this action was situated. Even though there were other inscriptions (other parts of the same inscription) that had already been created and were visibly displayed, the whole class focused their attention on the part of the inscription that was in the process of being created.

Record of Distributed Thinking

Once an inscription was created during whole group discussions, then it became a historical record of the dialog that took place and hence, could be recalled as a common exemplar to which all participants could attach meaning. Furthermore, the inscription also represented multiple viewpoints of several different students within the group—i.e., such an inscription represented the distributed expertise of the group.

The types of socio-mathematical norms that emerged included: 1) proving or defending one’s idea in relation to another student’s verification; 2) model competition, and 3) explaining and clarifying another student’s thinking (e.g., perspective taking).

Inscription Became a Tool to Coordinate Student Attention to the Problem Context

Inscriptions were used as tools to focus student attention to the problem context. The inscription was used as a reference point to re-create previous conversations and actions. Most whole group mathematical
discussions that took place focused on uncovering "essential mistakes" or misconceptions that student were experiencing during that day's lesson or the previous day's activities.

The teacher influenced the focus and direction of the whole group conversation, which became part of the inscriptive practices that took place. In other words, the topic of conversation and the nature of the inscriptions were influenced by the actions of the teacher. The teacher also played an instrumental role through her questioning and statements to facilitate the coordination of inscriptions and dialog to make mathematical meaning.

Analyzing Another Student's Thinking About a "Taken-as-Shared" Inscription

Analyzing another student's thinking during the whole group discussions became another mathematical norm. In doing so, students were forced to actively think about another student's strategy and reasoning and relate it to how they thought about the problem.

Continuous Reconstruction of Meaning

Ideas recorded in inscriptions were continually re-examined throughout the teaching episodes and reconstructed in the process of developing meaning. Inscriptions were initially interpreted on a surface level. This meant that the students were focusing on examining what the immediate problem represented and what was required to solve the problem. A deeper level of understanding was reached when the students were able to connect their understanding of the immediate problem to the mathematical concepts that could be abstracted to another situation.

Discussion

In this paper, we have documented the role of inscriptive practices in the development of student understanding of the quotient construct over a five week period. In doing so, we have pointed out that the inscriptive practices that took place mediated the creation and translation of inscriptions which ultimately influenced the type of knowledge constructed as reflected in the learning trajectory that emerged. The inscriptive practices that took place were part of the classroom microculture and became part of the classroom norms. Therefore these practices must be taken into consideration when examining how knowledge is constructed in the classroom.

Agents and cultural tools mediate human action Wertsch (1998). The agents were the students and the teacher and the inscriptions represented the
cultural tools produced through interactions between the agents and the tools within the classroom. These interactions of creating and translating inscriptions to make sense of the quotient construct became the mediational means through which the learning trajectory emerged.

The inscriptive practices that are described in this paper also illustrate how ideas that were recorded as inscriptions were adapted and modified through time. Inscriptions became used as tools. The nature of a tool has meaning and significance based on the context in which it is used. A tool by itself does not have any significance. The use of the tool changes the situation and perception of the user (Wertsch, 1998). In this whole class teaching experiment, students created inscriptions as tools to make their thinking explicit and communicate their thinking to others. They translated inscriptions by examining them to make meaning. Inscriptive practices that took place represented individual contributions as well as the distributed thinking of the group. The usefulness and the meaning of these inscriptive practices must be understood with regard to the learning trajectory that emerged.

Lastly, the inscriptive practices described in this paper, because they packaged a complex discourse into relatively few retrievable exemplars whose structure embodied key features of quotients, afforded students the opportunity to revisit and build upon ideas efficiently to make sense of the quotient construct. The purpose of making sense of the division and fraction relationship to understand the concepts guided the meaning making that took place within the inscriptive practices. There was a continuity of ideas that were revisited and build over time through these inscriptive practices, as opposed to the inscriptions being generated as a series of disconnected activities (e.g., as "representations"—temporally static pictures with a fixed meaning). Therefore the nature of the inscriptive practices in a classroom can either afford or constrain concept building that takes place in the classroom.

Further investigation is needed to fully understand the role of inscriptive practices within the classroom. How do inscriptive practices get established as classroom norms in the classroom? What elements of the inscriptive practices can afford or constrain thinking?

REFERENCES

In this research work we explored the nature of 9-12 year old pupils' responses to probability problems. Analysis of pupils' arguments in 'Explain why' questions uncovered their thinking strategies, which we compared for pupils of different age and gender. The results revealed the existence of subjective elements and other errors in pupils' probabilistic thinking. The data were generated in year 2000 when the new mathematics books had just introduced probability extensively in the primary curriculum. Since the relevant literature in Cyprus is sparse, the results of the study form a general overview of the pupils' errors and build the basis for further in-depth and more focused research.

INTRODUCTION

Probabilistic thinking is a mode of reasoning attempting to quantify uncertainty, as a tool for decision making. A worldwide increased attention to probability and statistics is given and in Cyprus new mathematics books were written that introduced probabilities extensively in the primary curriculum. Nevertheless, pupils' probabilistic thinking is influenced by culture and is sensitive to cultural experience (Amir & Williams, 1994, 1999). There is, however, very little research in Cyprus focused on pupils' errors and probabilistic thinking (Gagatsis et al, 2001).

Research into pupils' capacity to compare two probabilities started with Piaget and Inhelder (1951). Following Piaget and Inhelder, other researchers have undertaken the study of pupils' abilities to compare probabilities (Green, 1983; Fischbein & Gazit, 1984; Canizares et al, 1997). Since comparing probabilities entails the comparison of two fractions, proportional reasoning is considered to be a basic tool of probabilistic reasoning. An important difference between comparing fractions and comparing probabilities is that the result of a proportional problem refers to a certain event, while the result of a probability problem implies a degree of uncertainty. Therefore, pupils' answers might be influenced by intuitive judgments. These intuitions are somehow some cognitive beliefs that sometimes may coincide with scientific accepted statements but some other times they may not or may contradict them. Furthermore, pupils consider subjective elements to assign probabilities.

In a previous study (Canizares et al, 1997) pupils' strategies, when comparing probabilities in tasks, were analysed and pupils' arguments were classified according to the following strategies: (a) Single variable
strategies (comparing the number of possible cases; comparing the number of favourable cases and comparing the number of unfavourable cases), (b) two variables strategies (additive strategies, correspondence and multiplicative strategies) and (c) other types (equiprobability bias, outcome approach, taking decision depending on other irrelevant aspects in the task).

It has long been known that pupils’ errors and misconceptions can be a starting point for effective diagnostically designed mathematics teaching (Williams & Ryan, 2000). If the teachers are aware of the most common errors and misconceptions that pupils have in probabilities, they will try to develop classroom strategies for helping students to confront them (Fischbein & Gazit, 1984; O’Connell, 1999).

This study aims to explore the probabilistic thinking of primary school pupils in Cyprus aged between 9-12 year old and to study the effect of age and gender.

**METHOD AND INSTRUMENT**

The research instrument was developed through several pilot steps. Informal unstructured interviews with pupils and teachers helped us to evaluate whether they interpreted the questions correctly. The pilot test was administered to pupils in Year 4 (90), Year 5 (51) and Year 6 (47).

The final version of the test consisted of nine questions clustered into three subtests. The first subtest consisted of Questions 1 and 2. Both tested the ability of the pupils to identify the most likely event from a single sample space (Single Variable questions). Question 1 was:

- **Q1**: There are 5 blue, 4 yellow and 3 green rubbers in a drawer. I pick a rubber randomly, without looking into the drawer. (a)What colour of rubber is more likely to pick? (b)Why?

The second subtest is cognitively more demanding than the first one. Questions 3, 4, 5 and 7 tested the ability of the pupils to define the probability of two independent events and to compare the two probabilities to decide which of the two events was the most likely.

- **Q3**: I have two bags with marbles. Bag A has 4 marbles, 2 blue and 2 green. Bag B has 6 marbles, 3 blue and 3 green. (a)From which bag do I have the largest probability of picking randomly, without looking in the bag, a blue marble? (b)Why?

- **Q4**: The yellow box contains 3 chocolate biscuits and 6 strawberry biscuits. The green box contains 1 chocolate biscuit and 2 strawberry
biscuits. (a) From which box would you prefer picking randomly a biscuit in order to have a larger probability to get a chocolate biscuit? (b) Why?

Questions 6, 8 and 9 tested the reactions of the pupils to additional but irrelevant information gathered from the every day life. It was noticed from the pilot test that some pupils omitted the quantitative information they were given (numbers) and focused on irrelevant information like the size of an animal, the size of a marble and the number written on a card.

• Q6: Andrew wants to decorate his Christmas tree. On the carpet, there are 4 big and 6 small golden balls. Since he does not care if he starts the decoration with a small or with a big ball, he selects randomly a ball from the carpet. (a) What is it more likely to select firstly, a small or a big ball? (b) Why?

• Q8: In a zoo there are 2 elephants and 4 monkeys. Today the staff of the zoo wants to choose randomly an animal to wash. (a) What is it more likely to choose, an elephant or a monkey? (b) Why?

THE SAMPLE

The final instrument was administered to 426 pupils in four different district schools in Cyprus, 222 boys and 204 girls. The sample consisted of 169 pupils in Year 4, 132 pupils in Year 5 and 125 pupils in Year 6.

RESULTS & DISCUSSION

Single Variable Strategies: Pupils’ correct responses can be based on intuition

In Question 1a, 381 pupils (90%) answered correctly but only 32 pupils (7.5%) explained their thinking strategy mentioning the concept of probability. Sub-questions Q1c, Q1d and Q1e asked pupils to identify the probability of drawing randomly a blue, a yellow and a green rubber. 44.8% of the sample gave a correct response to all three questions but 106 pupils (25%) failed to identify any of the probabilities correctly. 90 of them (21.2%) answered correctly that a blue rubber was more likely to be picked than a yellow or a green rubber. This result indicated that one to five pupils answered the question intuitively without being able to express in written any formal probabilistic thinking. Indeed, 87 of those 90 pupils explained that a blue rubber was more likely to be picked because “there are more blue rubbers in the drawer than rubbers of the other colours” but they failed to identify any of the probabilities of the three alternative events.

Single Variable Strategies: The effect of subjective elements

In Question 6, 69.7% of the sample answered correctly that it was more likely to pick randomly a small than a big ball. However, 72 pupils,
approximately 17% of the sample, responded that it was more likely to select a big ball. Approximately 11% supported their response by saying that "it is easier to pick a large ball than a small one" or "because the small balls are harder to pick" and other similar statements.

In Question 8, 76.8% of the sample answered correctly that it was more likely for the staff to randomly select a monkey than an elephant. In total, 19% explained their thought mentioning physical and other characteristics of the two animals. For example, 15% of the pupils based their answer on the physical size of the elephant. Other wrong explanations included information about the elephants being quieter or dirtier than monkeys. Four pupils from different classes mentioned that one elephant equaled two monkeys (probably in size), therefore, two elephants equaled 4 monkeys and, consequently, the probability to select a monkey or an elephant was the same.

In Question 9 we had comparable results. The results showed that the probabilistic thinking of some pupils might be influenced by subjective elements. The percentages of those pupils according to the three questions above might lie in the area of 11% (Q6), 19% (Q8) and 10% (Q9). These percentages may be significantly underestimated because sometimes it was difficult to distinguish from the written explanation whether pupils’ thought was influenced by subjective elements or not.

Two Variables Strategies: Comparisons between favourable or unfavourable events

In Question 3, only 21.1% of the pupils realized that the probability of getting a blue marble was the same in both bags. 257 (60%) of the pupils declared that they would have a larger probability of picking a blue marble from bag B. 246 of them (57.8%) explained their response in Question 3b by saying "bag B contains more blue marbles than bag A". From the responses of the pupils, it seems that they mainly compared the number of blue marbles in the two bags instead of the probability of getting a blue marble from each bag.

106 pupils (24.9%) gave correct responses to Q3c and Q3d that asked for the probabilities of getting a blue marble out of each of the two bags (they were ½ in both cases) but also claimed that it was more likely to get a blue marble out of bag B. Most of them explained that there were more blue marbles in bag B indicating that although these pupils knew how to find the relevant probabilities of the two events, they still used their own intuitive rules to take the decision of the most likely event.

In Question 4 we had similar results. Only 18.1% of the pupils realized that both boxes contained the same proportion of chocolate biscuits. 232
(54.5% of the sample) responded that the yellow box would give a larger probability to pick a chocolate biscuit. 218 of them (94%) explained their response by saying "there are more chocolate biscuits in the yellow rather than in the green box". Again, it seems that they focused on the number of chocolate biscuits in the two boxes instead of the proportion of chocolate biscuits in each box. 69 pupils (16.2% of the sample) gave correct responses to Q4c and Q4d that asked for the probabilities to get a chocolate biscuit out of each of the two boxes (1/3 in both cases) but used their own intuitive rule to answer incorrectly Question 4a. Questions 5 and 7 gave similar results with Questions 3 and 4.

**Construction of an ‘ability’ measure**

Eight of the nine questions of the test (excluding question 2) ask pupils to indicate the most probable between two events (e.g. to draw a blue marble from bag A or bag B) and to explain verbally their thinking strategy. A correct mark was awarded for a correct response to the question and one additional mark was awarded to the pupils whose explanation indicated a ‘correct’ probabilistic thinking strategy.

A Partial Credit Rasch model (Wright & Masters, 1982) was fitted on the data, using Quest. The mean difficulty for the questions was constrained to zero (SD=1.18 logits) and the reliability of question difficulty estimates was 0.96. The mean of the pupils’ ability was -0.18 logits (SD=0.98 logits) and the reliability of pupil estimates was 0.66. All questions had a satisfactory fit. The test and the sample may be interpreted as falling into a hierarchy of three levels (Figure 1).

At level A (-2.5 to -1.5 logits) pupils can succeed on answering correctly questions that tested for the identification of the most likely outcome from a single sample space (Single Variable problem). At level B (-1.5 to 0 logits) pupils can succeed on answering correctly questions that tested for the identification of the most likely outcome from a single sample space (Single Variable problem) without being carried away from subjective elements (e.g. elephants are quieter than monkeys). At level C (0 to 2.5 logits) the pupils can succeed on answering correctly even harder questions, which ask them to compare the probabilities of two independent events and decide which of the two is the most likely to happen (Two Variables problems). Pupils at higher level can also answer correctly the questions of the previous levels.

According to Figure 1, a percentage of pupils was influenced by the ‘Subjective Elements’ effect (from 10% to 19%). In general, this type of error is more representative of pupils of low ability. The mean ability of the pupils who made the errors associated with the ‘two variables’ is near
to the mean ability of the sample. The percentage of pupils making this error is relatively large (47\% to 66\%).

The pupils in Year 4 are significantly less able than pupils in Year 5 and Year 6 (F=17.35, df=2, p<0.01). The difference in the average ability of the three year groups (average ability: Year 4 = -0.52; Year 5 = 0.03; Year 6 = 0.12) was significant only between pupils in Year 4 and in Year 6.

Construction of the ‘likelihood ability’ measure

Some of the questions of the test were followed by sub-questions, which asked the pupils to identify the likelihood of certain events. A mark was awarded for each correct response and the simple Rasch model was fitted on the data, using Quest. The mean difficulty for the 13 questions was constrained to zero (SD=1.2) and the reliability of question estimates was 0.98. The mean ability for the pupils was -0.05 (SD=2.03) and the reliability of ability estimates was 0.83. The fit statistics were satisfactory except for one question, which was only marginally satisfactory.

The correlation between the ‘likelihood ability’ (ability to quantify the likelihood of events) and the ‘ability’ (performance to the test) of the pupils is 0.58, which is not as high as expected. Indeed, this showed that it was not necessary for the pupils to be able to quantify the probabilities of the events in order to give correct responses to the questions of the test.
It is possible that the pupils were able to answer the questions intuitively and the ability to numerically identify the likelihood of the events was not a prerequisite.

Predictors of pupils' 'ability'

The test included 8 questions, which asked the pupils to compare two fractions, similar to the ones used in the probability questions. This subtest was administered only to 223 pupils. A mark was awarded for each correct response and the distribution of pupils' scores had a mean of 4.7 and SD=2.5. The correlation between the 'ability' measure and the raw score in the fractions sub-test is 0.37; not as high as might be expected.

A multiple regression model was attempted using pupils’ ‘ability’ as a depended variable and the ‘fractions raw score’, the ‘likelihood ability’, the gender and the age as predictors. The stepwise procedure accepted in the model only two terms: the ‘fractions raw score’ and the ‘likelihood ability’ (R2=0.38). When the ‘fractions raw score’ was not included in the predictors, the stepwise procedure kept only the predictor 'likelihood ability' in the model with almost no loss of information (R2=0.33). Gender and age were not good predictors of ‘ability’.

CONCLUSION

We have managed to develop two scales describing pupils' responses to the instrument, which is revealing about their probabilistic thinking, especially as regards their inappropriate use of intuitions. We have further identified from pupils’ responses that some pupils were influenced by other irrelevant aspects in the tasks (subjective elements). The knowledge that teachers would collect from these scales would enrich teachers’ mental models of their learners and would help them improve their classroom practice.

Having collected these data, however, we should further continue interviewing pupils in order to shed more light into pupils' probabilistic thinking. Further research into pupils' probabilistic reasoning would be an essential step for selecting teaching and assessment situations. We will be studying this aspect in the next stage of the work.

"What if not?" Problem Posing and Spatial Geometry - A Case Study

Ilana Lavy, Emek Yezreel College
Irina Bershadsky, Technion - I.I.T, Haifa

Abstract
The aim of the study was to try to find out what kinds of problems are posed by prospective teachers on the basis of complex spatial geometry tasks using the "what if not?" strategy, and what is the educational value of such an activity. Analyzing the posed problems revealed a wide range of problems ranging from problems including a change of one of the numerical data to another specific one, to a proof problem. We also discuss the educational aspects of problem posing in spatial geometry using the "what if not?" strategy, which could encourage the learner to rethink spatial geometry concepts and make connections between them.

Background
Generally the term "problem posing " refers to three kinds of cognitive activities: (a) posing sub-problems within the process of solving a complex problem; (b) posing new problems on the basis of a solved problem; (c) posing problems regardless of the referred problem solution (Technai, 2001). Three types of problem posing can be distinguished in regard to posing new problems on the basis of a given problem: problem posing on basis of free, semi-structured and structured problems (Southwell, 1998). The term "problem posing" in the literature usually refers to an activity in which the problem posing itself is the focus of attention and not as a problem-solving tool.

This study focuses on problem posing on the basis of a given structured problem using the "what if not?" strategy (Brown & Walter, 1993). According to "what if not?" strategy, we examine each component of the problem and manipulate it through the process of asking "what if not?"

The problem posing role in students' mathematics learning

During the study of school mathematics, students experience problem solving. Usually they get the problems from the math teacher or from text books and only rarely are they asked to pose problems of their own. Mathematics educational researchers emphasized the important educational value of problem posing by students and suggested incorporation of activities of problem posing within the mathematics sessions in school (Goldenberg, 1993; Leung & Silver, 1997; Mason, 2000; NCTM, 2000; Silver, Mamona-Downs, Leung & Kenney, 1996). The importance of an ability to pose significant problems was recognized by Einstein and Infeld (1938), who wrote:

"The formulation of a problem is often more essential than its solution, which may be merely a matter of mathematical or experimental skills. To raise new questions,
new possibilities, to regard old questions from a new angle, require creative imagination and marks real advance in science" (p.92) (in Ellerton and Clarkson (1996).

Students who engage in problem posing activities become enterprising, creative and active learners. They have the opportunity to navigate the problems they pose to their domains of interest according to their cognitive abilities (Goldenberg, 1993; Mason, 2000). Studies show that problem posing might reduce mathematics anxiety (Brown & Walter, 1993; Moses, Bjork & Goldenberg, 1990). Including activities of problem posing might improve the students' attitude towards mathematics and make them more responsible for their learning (Brown & Walter, 1993; Silver, Mamona-Downs, Leung & Kenney, 1996). Researchers emphasized the inverse process in which developing of problem solving skills can be helpful to the developing of problem posing skills (Brown & Walter, 1993).

The problem posing role in teachers’ mathematics learning

Developing skills of mathematical problem posing is important for mathematics teachers as well (Silver, Mamona-Downs, Leung & Kenney, 1996; Southwell, 1998). Southwell (1998) found that posing problems based on given problems could be a useful strategy for developing the problem solving ability of prospective mathematics teachers. Integrating problem posing activities in their mathematics lessons enabled them to get to know their students' mathematical knowledge and understanding better. Since teachers have an essential role in the use of problem posing activities in their mathematics classrooms, they should develop their own problem posing skills (Leung & Silver, 1997).

The study

In the present study we explored two questions:
1. What are the kinds of problems posed by prospective teachers on the basis of complex spatial geometry tasks using the "what if not?" strategy?
2. What is the educational value of posing problems using the "what if not?" strategy referring to spatial geometry?

Eighteen prospective teachers participated in the present research. The participants were participating in the "teaching methods for secondary school mathematics" course in which they were introduced to methods and activities referring to central topics studied in school. The participants were asked to pose as many problems as possible on the base of the following problem:

Find the distance from the center of the base of a regular triangular pyramid to the pyramid’s lateral face given that the pyramid’s height is 10 cm and the dihedral angle (the angle between the two faces) is 67°.
Our data comes from two sources:
(1) written protocols submitted by the participants.
(2) clinical interviews with several participants.

Results and discussion

The problems posed by the participants can be divided into two main categories: changing one of the given problem components; changing the problem question. Each one of the above categories was refined into subcategories, which we describe below. The changing of one of the components given in the problem can be divided into two subcategories: 1. Changing of the numerical value of the data; 2. Changing of the kind of data. The subcategory "Changing of the numerical value of data" refers to:

1.1. A change of a specific numerical value, given in the problem, to another one. For example, the pyramid height was changed from 10 cm into 12 cm.
1.2. A change of a specific numerical value, given in the problem, into a range of values. For example, the angle between the lateral faces was changed from 67° into an angle between 67° and 90°.
1.3. Negation of the specific numerical value given in the problem. For example, what if the height is not 10?
1.4. Implied generalization of the given numerical value of data. For example, the height of the pyramid is not 10 cm (for example, 12, 20 and so on).

The subcategory "Changing of the kind of data" refers to:

2.1. A change of a specific kind of data, given in the problem, into another kind. For example, from a triangular base pyramid to a square base pyramid.
2.2. Negation of the given data kind. For example, what if not a pyramid?
2.3. Generalization of the given data kind. This sub-category can be divided again into implied and formal generalization. The term "implied generalization" refers to the participants' answers in which they offered a number of alternative examples to the negated component of the problem finishing their answer by the words: "and so on". This term is taken from a similar classification of students' utterances in Lavy (1999).
2.3.1. Implied generalization of the given data kind. For example, a pyramid does not have a triangular base (for example, quadrangular, pentagonal and so on).
2.3.2. Formal generalization of the given data kind. For example, the pyramid has an n regular polygon base.

The second category "Changing of the problem question" refers to another specific question. For example find the pyramid base area. It can be referred also to the changing of the given problem into a proof problem, for example, proof that sin α/2 = 5/8 while the relation between a lateral edge of the regular triangle pyramid to the base edge is 5/9.
The sub-categories related to the negation of one of the problem data components could be considered as an uncompleted new posed problem, since the participants did not offer an alternative to the negated data component.

To visualize our findings, we draw the following diagram:

Diagram 1: Classification according to data and question change

In cases where we had difficulty deciding to which category a suggested posed problem belongs, we were aided by the participant's interview. For example, the participant’s utterance "what if not a triangle?" was interpreted as an implied generalization. Since in other posed questions of the same participant when he or she indicated another specific shape, he or she wrote so explicitly.

Classification of the posed problems reveals a wide range of problems ranging from easily phrased problems to the inverting of the original problem to a proof problem. The term "easily phrased" problems, refers to the change of one (or more) components in the original numerical data to another specific one. The study revealed that the number of posed problems with another numerical value had a greater frequency than generalized posed problems (9 versus 3). It could be explained that posing another numerical example is a common activity in mathematics lessons in school and students are more familiar with this kind of activity than with posing generalized problem on the base of the numerical data. In other words, it could be said that when students are asked to pose a new problem on a basis of a given numerical data problem, the technical and the immediate widespread strategy is to pose a similar problem with another numerical value. Analyzing the solution of numerical data problems during school mathematics, is not a common activity (Polya, 1981; Schoenfeld, 1985). The solution analysis
including the testing of different numerical values could result in problems with another type of solution (if any) and might lead eventually to problem generalization. In addition, posing a generalized problem on a basis of a given problem is a complex cognitive activity rather than a technical change.

Another issue referring to posing problems with different numerical data emerged from Maria's interview. Observing her posed problems revealed that none of them included similar problems with new numerical values.

Maria: "What if the height is not 10 cm? If I had the problem solution I would have seen how the change of height influences it. Without the solution it is difficult for me to decide what to take instead of 10. Maybe there is a number that doesn't influence the solution, but may be there exists a value that will change the problem to another one with a different way of solution".

From the above excerpt it follows that Maria added another constraint to the given task. She strove to pose problems that will have another mathematical solution, different from the original one and not just a cosmetic solution change. If she had solved the problem first, it could have helped her to estimate new numerical values that could lead to different ways of solution.

Maria: "It was difficult to me at the beginning. I did not know where to start. When I solve the problem I know what I am using, and what can influence the solution. Without the solution it is difficult for me to visualize influential changes, that will lead eventually to a reasonable solution. I felt I needed to solve the problem first. I tried to pose a problem, but I could not come up with anything".

According to Maria's interview the fact that the participants were not asked to solve the problem first prevented her from posing meaningful new problems.

Julia, on the other hand, said that it was easy for her to pose many problems on the basis of the given one, emphasizing that if she had to solve the given problem first, she would have difficulties in posing many new problems.

Julia: "Because you do not see the spatial problem, you are in the computing process. You become technical and after that you cannot disconnect yourself".

Julia needed the overview of the problem to be able to pose many new problems on a basis of the given one. For her, getting into the solution process diverted her attention from having the global viewpoint that enabled her to focus on the activity of posing problems.

Students differ in their view as to the assistance that a familiarity with a solution provides in problem posing.

One of the interesting phenomena is the lack of posed problems including formal generalization and the relatively small number of posed problems including implied generalization. As to posing problems including implied generalization, there is a difference between the number of posed problems including changing of numerical data versus posed problems including generalization of the given geometrical shape. The process of generalizing the numerical value of data in geometric problems leads to the analysis of extreme cases such as zero. Most of
other numerical data changes cause mainly a cosmetic change of the problem, while the change of the data kind usually offers a new problem with a totally different solution.

Observing carefully the data reveals also that in "data kind change" posed problems there were more changes of plane data kind than spatial data kind (9 versus 2). There was a small scope of spatial shapes than of plane shapes in the posed problems. The most common plane shape was a square and it can be explained that the common students' example for a quadrangle is a square (Hershkowitz et al., 1990).

Considering the educational aspect of problem posing in spatial geometry using the "what if not?" strategy, such an activity makes the learner rethink different spatial geometry concepts. For example, questions such as "what if not a pyramid?" or "what if not a regular pyramid?" require the learner to know and understand the relevant geometrical concepts appearing in the problem and at the same time to think of the meanings and outcomes emerging from the negation of them. For example, if the concept in the given problem is a pyramid, the learner should know and understand the pyramid definition and think of the potential alternative concepts that might replace this concept, such as a cube, in the process of posing problem using the "what if not?" strategy. Concerning the question: "what if not a regular pyramid?" we will refer to the following paragraph from Maria's interview:

Interviewer: "Let's have a look at your posed questions. Could you clarify some of them? You wrote, what if not a pyramid? What did you mean?"

Maria: "Another shape, cone or rectangular parallelepiped. What if not a triangular pyramid: quadrilateral, pentagonal or any other polygon. What if not a regular pyramid: regular means that all the triangles are equilateral triangles...no...[mumbling] only the base, the others are isosceles. What if not equilateral triangular base, but isosceles triangle or anything."

Observing Maria's posed problems during the workshop made us decide to interview her, since Maria posed, in comparison to others, many problems which had a foggy formulation and we thought it would be helpful for our analysis to get some clarifications. We asked Maria to tell us what she meant by her posed problem: "what if not a pyramid?" and her answer appears in the first part of the quoted paragraph. As to the question "what if not a regular pyramid?", Maria was thinking aloud about the meaning of a regular pyramid: a pyramid composed of equilateral triangles which later on she corrects herself to the definition that only the pyramid base has to be equilateral and the pyramid faces should be isosceles triangles. Maria's rethinking creates a new problem, which negates the regularity property of the pyramid. "What if not equilateral triangular base, but isosceles triangle or anything else."

Maria posed a new problem using the negation of the pyramid base regularity property. By doing so, she created a non-regular pyramid since its base is not an..."
equilateral triangle anymore. As an alternative to the given pyramid base, she offered an isosceles triangular base or non particular triangular base.

In order to be able to raise problems using the "what if not?" strategy, Maria deconstructs the term "regular pyramid" into a list of properties which define this term, negates one of them and builds an alternative geometric entity. The act of thinking reflectively about the properties of a certain geometric shape and the geometric implications emanating from the negation of one of the properties is a cognitive activity leading to deeper understanding of the relevant geometric terms. If we continue the same line of thinking, several other problems could be raised such as: what if the pyramid is not right? What if the pyramid faces are also equilateral triangles? What if the pyramid consists of scalene triangles? etc. Such a discussion could contribute to strengthening the connections between the various geometric terms and as a result to deepen the understanding of them.

An additional educational benefit of problem posing using the "what if not?" strategy is connected with the following issues: Whether the data change of one (or more) of the given problems leads to a solvable or unsolvable problem? Whether the created problem solution is totally different from the original one or are there only cosmetic changes in it? These issues appear in diagram 2.

The second classification we made was the influence of data change on the solvability of the problem and its solution.

![Diagram 2: Classification according to data influence on the problem solution (if any)](image)

Although our study is a case study, we found interesting phenomena with educational and learning benefits. The present case study raises some questions, which could be the basis to further studies, such as:

1. How can we cause learners to "produce" new correct mathematical problems?
2. How can we explain the phenomena of raising many problems (or few) and the reasons for it?
3. Does solving the given problem first influence the posing of problems based on it?
The activity of posing new problems on the basis of a given spatial problem made the students interact with their geometrical knowledge and use it as a basis for both a widening and deepening of their understanding.

References:

Recent literature indicates that there has been some change since Freudenthal (1973) expressed concern for the future of geometry instruction. This has mainly been due to research based around the van Hiele Theory. However, in the field of 3-dimensional geometry there is still room for great concern. In analysing the understanding expressed by students in their descriptions of a cross-section of a solid, the authors present a frame that has the potential to be used for curriculum development in 3-dimensional geometry.

While researchers lament the lack of importance attached to geometry in school curricula (Freudenthal 1973; Meissner 2001; van der Sandt 2001), they are unanimous in their espousal of its importance. Geometry offers a way to interpret and reflect on our physical environment, while spatial thinking has been suggested to be essential to creative thought. Recent literature (Meissner 2001; van der Sandt 2001) suggests that little has changed since Freudenthal (1973, p.402) expressed fears that "the days of traditional geometry are counted, ... there is cause to be concerned about the future of geometry instruction. The lack of attention to solid geometry is matched by the lack of published research on the topic. The only research reports on 3-dimensional geometry published in recent years appear to be on nets of solids (Despina, Leikin & Silver 1999; Lawrie, Pegg & Gutiérrez 2000; Mariotti 1989). Mariotti (p.260), in attempting to identify specific didactic variables related to the utilisation of mental images, hypothesised that there are two levels of complexity; the first level is when the image is global, and the second occurs when an operative organisation of images is required for coordination. Lawrie, Pegg & Gutiérrez (2000), in their analysis of students' responses expressing understanding of a net, demonstrated that there is a hierarchy of difficulties within Mariotti's second level.

If one considers geometry to be the poor relation of mathematics, 3-dimensional geometry must surely be the Cinderella. If the above situation is to be addressed, there is need first to address development of school curricula. A framework
demonstrating the didactic hierarchy in 3-dimensional geometry needs to be determined.

**RESEARCH DESIGN**

The authors developed a test to investigate secondary-school students' understanding of various aspects of 3-dimensional figures, i.e., the solid form and its cross-sections, and nets of 3-dimensional figures. The analysis of students' perceptions of nets of solids has already been presented by Lawrie, Pegg & Gutiérrez ((2000). This report considers the coding of the students' responses to a second aspect, one in which students express their understanding of cross-sections of 3-dimensional figures. A cross-section is defined as:

A section is a plane geometric configuration formed by cutting a given figure with a plane. A *cross-section* is a section in which the plane is at right angles to an axis of the figure.

Daintith & Nelson 1989, p.290

Two frameworks, the SOLO Taxonomy (Biggs & Collis 1982) and the van Hiele levels of understanding (van Hiele 1986) are used in coding the nature of thinking displayed by the students in their responses.

**BACKGROUND**

**The SOLO taxonomy**

The SOLO Taxonomy (Biggs & Collis 1982) has been identified by several writers (e.g., Pegg & Davey 1998) as having strong similarities with the van Hiele Theory, despite some philosophical differences. It is concerned with evaluating the quality of students' responses to various items. A SOLO classification involves two aspects. The first of these is a mode of functioning, and, the second, a level of quality of response within the targeted mode. Of relevance to this study are the three modes, ikonic, concrete symbolic, and formal. Within each of these modes, students may demonstrate a unistructural, multistructural or relational level of response.

In the *ikonic mode* students internalise outcomes in the form of images and can be said to have intuitive knowledge. By contrast, in the *concrete symbolic mode*, students are able to use, or learn to use, a symbol system such as a written language and number notation. This is the most common mode addressed in learning in the upper primary and secondary schools. When operating in the *formal mode*, the student is able to consider more abstract concepts, and to work in terms of general principles.

A description of the levels that occur within the modes is given:

The *unistructural level* of response draws on only one relevant concept or aspect from all those available.
The multistructural level of response is one that contains several relevant but independent concepts or aspects.

The relational level of response is one that relates concepts or aspects. These relevant concepts are woven together to form a coherent structure.

The targeting of the concrete symbolic mode for instruction in primary and secondary schools, and the implication that most students are capable of operating within the concrete symbolic mode (Collis 1988) has resulted in the exploration of the nature of student responses within that mode. This has led to the identification of at least two unistructural (U) - multistructural (M) - relational (R) cycles within the concrete symbolic mode (Pegg & Davey 1998). One noticeable characteristic of the cyclic form of the levels is that the relational response (R₁) in the first cycle becomes a single entity as the unistructural element (U₂) in the second cycle. This cyclical nomenclature has been used in the coding of concrete symbolic responses for this study.

The van Hiele Theory

Pierre van Hiele’s (1986) work developed the theory involving five levels of insight. A brief description of the first four van Hiele levels, the ones commonly displayed by secondary students and most relevant to this study, is given for 3-dimensional geometry (Pegg’s (1997) differentiation between Levels 2A and 2B is used):

Level 1  Perception is visual only. A solid is seen as a total entity and as a specific shape. Students are able to recognise solids and to distinguish between different solids. Properties play no explicit part in the recognition of the shape, even when referring to faces, edges or vertices.

Level 2A  A solid is identified now by a single geometric property rather than by its overall shape. For example, a cube may be recognised by either its twelve equal edges or its six square faces.

Level 2B  A solid is identified in terms of its individual elements or properties. These are seen as independent of one another. They include side length, angle size, and parallelism of faces.

Level 3  The significance of the properties is seen. Properties are ordered logically and relationships between the properties are recognised. Symmetry follows as a consequence. Simple proofs and informal deductions are justified. Families of solids can be classified.

Level 4  Logical reasoning is developed. Geometric proofs are constructed with meaning. Necessary and sufficient conditions in definitions are used with understanding, as are equivalent definitions for the same concept.

Van Hiele saw his levels as forming a hierarchy of growth. A student can only achieve understanding at a level if he/she has mastered the previous level(s). Van Hiele also saw (i) the levels as discontinuous, i.e., students do not move through the
levels smoothly; (ii) the need for a student to reach a 'crisis of thinking' before proceeding to a new level; and (iii) students at different levels speaking a 'different language' and having a different mental organisation.

ANALYSIS OF RESPONSES

The 3-dimensional geometry test designed by the authors was given to students from all except the final year (i.e., to Years 7 to 11, ages 12 to 17 years) of four secondary schools in a rural city in New South Wales, Australia. The students were of mixed ability, and were not drawn equally from across the years; rather, the researchers were dependent on the availability of classes and the goodwill of the schools and their teachers. This resulted in there being many more students from Years 7 and 11 than from Years 8, 9, and 10.

Because of page limitations, this paper considers in depth the responses to one of the questions on cross-section of 3-dimensional figures, namely:

"Describe in as much detail as possible what is a cross-section of a solid."

An indication of the difficulty students experienced with the notion of cross-sections is that only 181 students attempted the question. The response rate differed across the various years, with 18, 12, 31, 51 and 69 from Years 7, 8, 9, 10 and 11 respectively. It should be noted that in Australia cross-sections are considered in a global sense in primary schools and are not considered in any greater depth until late in Year 8, with further treatment in Years 9 and 10.

Analysis of responses (SOLO)

The responses were coded first with relation to the SOLO Taxonomy. Of the 181 responses, it was possible to code 177 (98%); only 4 responses were considered uncodable. No responses were identified as belonging to either the ikonic or formal modes, i.e., it was considered that all responses were concrete symbolic.

Initially, the responses were classified according to their cycle within the mode. This was done depending on whether a response expressed the notion of a cross-section being a single cut or halving of the solid (first cycle), or whether the response inferred multiple cuts or slices (second cycle). After considering several features in responses, e.g., the cut, direction, result of the cut, together with various combinations of these, it was felt that the significant factors for indicating levels in the responses were:

- single versus repeated cut(s) or slice(s);
- whether the result of the cut(s)/slice(s) was acknowledged;
- qualification of the result, i.e., the linkage between the cut(s)/slice(s) and the result(s).

The term 'slice' rather than 'cut' was used frequently by students giving second-cycle responses, yet did not appear in responses of the first-cycle. In the first-
cycle responses, students frequently used the terms 'cutting in half', 'cutting down the middle', 'bisecting'. Almost all students applied their notion of a cross-section to figures with a constant cross-section (prisms and cylinders), not mentioning cross-sections of pyramids nor 3-dimensional figures in general.

This initial classification of responses led to the following description of each SOLO level, U, M, R, for the two cycles in the concrete symbolic mode (Table 1).

**Table 1: Response descriptors for SOLO levels with examples of student responses**

<table>
<thead>
<tr>
<th>Level</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Single cut</strong></td>
<td></td>
</tr>
</tbody>
</table>
| U₁ | One cut  
  e.g., cut a solid in half; a solid is divided through the middle. |
| M₁ | One cut and look at the result  
  e.g., what you see when you cut a solid into two pieces; cut down the middle and the cross-section is the result. |
| R₁ | The effect of the cut; qualifying the 'look'  
  e.g., It is when you cut it in half and both sides match. |
| **Multiple cuts/slices** | |
| U₂ | Multiple cuts/slices  
  e.g., when the solid is cut straight anywhere; ... is cut into slices. |
| M₂ | Multiple cuts/slices and the resulting shape stays the same  
  e.g., A cross-section of a solid is an imaginary line that can be cut anywhere so that the same shape remains throughout. |
| R₂ | Direction of the cut is the integrating factor that links multiple cuts and same shape  
  e.g., The section where the solid is cut down, parallel to the front face. The cross-section is the same shape as this face. |

Of the four responses considered not able to be classified in accordance with the descriptors listed in Table 1, two very similar responses appeared to reflect the appearance of a pyramid if viewed from above the vertex:

*The cross-section of a solid is the section where, when drawn, all the vertices intercept each other; straight down the middle.*

In the third response the student, while demonstrating understanding of the general concept of a cross-section, gave a response for topography;
The shape meaning the ascension and descensions of the shape – just like the cross-section from one point to another on a topographic map.

The fourth student's response seemed to reflect general geometric awareness, but no specific knowledge of a cross-section:

A particular part to the solid, looked at thoroughly unto detail. Things which might be taken into account are length of sides, edges.

The results of the analysis of the 177 responses are shown in Table 2. As the number of students giving a response to the question varied, results of the analysis will be given as percentages in parenthesis after the number of students.

Analysis of responses (van Hiele)

The students' responses were also coded according to the van Hiele levels of understanding. It was considered that there were no students displaying understanding at either Level 1, the visual level, or at Level 4, the formal level in which logical reasoning can be demonstrated. All students were considered to be displaying reasoning at Level 2A, i.e., identifying a single geometric element, Level 2B, i.e., identifying individual elements, or at Level 3 in which students display a degree of analysis or logical ordering. Table 3 gives descriptors of the van Hiele levels and the correspondence with the SOLO levels, and Table 4 gives the results of the analysis of student understanding as van Hiele levels. Again, percentages are given in parenthesis.

CONCLUSION

The analysis given in this report demonstrates a hierarchy of difficulties in the understanding of cross-sections of solids. Not only does the hierarchy fit into Mariotti's (1989) second level of complexity in the manipulation of mental images in which an operative organisation of images is required for coordination, it also provides a frame for the development of a curriculum for instruction in cross-sections of 3-dimensional figures. This frame could be expanded to encompass the study of the whole of 3-dimensional geometry and spatial reasoning. However, care should be taken that within a curriculum, adequate time is allotted to the various hierarchical strata demonstrated above as levels in the two SOLO cycles. In particular, there should be adequate time allowed for students to develop through the first SOLO cycle, thus allowing students to come to an understanding of Level 2A in van Hiele. Instructors, in observing students from their higher level of understanding, do not always consider the importance of establishing sound understanding at the lower levels. To move students from one level to the next requires interaction between the teacher, students and subject matter and interaction requires time.

Mathematics Pedagogical Value System Oriented Towards the Acquisition of Knowledge in Elementary School

*Yuh-Chyn Leu **Chao-Jung Wu

* Department of Mathematics Education, National Taipei Teachers College, Taiwan, R. O. C.
** Department of Educational Psychology & Counseling, National Taipei Teachers College, Taiwan, R. O. C.

The purpose of this study is to investigate the mathematics pedagogical values of a fifth grade elementary school teacher. The main methodology encompasses classroom observations and interviews. The result of the research reveals that the teacher has three mathematics pedagogical values, which are emphasized differently. However, the statement “the goal of mathematics teaching is to induce students to acquire knowledge from the textbook” serves as the main core of these three values.

Introduction

After six years of development and pilot tests, a new national elementary mathematics curriculum in Taiwan was launched in 1996. The new curriculum emphasizes on problem solving, communication, reasoning and mathematical connections, as the Standard in the United States stressed (NCTM, 1989). The reform-oriented modes of teaching tend to transfer from teacher-centered lecturing into pupil-centered learning, and put more emphasis on group discussions than classroom lecturing. Taiwan’s elementary schools’ mathematics curriculum and teaching is deeply influenced by that of the West. Do we have to cogitate if this approach is suitable in Taiwan’s education environment? Is this approach worthy of advocating? When we are considering if it is worthwhile, we shall discuss about the mathematics pedagogical values we hold.

Mathematics pedagogical value is a new research domain (Chin, Leu, & Lin, 2001; Bishop, FitzSimous, Seah, & Clarkson, 2001). According to the view of Bishop et al, there is widespread misunderstanding that mathematics is the most value-free of all academic subjects. Since mathematics is human and cultural knowledge, teachers inevitably teach values at mathematics class. It is generally agreed that the quality of mathematics teaching would be improved if there were more understanding about teachers’ values and influences. But what are those salient values regarding mathematics, mathematics education and education in general, that Taiwan’s experienced elementary school mathematics teachers have?
Do those values accord with current education policies?

In this paper, the values regarding mathematics education are investigated. We identified an elementary school teacher’s three mathematics pedagogical values, disclosing the relationship among these values.

**Sample and Methodology**

The research sample of this study was Ms. Lin, who has had nine years of teaching experience in elementary school. She is currently teaching one class of twenty-seven fifth graders. In the first interview, she mentioned that “I would give extra exercises to my class in addition to the official workbook”, “I felt a lot of pressure following the syllabus since there was too much material in the textbook for fifth or sixth graders”, and “I struggled a lot because I felt that I was unable to help students obtain good scores”. These thoughts were typical of the views expressed by most elementary school teachers when asked about their mathematics teaching experience in Taiwan. They emphasized good scores, asked students to do more exercises, and felt lots of pressure to follow the syllabus. Hence, we chose her as one of our research subjects.

According to the theory of the process of valuing by Raths, Harimn & Simon (1987), values are defined as any beliefs, attitudes, activities or feelings that satisfy the following three criteria: choosing, prizing, and acting. What satisfies the criterion of choosing is the belief or attitude chosen under free will, among several differing options or after thorough consideration. What satisfies the criterion of prizing is the belief or attitude of cherishing showing pride of or willingly made known publicly. The belief or attitude that satisfies the criterion of acting is a performance acted out repeatedly.

Based on Raths et al’s theory, we used classroom observations and interviews to collect data. The purpose of classroom observation is to notice repeated behavioral patterns during the mathematics lessons. The purpose of the interviews is to recognize the reasons why Ms. Lin developed these behavioral patterns in order to form some value indicators, as well as to examine if the value indicators met the criteria of “choosing” and “prizing”. The time for research is one year. Ten lessons are observed and 18 interviews are conducted.

**Results**

Ms. Lin’s three mathematics pedagogical values are of the following goals: to teach students to acquire mathematics textbook knowledge, to have students enjoy learning mathematics, and to use mathematics in solving their daily problems. According to Raths et al’s theory (1987), we present our data in attempt to explain Ms. Lin’s first acting value under the criteria of acting, choosing, and prizing. The
latter two values are only outlined briefly.

In the following excerpts, “I” stands for the interviewer and “S” for Ms. Lin’s students.

1. **Acquiring knowledge from the mathematics textbook**

   **Acting**  Ms. Lin instructed her students to preview the mathematics material before the respective class because she believed that preparation would help her students to understand the lectures more easily. Besides, preparation also allowed the more capable students to help explain the contents in the mathematics textbook to the class as teaching assistants.

   Ms. Lin’s teaching method consisted in teacher-centered lectures. She admitted that she liked being given the leading role to lecture. She usually requested students to read out loudly the textbook problems and then they were explained by the teacher. Then, she guided students to solve problems by additional practice testing questions (Ainley, 1988), as demonstrated in case 1.

   **Case 1**

   (A problem on page 93 of the textbook: Draw a circle with a diameter of 5 cm, and then compute the circumference of this circle.)

   Lin: What is π? 3.14. In other words, how many times of diameter is the circumference? 3.14. Since we know the diameter, how do you solve this problem then? How many times should the diameter be multiplied by?

   S: 3.14.

   Lin: The answer is the diameter times by 3.14, isn’t it? Thus, the answer to this problem is 5×3.14 = 15.7.

   A self-answering questions style by the teacher is often adopted in the classroom, such as “What is π? 3.14.” in the above case. There are also some testing questions such as, “How many times should the diameter be multiplied by?”. Taking a forty-minute classroom observation on June 8th, 1999 for example, there were 24 questions which she raised and answered on her own, as well as providing 69 practice testing questions in that class.

   Sometimes, Ms. Lin would have students solve problems on the podium and explain the solutions to all students. She said, “There are about two problems on a page in the textbook. I do one first, and then have some students to do the other similar one in front of the whole class.” When asked would she have students try the first problem? She replied, “Yes, but not often. If the students do not give good explanations, it will take me more time to clarify the confusions”.

   From the interview described above, we realized that Ms. Lin emphasized more on whether students learned how to solve problems in the mathematics textbook.
And that was the reason why she would always solve and explain those problems one by one in detail. Meanwhile, she does not stress the cultivation of students' active attitude in solving problems on their own. Therefore, she did not let students first try to solve problem on their own, in order to avoid spending more time to correct students' misconceptions. Nonetheless, we also found that in her class, she seldom allowed the students to express different solving strategies from those written in the mathematics textbook. Neither did she discuss the incorrect problem solving strategies of some students.

Why didn’t she have students express their different strategies in solving mathematics problems or discuss those incorrect problem solving strategies that students used?

According to interview data, there are two reasons to explain why Ms. Lin did not encourage students use their own strategies different from those in the mathematics textbook. One is the obedience of authority. She believed strategies developed by the experts were more suitable for students. The other is the examination score issue. She was afraid that the slow speed of students' own strategies would affect their scores on paper-and-pencil tests.

The reason why Ms. Lin would not discuss the incorrect problem solving strategies is that she found more errors raised in Chinese language workbooks after showing students those errors during Chinese language class. She extended her disastrous experience from the Chinese language class to the mathematics class and thus would try not to discuss mathematics misconceptions in class.

In addition to the teaching behaviors described above, we also discovered that Ms. Lin would ask her class to review what they had learned before the end of each lecture. "The object of review on the same day is to seize the golden time for memorization when students still can remember clearly what had just been taught", she explained. From the word, “memorization”, it is obvious that she emphasized not the 'process' of learning but rather the actual ‘results’ of learning mathematics from the textbooks.

Judging from the request for preview and review, the development of testing questions, and the avoidance of explaining incorrect problem solving strategies, we concluded that Ms. Lin’s value toward goal in mathematics teaching was to have students only acquire knowledge from the textbook.

**Choosing** We raised two different ways of teaching and Ms. Lin commented on them. The first one was for teachers to take a leading role and for students to follow the textbook. The other was for students to initiate learning and for them to discuss and solve problems in a group. Ms. Lin favored the first approach for the speed and effectiveness of the whole learning process. But the drawback of this approach was
that some students may become absent-minded. She said, “The advantage of the latter approach would be to develop an awareness of the possible incorrect problem solving strategies and mistakes and to avoid them. However, if students are too lazy to participate in discussion, the group leader will let me know. I will then instruct the distracted students to be attentive.” She said at the interview, “The drawback is schedule delay. Sometimes, I felt that even if I spent twice as much time, I still could not finish all the materials.” “Some students might even be misled with the incorrect problem solving strategies discussion and become confused, consequently.”

Ms. Lin reviewed all the pros and cons for these two approaches of mathematics teaching, considering also the time constraints involved and students’ misunderstandings over incorrect problem solving strategies. She still chose the first approach where teachers took the leading role in order to instruct students to learn knowledge from the textbooks.

**Prizing** Ms. Lin emphasized previews and reviews on mathematics textbooks because she said, “Going over them three times is better than going over them twice; and twice is better than once.” These words revealed that she stressed that students must acquire knowledge from the textbooks well.

According with the three criteria of acting, choosing and prizing, we are able to identify that the mathematics pedagogical value of Ms. Lin is to induce students to obtain mathematics knowledge from the textbook.

2. **Learning mathematics happily and using it to solve daily problems**

In her mathematics class, we sometimes saw Ms. Lin use daily life examples to demonstrate mathematical concepts. For example, when she was teaching how to compute the area of circles, she mentioned cakes, and cake diameters. Why would she mention things such as cakes? She said, “To mention something edible would revive tired students, draw attention, and regain classroom focus. In the mean time, I hope students would apply what they learned in class to aspects of daily life. Mathematics is not as hard as someone would imagine. It relates with one’s daily life.”

In one interview, she also said, “I asked students to do an assignment about Kao’s lottery last year. I gave the data from the lottery enrollment showing the winners from the newspaper, and then asked them to figure out the probability of winning a car based on the data given. It turned out that the students were very interested in this assignment, since figuring lottery probability is applicable to daily life. Through this assignment, they realized and accepted that is one of the reasons for learning mathematics in school.”

From the above quoted, we know that Ms. Lin preferred students to relate
mathematics with aspects of their daily life, in hope that this would revive an interest for mathematics. She added, “I tried to use examples from daily life, making those examples as vivid as possible with jokes and humor during mathematics class, thereby transferring more joy in the learning process. Besides, operating with tools for learning on their own, students justify more joyful learning. Students like using their own instruments for learning mathematics because they could relax with their group members when solving a problem. Of course, they may converse among the group members, however, it provides for a better learning atmosphere, since students feel comfortable talking and focusing in class”.

Although she had the idea of grouping students together to operate with their own learning tools, she seldom conducted this because she had a tight schedule to keep up with. She would instruct the class to be absolutely quiet, or else she would scold the students, timing them to stand when they were noisy. Therefore, Ms. Lin acknowledged the learning tools to allow for more joyful learning, but she was unable to use this systematic learning process and to have the students to learn actively the mathematics knowledge.

According with the above situation, note that two of Ms. Lin’s value indicators are that, “Mathematics teaching’s goal is having students learn mathematics happily” and “Mathematics teaching’s goal is for students to use mathematics in solving their daily problems”.

However, Ms. Lin chose to help students learn mathematics happily and relate mathematics problems to things in daily life only when she could keep up with the syllabus and students’ examination scores. In addition, she believed, “It was most important to have students learn mathematics without pressure and happily.” She also said, “Through solving specific problems in daily life, students became more aware the reasons to learn mathematics.” Those words showed that Ms. Lin emphasized the importance of these two value indicators. Based on the criteria of acting, choosing, and prizing, we concluded that the above two value indicators enlist as two of Ms. Lin’s mathematics pedagogical values.

3. Relationships among mathematics pedagogical values

Ms. Lin mentioned that one of the most important things about teaching mathematics is allowing students to happily learn mathematics. However, learning happily became just a means for learning mathematics well in the interview Case 2. Case 3, showed that teaching mathematics contents of the tests took priority over solving daily mathematical problems and learning happily.
Case 2
I: Ms. Lin, You said that when students learn with joy, it was to induce their motivation for learning even if they could not learn well. Hence, it seems that the ultimate goal of mathematics teaching is to motivate students to learn mathematics and learn well. Thus, learning with joy is not the ultimate goal, isn’t it?
Lin: No, learning happily would not be the ultimate goal.

Case 3
I: Earlier in the interview, you mentioned that some abstract and mechanical topics, would later become the base for future learning, like the common divisor and common multiple. If there were some topics you had to teach within a given period before an examination, including such abstract and mechanical topics mentioned, along with those related with daily life and enjoyment, how would you schedule them under time limitations before the examinations?
Lin: I probably would compromise with the examination, giving priority in teaching topics about the common divisor and common multiple.

To synthesize teaching behaviors of mathematics at interviews and analyze mathematics pedagogical values of Ms. Lin, we maintain that relating mathematics to daily life was a means only for Ms. Lin to encourage students to joyfully learn mathematics. Correspondingly, learning with joy also meant to facilitate learning mathematics. That is, the value that mathematics teaching aims to help students use mathematics to solve their daily problems was only the instrumental value (Chen & Chen, 1990) which is a means to get the other value that teaching mathematics is to have students learn mathematics happily. While the value that teaching mathematics is to have students learn mathematics happily was also only an instrumental value which is a means to get further value that the goal of mathematics teaching is to teach students to learn the knowledge in the textbook. Therefore, “the goal of mathematics teaching is to induce students to acquire textbook knowledge.” became the core of the above three values.

Implication
In exploring the mathematics pedagogical values of Ms. Lin, we discussed the pros and cons of teacher-centered teaching and group discussion. Ms. Lin only accepted them as teaching strategies, without realizing their hidden values and implications. For example, allowing students to solve problems in discussion groups would cultivate students’ to initiate problem solving, thinking, and reasoning
abilities. The findings revealed that during teacher education of mathematics teachers, educators must not only discuss effective teaching strategies, but also those values hidden behind the strategies. Accordingly, teachers will know which strategies to choose and why those strategies are selected for teaching mathematics.

We identified, “The goal of mathematics teaching is to teach students to acquire the knowledge from the textbook.” “Teaching mathematics is to have students joyfully learn mathematics.” “Part of mathematics teaching is to help students use mathematics to apply to daily life problems.” These were the three mathematics pedagogical values of Ms. Lin. The relationship among the values are illustrated in Figure 1.

![Figure 1: Mathematics Pedagogical Value System, centering on mathematics knowledge acquisition in elementary school](image)

The mathematics pedagogical value system in Figure 1 provides mathematics teacher educators the implications. Though teachers in elementary schools have many mathematics pedagogical values, their values are emphasized differently. The relationship among the values must be clarified and the core values must be identified first. Then, we may examine further whether the core values accord with current education policies. If not, then in modifying teachers’ mathematics pedagogical values, changing of those core values becomes an underlying solution. Of course, how to change teachers’ mathematics pedagogical values is a new research subject.

Acknowledgements: Thanks is given to the teacher Ms. Lin, who was kind and open in sharing her ideas with us. We thank our assistant Ms. I.H. Hong, who did a great job on the audio-video tape transcriptions. We are grateful to NSC for funding the project. The opinions expressed do not necessarily reflect the views of NSC.

EXPLORING THE RELATIONSHIP BETWEEN SIMILAR
SOLUTION STRATEGIES AND ANALOGICAL REASONING

Peter Liljedahl
Simon Fraser University

Analogue reasoning is a powerful problem solving strategy that exploits the isomorphic relationship between two problems. The result of this exploitation is the production of similar solution strategies for the two problems. However, the presence of similar solution strategies is not a result exclusive to analogue reasoning. This study examines the use of similar solution strategies as an indicator of analogue reasoning in pre-service elementary school teachers' attempts to solve repeating pattern problems. Findings show that an awareness of problem similarity is not a necessary requirement for the production of similar solution strategies. As a result, the use of similar solution strategies as a measure of analogue reasoning needs to be modified.

INTRODUCTION

Making connections and utilizing similarities between problems is at the core of mathematical reasoning (English, 1998; National Council of Teachers of Mathematics, 2000). There are several proposed mechanisms by which learners weave a thread between what is known and what is new. One such mechanism, referred to as analogue reasoning, builds this connection by exploiting the tension between the similarities and the differences of two situations (Jardine & Morgan, 1987). However, a “subjects’ conceptions of similarities between situations are analyzed relative to normative criteria with respect to predetermined mapping between the situations, built into the experimental set-up by the researcher.” (Greer & Harel, 1998, p. 11)

This article examines the use of similar problem solving strategies as an indicator of analogue reasoning. I make the argument that strict adherence to similar solution strategies as an indicator of analogue reasoning causes improbable results to emerge from the data. An alternate form of reasoning is proposed that can be used to explain situations in which similar solution strategies are utilized in the absence of analogue reasoning.

ANALOGICAL REASONING

Mathematical reasoning in general, and analogue reasoning in particular are most closely associated with how students solve mathematical problems. Polya (1957) acknowledged reasoning by analogy as an explicit part of problem solving with such strategies as “think of
a related problem”, and “use a simpler (but similar) problem”. These are very general recommendations to problem solvers as to how to proceed when faced with a challenging problem. Reasoning by analogy is a more specific description of the mechanism that forms the underpinnings of these strategies. As it applies to problem solving, analogical reasoning involves mapping the relational structure of a known problem (that has been solved previously, referred to as the source) onto a similar problem (referred to as the target) and using this known structure to help solve the similar problem (English, 1997, 1998; Novick, 1990, 1995; Novick & Holyoak, 1991). If the source problem and the target problem are almost isomorphic (that is, the source problem is isomorphic to part of the target problem or vice versa) then some adaptation or extension of the solution strategy may be required (English, 1998; Novick & Holyoak, 1991)

ANALOGICAL REASONING: A FRAMEWORK FOR ANALYSIS

Studies examining students’ abilities to utilize analogical reasoning can be classified by what I refer to as their degree of openness (ranging from closed to open). Closed studies are ones that direct students, through the experimental set up, to use analogical reasoning skills. Experiments involving problem sorting, grouping tasks, or possible source problem identification from a list of problems are examples of such studies (e.g. English, 1998). These studies do not determine whether or not a student uses analogical reasoning skills but how well they use it as indicated by correct selection of source problems or normative sorting of problems.

Open studies on analogical reasoning abilities are ones in which the experimental design allows the students the freedom to invoke whatever problem solving strategies they see fit and then to analyze the results for evidence of analogical reasoning skills as indicated by similar problem solving strategies. In order to assure that participants are utilizing analogical reasoning it is necessary that the problems presented to the participant have many possible solution strategies (Bassok & Holyoak, 1989; Novick & Holyoak, 1991).

A particular study’s openness is dependent on the impact that the experimental set-up has on the participants’ choice of problem solving strategy. A partially open study would be one in which the participants are operating in a problem solving situation but the experimental structure may guide them into using analogical reasoning. Studies using a hint/no hint paradigm (e.g. Novick & Holyoak, 1991) to measure the impact of retrieval on successful solution strategy transfer are an example of a partially open study. Successful use of analogical reasoning is again indicated through the use of similar problem solving strategies.

With open, or partially open studies, however, analysis of data operates on two assumptions. The first is that the use of different problem solving strategies on similar problems indicates a lack of analogical reasoning, and the second is that the use of similar problem solving strategy indicates analogical reasoning. Analogical reasoning hinges on a solver’s explicit identification of the similarity between two problems. This is a description (or a definition)
of the mechanism of analogical reasoning. Similar solution strategies are a product of this mechanism. The question is, is the product an indicator of the process? Is the presence of similar solution strategies an accurate indicator of analogical reasoning?

METHODOLOGY

This study was designed to probe the relationship between the students’ explicit identification of problem pair isomorphism and the use of similar solution strategies. Participants in this study were preservice elementary school teachers enrolled in a “Foundations of Mathematics for Teachers” course. Twelve of the students enrolled in the course volunteered to participate in clinical interviews. The tasks, along with some of the questions they were asked to solve were:

The Calendar Problem.

I’ve chosen a calendar page, October 2000, and I’m going to place a red marker on the 1, a blue on the 2, a green on the 3, and a yellow on the 4. Now, I’m going to repeat this pattern; red on the 5, blue on the 6, green on the 7, and yellow on the 8.

a. What colour will number 13 be? What colour will 28 be?

b. If the calendar continued on forever, what colour would 61 be? 178? 799?
c. If there were five colours (red, blue, green, yellow, and black), what colour would 799 be? If there were 6 colours, what colour would 799 be?

The Sequence Problem

a. Consider the sequence 1, 5, 9, … What will the next few numbers in the sequence be?

b. Will the number 48 be in this sequence? Will 63?

d. Can you give me a big number that you know for sure will be in the sequence?
e. Consider the sequence 5, 12, 19, … Is 96 going to be in this sequence?
f. Can you give me a big number that you know for sure will be in the sequence?
g. Consider the sequence 8, 15, 22, … Can you give me a big number that you know for sure will be in the sequence?
h. Consider the sequence 15, 28, 41, … Is 1302 going to be in this sequence?

Comparison of the Two Problems

a. Consider the two problems you have worked on here: the calendar problem and the sequence problem. Is there any similarity between the two problems?
b. Is there a similarity between the strategies you used?

The interviews were conducted in the later part of the course. Students had studied the topic of ‘arithmetic sequences’ in the earlier part of the course.

The calendar problem and the sequence problem were chosen in order to present students with two situations that were almost isomorphic. The questions in the sequence problem
were chosen to be 'twist' or 'inverse' problems (Zazkis & Hazzan, 1998). Rather than ask standard questions of finding the $n^{th}$ element or which term a given element is, these questions 'twist' what is sought and what is given. Similar problems were used in Zazkis and Liljedahl (2002) and have been shown to be useful in getting students to examine the situation rather than simply use established algorithms.

Specific questions within each of the two tasks were removed or added (at the discretion of the interviewer) in order to help establish solid understanding of the problems before proceeding with the interview.

The two main tasks, the calendar problem and the sequence problem, were chosen for their implicit isomorphic relationship. Comparing the two it becomes clear that arithmetic sequences can be viewed as a special subset of the calendar problem. That is, the sequence 1, 5, 9, ... represents the sequence of red markers in the calendar problem.

RESULTS AND ANALYSIS

The transcripts of the clinical interviews, written work, and the audiotapes themselves, were used to analyze the problem solving strategies utilized by the students. A simple partitioning of the data using solution strategies as a gauge produced two groups: those who did not use similar solution strategies, and those who did.

Initial analysis revealed that five of the participants utilized different strategies, six utilized the same strategy, and one used multiple strategies for both questions. Of specific interest to this study were the six students who used similar solution strategies to solve both the calendar problem and the sequence problem.

Although the use of similar solution strategies for the almost isomorphic problems could be taken as indication of the use of analogical reasoning in solving the sequence problem, the responses to the probing questions indicated otherwise.

When asked to comment on the similarity between the problems both Deanna and Helen have difficulties identifying any.

Deanna: They're kind of hard to connect right away, or at all. [...] But it's hard to see that they're similar, for me at least. It's hard to recognize that and see that, it's very hard to play around with numbers and to kind of see the relationships between the different numbers.

Helen: I used multiples of 4 for all of them, ...
Interviewer: Okay, anything else?
Helen: Um, they all continue in a pattern ...
Interviewer: Okay, anything else?
Helen: No ...
John, on the other hand, has no difficulty identifying the similarity between the problems when prompted to do so. However, probing for his views on the similarity of his strategies reveals that he cannot recall the strategy he used in the calendar problem.

Interviewer: *Um, the strategy you used here for solving those types of questions, would you say it's the same as the strategy you used here?*
John: *(pause)* You would ask me, so if I was going to say...\nInterviewer: Do you remember the strategy you used here?
John: Uh, I would like to go over one example just so [...] So yeah they are the same.

After some time to refresh his memory, John indicates that he sees the strategies as being the same. This delay, however, shows that he was not exploiting the similarity of the problems and utilizing his strategy for the calendar problem while he was working on the sequence problem.

Each of the six participants who produced similar solution strategies either failed to explicitly identify the similarities between the problems or gave indication that, although they now saw the similarity, they failed to capitalize on it during their efforts to solve the sequence problem.

Greer and Harel (1998) take a broader view of the analysis of solution strategies of isomorphic problems. They classify the isomorphic relationship into three cases. The first two are identical to the processes of analogical reasoning (see English, 1998 for more details). The third is a case which Greer and Harel refer to as 'mediated isomorphism'.

![Figure 1](image-url)

Mediated Isomorphism (Greer & Harel, 1998, p. 12)

Mediated isomorphism relies on the solver first identifying the similarities of the two problems $S_1$ and $S_2$ to the more general problem $S$, and then using these similarities to help establish an isomorphic relationship between the two problems $S_1$ and $S_2$. This mechanism has many of the same markers as analogical reasoning: two similar problems, similar solution strategies, an awareness of problem similarity. However, it is a mechanism different...
from analogical reasoning in that it lacks the willful exploitation of problem similarity for the purpose of solving the second problem. In fact, problem similarity is more a byproduct of the solutions than a mechanism towards the solution. Two of the participants showed evidence of this mediating effect as they became aware of the problem similarity while answering the comparison questions.

However, this mechanism fails to explain the results displayed by Deanna. Deanna's solution to both the calendar problem and the sequence problem indicated that she treated both problems as special cases of repeating pattern problems. Yet, she was not aware of the inherent relationship that existed between them. As an isolated case it could be classified as an incomplete execution of mediated isomorphism. However, the prevalence of this result in this study necessitates the recognition of this process as a different form of reasoning. I call this mechanism non-mediated generalization, where, as shown in figure 2, there is no direct connection between $S_1$ and $S_2$.

![Non-mediated Generalization](image)

All six of the participants who produced similar solution strategies for the calendar problem and the sequence problem indicated (through their responses to the comparison questions) that they were unaware of the similarity between the problems while they were actually engaged in the solving of the problems.

**CONCLUSION**

There is no denying that reasoning by analogy is a powerful problem solving strategy. As mathematicians we have come to rely on its strength. As teachers we make it our goal to give students the experiences and guidance necessary to improve this skill. As researchers we try to measure its use and effectiveness and try to identify the factors that aid or impede its success. However, there are other forms of reasoning, valid and invalid, available to the student in an analogical problem-solving situation. Carefully constructed instruments will be able to guarantee the willful use of analogical reasoning, but only in very controlled
environments. Tasks such as problem sorting and source/target pairing direct participants to utilize reasoning by analogy through the experimental set-up. Studies using such tasks will, therefore, be able to discern the sorts of features that are attended to and allow analysis as to how well analogical reasoning is invoked. But if we utilize the same sort of analysis in less controlled environments we are making the assumption that solvers are, indeed, intending to utilize analogical reasoning. If true problem solving efforts are to be evaluated for the application of analogical reasoning then there must be a contingency for alternate forms of reasoning in any subsequent analysis.

This study has shown that even seemingly successful cases of analogical reasoning as indicated by similar solution strategies must be treated carefully. The theory of analogical reasoning is constructed on the explicit awareness of the similarity between the source problem and the target problem and the willful exploitation of this similarity in solving the target problem. Although a similar solution strategy is a good indicator of this form of problem solving it is not an exclusive outcome of analogical reasoning. Mediated isomorphism also relies on the explicit awareness of the similarity. However, because the similarity between the problems is not identified through direct comparison of the two problems as suggested by the theory of analogical reasoning, the purposeful use of the similarity is absent. Non-mediated generalization is a theoretical refinement of mediated isomorphism in that it lacks not only the willful use of the problem similarity, but more fundamentally, it lacks the very awareness of the similarity. However, both mediated isomorphism and non-mediated generalization have been shown to be present in cases in which similar solution strategies were used. Researchers need to be conscious of these subtleties both when considering experimental design and when analyzing data in order to avoid misattributing student’s efforts to analogical reasoning.

SUPPORTING TEACHERS IN BUILDING MATHEMATICAL
DISCOURSE COMMUNITIES BY USING RESEARCH-BASED CASES

Pi-Jen Lin
National HsinChu Teachers College, Taiwan
linpj@mail.nhctc.edu.tw

Abstract

This study was designed to examine the effect of using research-based written cases on supporting teachers in building mathematical discourse communities. Four first-grade teachers enrolled in five workshops in which they studied the cases about first-graders' learning and teacher's roles in discourse. Through case discussion, the participants were supplied with needed experience and support for evolving their pedagogy. Asking students to explain, to clarify and justify their ideas orally, and criticizing for challenging their thinking were the three ways the participants used most frequently to encourage students to engage in discourse. The set of discussion questions in each case appeared to be an essential contributor to have a salient focus for the case discussion.

Key words: cases, narratives, mathematical communication, discourse.

Introduction

Communication is central to the current vision of desirable mathematics teaching (NCTM, 2000; MET, 1993). The process of creating mathematical discourse communities dealing with complex and multifaceted undertaking is a challenge for teachers (Lin, 2000; Silver, 1996). Teachers are challenged by the interplay between the reform vision of instruction and their own experience with more traditional tasks and pedagogy. Helping teachers toward an instruction rich in communication is likely to require new experience of learning mathematics in a manner that emphasized discourse and require needed support from collaborative communities of practice in which mathematical discourse occurs. One of the ways to meet the needed support and acquire new experience for teachers is through the use of cases that reflect others' experience on encouraging students to participate in discourse and centering discourse on mathematical ideas (Harrington, 1995). Therefore, case discussion is considered to be the kernel part of the study for helping teachers creating mathematics discourse communities.

The research-based cases involved in the study refer that the cases were constructed collaboratively by the researcher and teachers participating in a previous school-based teachers' professional program. The program is designed to help teachers keep with the tenet of 1993 vision of curriculum reform that emphasized engaging students with challenging mathematical tasks and enhancing students' levels of discourse about mathematical ideas. The effect of cases on supporting teachers' professional development has been examined (Lin, 2000). It indicates that both case discussion and case writing are two critical aspects of cases on developing teachers' thinking (Lin, 2000;
Cases referred to in part of previous studies are conducted by personal practical experience (Barnett, 1998; Shulman, 1992). Thus, such kind of cases is intimately tied to personal practice and lacking of multiple levels of interpretation and analysis. As suggested by Merseth (1996), the research-based written cases referred to in the study are characterized in four essential ways. (1) Cases are based on careful research. The first-grade case-teachers participating in the previous professional program have been collaborated with the researcher to enhance their mathematical instruction through an emphasis on mathematical communication within the context of innovative curriculum. (2) Cases present reality. (3) Cases are developed to stimulate thought and debate for expanding the perspectives of users, but not to provide best practices. (4) Cases are potential to help users to recognize salient aspects launched from a set of discussion questions.

Researchers have examined how teachers interact each other through case discussion (Levin, 1995; Richardson, 1993), but little empirical work describes how case discussion influences teachers creating mathematical discourse communities. Thus, this study was designed to examine what teachers learn and investigate how teachers establish mathematical discourse communities in their classrooms through the discussion of research-based written cases.

Theoretical Perspectives

The theoretical rationale for this study stems from the constructivist's perspectives. Piaget (1932) suggests that children's conflicting ideas are resulted from peer interactions. Cognitive conflicts result in an imbalance providing the internal motivation for an accommodation. Similarly, conflicts can occur for teachers, when they learn to teach individually or socially. The social interaction in a group discussion has the potential for initiating cognitive conflicts, hence to result in teachers' change. Vygotsky (1978) asserts that what is learned in the social interaction of the group is prerequisite to cognitive development. From this perspective, the interaction and the content of the group discussion are crucial to what is learned from cases. This would manifest itself in differences in understanding the issues in cases between those who do and do not participate in the process of constructing cases. In addition, his notion about "the Zone of Proximal Development" can be interpreted as suggesting that cognitive conflicts, caused by discussing, debating and negotiating in interactions between learners and more capable peers, act as a catalyst for reaching a higher development level. This indicates that case-teachers with more experience should influence the thinking of other teachers with less experience who interact with them in the case discussion. The two theoretical perspectives from development and social psychology
provide a basis for helping us think about how knowledge is constructed both individually and socially. Case discussion fosters personal reflection through an external process (Shulman and Colbert, 1989). This notion suggests that social interaction during case discussion among the case-teachers and the teachers in a group seems to be likely to initiate cognitive conflicts and then contribute to reaching a higher level of psychological development.

Method

The participants in the study were four first grade teachers (Lao, Pan, Hu, and Wu) at two schools, located in a suburban area. They were experienced teachers with at least 10 years of teaching experience, but they were beginning teachers in their second year of teaching the 1993 vision of innovative curriculum. The participants were volunteers to participate in five workshops as part of a teacher education program that was designed to help teachers understand how first-graders develop mathematics concepts and identify various aspects of a teacher’s role in mathematical discourse.

The research-based cases have the following major issues: (1) a mismatch between teacher’s goal and objectives of a lesson, (2) students’ various solutions of resolving a problem, (3) inappropriate tasks, and (4) framework of underpinning the curriculum. Through the cases, teachers are expected to deepen their understanding and expand their views of students’ ways of thinking, hence to identify various situations in deciding what to pursue in depth, when to model, and how to encourage student to engage in tasks.

A set of discussion questions is one of the six components included in a case (Lin, 2000). The discussion questions”, as kernel part of each case, are incorporated the reflections of case-teachers who involved in constructing the case into the major concepts to be learned of the lesson. The questions listed in cases are to stimulate teachers’ rethinking about mathematical teaching and reflect to their practices. A set of focus questions of the case entitled “How do you categorize them?” serves as an example (see Figure 1).

Figure 1  Discussion Questions in a Research-Based Written Cases

As part of the workshops, the discussion of each case is used to probe for responses to the questions in the written cases. To structure case discussion, I, as the leader of the discussion, played various roles in order to guide, probe,
give feedback, and observe each participant's thinking about cases. There were two common questions to be addressed across cases in the case discussion session. (1) How would you respond to each question of the "Discussion questions"? (2) What are some of the issues in this case coming up in your mind in this case?

The participants read and discussed eleven cases in the five workshops. They were observed during their mathematical instructions in the entire year. To document the efficiency of cases resulted in teachers' change, each workshop determined the time of each observation. There was around one-month difference between two workshops. The time of the four classroom observations and five workshops was depicted as $O_1-W_1-W_2-O_2-W_3-W_4-O_3-W_5-O_4$, $O_i$: the $i^{th}$ observation, $W_j$: the $j^{th}$ workshop. Available data for each participant's four curriculum units include 12 classroom observations. $O_{pre}$ including the $O_1$ and $O_2$ observations occurred in the first school term and $O_{pos}$ including the $O_3$ and $O_4$ observations in the second term.

The data were collected from the participants' responses to questions of each case in the five workshops and their instructions to be observed. The videos and audiotapes were recorded and transcribed verbatim. The data was analyzed by using Strauss and Corbin's grounded theory (1994). Through recursive reading the transcriptions of each video teaching, a coding scheme including ways of communication and contents of teaching was developed. There were nine ways of commutation in mathematics emerged: restating students' statements (R), asking students to explain what they understood (E), asking students to clarify and justify their ideas orally (C), criticizing for challenging students' thinking (J), giving students hints when students struggle with a difficulty (H), encouraging students to share their answers (S), asking students to model or demonstrate their understanding (D), motivating students to provide multiple ways of thinking (M), and inviting other students' follow-up ideas for making up an incomplete interpretation (I). Each lesson was categorized into various phases of teaching across mathematics contents when discussing the problem to be solved, the use of hands-on, symbols and number sentences given by students. Each sentence in the transcription under a unit of analysis was encoded and the frequencies were counted for each lesson. The constant comparative analysis was used to compare data segment, determine similarities.

Limited space prevents to report what the teachers learned from each research-based written case and how they learned about building mathematical discourse communities. An illustration of the case influencing on teachers' thinking about cases is taken from one case that deals with three levels of representation. To illustrate in-depth the effect of case on teachers' ways of communicating mathematics with students, a participant's lessons as an example will be the focus of analysis reported in this paper.

Case discussion on teachers’ awareness of students’ learning mathematics

Initially, the four teachers were puzzled with their students' early use of number sentences prior to teaching it. They were not aware of the importance
of the development from concrete, pictorial and to symbolic representations to first-graders. The issue of representations listed in the discussion questions of a case was brought up in the second workshop to discuss as follows.

As observed, a student wrote a number sentence 8-5=3 first, and followed by drawing the circles 00000000 - 00000 = 000 representing the given problem: “There are 8 children and 5 presents. Each child gets a present. Are the presents enough?” Do you accept the student’s representation, 00000000 - 00000 = 000? Why? What instructional strategy would you take to reduce the use of 00000000 - 00000 = 000? (2nd workshop, 11/08/2000).

In the discussion, Ms. Lao and Ms. Wu reflected their students’ high frequencies of using number sentence to their first year of teaching using the innovative curriculum. They faced the challenge of students’ disordering learning of pictorial with symbolic representation, but they did not realize its hindrance of learning in multiplication. They perceived that their students did not make sense to the meaning of the number sentence at this time, so that the circles most first-graders drew merely meet teacher’s needs rather than represent a process of student’s thinking. Understanding a mathematics concept meant by them was that students are capable to use it. Thus, prior to teaching it, they accepted students’ use of the number sentence 8-5=3 followed by 00000000 - 00000 = 000 no matter who they learned from. Lao suspected why students must go through the use of hands-on and drawings, since they had used 8-5=3 to solve the problem. According to Lao’s response to the issue, she did not appreciate the importance of the developmental processes among the three levels of representation to the future learning.

To resolve the puzzle, Ms. Hu offered an instructional strategy in the group discussion. “Decomposing a step into sub-step” means that “a word problem is divided into several parts, one part is presented at a time and students’ follows”. A problem described by “There are 8 children and 5 presents. Each child gets a present. Are the presents enough?” is a typically complete statement. Alternatively, the problem is posed by decomposing it into three sub-steps as “There are 8 children, representing the 8 children by chips; 5 presents, showing the presents by chips. Are they enough? (counting the amount of chips indicating the answer)”. In the discussion of the case, Hu not only introduced its meaning but also explained the merits of the alternative approach to other three teachers who have never heard this term before.

They supported mutually. Lao, Pan, and Wu learned the meaning and the strategy of “Decomposing a step into sub-step” from Hu and put it into their following lessons. Moreover, they became an opponent of the approach, since the strategy indeed resulted in the low frequencies of their students’ early use of number sentence. Lao stated the efficiency of cases in the third workshop.

The previous case discussion helped me perceive my blind spots in instruction. Reading and discussing it ahead of my teaching make significantly effectiveness of teaching the innovative curriculum in this year. I re-taught previously unsuccessful lessons by taking “Decomposing a step into sub-step” approach aiming at the use of hands-on or pictorial representation of a word problem. Through the approach, I found that first-graders’ at this stage did not use the symbolic representation to solve the word problem any more. Thus,
if I can understand the main ideas of a lesson in which they are focus questions of a written case, then I would not be frustrated with students’ difficulty with learning. Moreover, I could predict students’ various solutions in advance and then help them have better understand (Lao, 3rd workshop, 12/06/2000).

Case discussion on supporting teacher in building mathematical discourse

The topic of the lessons determines what and how teachers communicate mathematics with students. To be coherent the effect of cases on teachers’ thinking about cases with supporting them in building mathematical discourse communities, the analysis of this section will be only focused on the lessons relating to number area. The lessons in a curricular unit is determined by each teacher’s instructional activities. The textbook Lao and Pan used is different that of Hu and Wu used. The lessons of number topic included in the textbooks scheduled on the list to be observed in the study were included only in Lao’s and Pan’s six lessons. Lao’s six lessons serve as an example shown in Table 1.

O_pre: observations occurred in the first school term. O_pos: observations occurred in the second school term.

The data of the Table 1 shows that the most three frequencies of ways Ms. Lao used to encourage students to participate in classroom discourse were asking students to explain what they understood (E), asking students to clarify and justify their ideas orally (C), criticizing for challenging students’ thinking (J). The frequencies of the three ways used by Lao were 180, 164, 126, respectively. Lao’s ignorance of the importance of the pictorial representation described earlier was also evidenced by the data shown in her communication in classrooms. The data suggest that Lao did not frequently encourage students to draw circles representing the process of their thinking in the first school term (33 frequencies) as compared to the second school term (141 frequencies). The result indicates that the cases influencing on Lao’s more attentions to the discussion of drawings with students. Lao improved her skills in asking students to explain (41 frequencies) and to clarify what they understood (46 frequencies) as she sought to engaging students in the meaning of drawings they drew.

As observed, Lao created a mathematical discourse community in discussing various strategies of a compare word problem. After posing the problem “Shiao has 11 marbles. Mei has 5 marbles. How many more marbles does Shiao have than Mei? Drawing pictures represents your thinking and writing its number senescence with subtraction.”, she furnished opportunity
for students to share their solutions and justify their thinking publicly. In the class discussion, Lao frequently asked students the question “Does anyone of you have different solutions?” to encourage students showing their different solutions from others’. To provoke thoughtfulness in the discourse, she asked students various questions about their answers. The questions were varied with students’ solutions. For instance, after Kao-Bin offered his solution as 11-5=6, Lao asked the questions to Kao-Bin “what do the circles mean presented in the above row?” “why did you use the way?” “What does 11 represent in 11-5=6? How about 5? How about 6?”. Likewise, Lao asked Uein-Jye the questions to clarify and justify his answer, after he provided the solution 11-6=5. “Why did you write 11-6=5?” “What did the part crossed out represent?” Could you tell us which part represents Shiao’s more marbles than Mei’s?” “What does the difference between your drawings and Kao-Bin’s?” Lao did not stop the discourse on students’ various solutions until Shin-Jane presented the solution 6+6=11. Because Lao learned first-graders’ possible solutions coming up in the problem from previous workshops, she expected the third solution showing up in the class discussion. Meanwhile, she asked a question to criticize for challenging students’ thinking, “Did 5+6=11 given by Shin-Jane meet the demand of the problem in which number sentence is expressed by the subtraction?” From the above scenario, Lao clearly had progressed in satisfying the demands of listening carefully to students ideas, encouraging students’ engaging in thinking about mathematical ideas, and asking students thoughtful questions to clarify and justifying their ideas orally.

Discussion

It is found that the use of research-based written cases enhanced the teachers’ ability in creating mathematical discourse communities. In the discussion of cases, the teachers were supplied with new experience and needed support of mathematical discourse community from the member of the discussion group. They learned about the role of the researcher in creating mathematical discourse communities from the case discussion in which the manner is similar to that of mathematical discourse in classroom. Likewise, the researcher learned from the teachers about what they responded to the discussion questions described in each written case and how they learned to teach. The teachers supported mutually in understanding how first-graders learned mathematics by the discussion of the case. Lao’s acquisition of students’ various solutions from case discussion was an important contributor to her success in moving toward the creation of authentic mathematical discourse communities in her classroom. The new experience and needed support indicate that the teachers appeared to evolve their thinking and pedagogy from a traditional form toward a form of instruction centered with mathematical discourse. In Piaget’s (1932) and Vygotsky’s (1978) notions, the case discussion in a group created the opportunity of social interaction for the teachers. The set of discussion questions integrated with case-teachers’ various perspectives are readily to initiate the teachers’ reflection to their practices and
cause their cognitive conflicts of mathematical teaching, hence to trigger change. The set of discussion questions are integrated with multiple perspectives of those who participated in practice-oriented research. The case-teachers embedded in research-based written cases play the significant role of more capable peers.

The research-based cases were not expected to provide best practices but to initiate the users' cognitive dissonance. Instead, the cases referred to the merits and breakdowns in classroom practices that call for solutions within the context of that practice. Thus, the use of research-based cases was more likely to support reflection-on-action and then oriented toward reflection-in-action (Schon, 1987). The discussion of written cases seemed to be a catalyst for the teachers creating mathematical discourses in classrooms. The set of discussion questions described in each written case appeared to be an essential contributor to have a salient focus for the case discussion. The set of discussion questions as a kernel part of the written cases become distinguished characteristics that are not possessed in the videotaped cases. The comparisons between the effect of cases presented in a written form and in a video form on either in-service or pre-service teachers' thinking about cases and decision-making of classroom are valuable for further investigations.

MATHEMATICAL REASONING IN CONTEXT:
WHAT IS THE ROLE OF SCHOOL MATHEMATICS?

Zlatan Magajna
University of Ljubljana, University of Leeds

This report considers the appropriateness of modelling and of a radical situated
paradigm for working out advanced (non-intuitively obvious) mathematical tasks in
work contexts. A case study of vocational school students and expert practitioners
solving geometry problems in a computer-drafting context indicates that neither of
these paradigms is appropriate. For the students school mathematics and drafting
context are, above all, important as frames of reference. The practitioners do employ
school mathematics but their way of mathematising undergoes a complex
transformation that cannot be simply explained by either paradigm and which
requires further conceptualisation and research.

INTRODUCTION

The relation between school and out-of-school mathematics is an important issue
which has been the object of many research studies. The apparently self-evident idea
that mathematical knowledge, learnt at school, is simply applied in out-of-school
practices via some sort of mathematical modelling is more of a myth than a matter of
empirical observation (Bishop, 1988, p. 8). Situated cognition and related theories
have pointed to a marked discontinuity between school and out-of-school practices
(Lave, 1988). In short, mathematical practices in specific activities, e.g. in work or
buying context, were found to have 'little' in common with school-learnt
mathematics. Many studies (e.g. Masingila, 1993; Millroy, 1992; Scribner, 1984)
have confirmed that contextual activities impose many conventions, social and
activity-related constraints, indeed, different conceptualisations of apparently purely
mathematical problems, and that practitioners, as they solve such problems, do not
base their mathematical reasoning on school-learnt knowledge.

In this report I present a self-contained part of a recently completed broader study
about geometric thinking in an out-of-school context. The research was motivated by
the observation that studies about the discontinuity between school and out-of-school
mathematics considered mathematical practices where it would hardly make sense to
use school-learnt procedures, for they are either ineffective or the problems are too
complicated to be solved by analytical means or they are so simple that the solutions
can be easily learnt from peers or can be even self-invented. The research considers
the situated vs. modelling dichotomy in activities and situations where advanced (i.e.
non-intuitively obvious) school-like mathematical knowledge could be profitably
applied. Several aspects of the situated vs. modelling paradigm of mathematisation in
out-of-school contexts are examined: the mathematical actions in activities (Magajna
& Monaghan, 1998), learning mathematical concepts in activities (Magajna, 1999),
and mathematical reasoning in activities. In this report I focus on the last issue: how
do people reason when they solve non-trivial geometric problems which arise in the
case of designing geometric shapes on computers using professional software for
computer aided design (CAD). In particular I consider the following questions:

1. Do practitioners in working out geometric problems (where school
mathematical knowledge can be profitably used) switch to school mathematics
by using some sort of modelling or do they stick to activity practices?

2. Do practitioners, as they solve geometric problems in context, take into
consideration, in any way, the context (e.g. the available tools, allowed ways
of working, the required precision)?

3. How does personal mathematical knowledge and work expertise reflect in the
way practitioners work out geometric problems in activity?

METHODOLOGY

The research questions were explored in two activities closely related to computer
technical drafting: designing moulds for glass containers (a work activity) and
learning computer-drafting in a school for machine technicians (a school-learning
activity). Since the aim of the study was to find cases of qualitatively different ways
of mathematical reasoning in context the participants were purposefully selected
from those that took part in the broader research. In this part of the research eight
participants were studied as they solved problems given in a computer-drafting
context. Two of the participants were machine technicians with six and 15 years of
experience, selected from a group of six designers and technologists in a small
mould-making factory in Slovenia. As part of the broader research the group was
studied using several techniques (interviews, ethnographic observations, scheduled
observations, document analysis). The other six participants were selected from a
class of 22 students, aged 18, from a vocational school of machine technicians in
Slovenia. The students attended a computer-drafting course, which lasted several
months (two hours per week) and were observed as part of the broader research. The
six participants were selected on the basis of a special filtering procedure aimed at
selecting students that avoid and students that are inclined to use non-intuitively
obvious ideas in computer-drafting.

The participants' reasoning in solving geometric problems was studied by analysing
verbal protocols of participants' speech as they solved geometric tasks in a drafting
context under think-aloud instructions. In simple terms, the method consists in
recording and analysing the vocalisations of subjects who work out a task and
simultaneously talk, i.e. they are verbalising what is 'going through their mind' as
they work on a task. More details about the method are in (Ericsson & Simon, 1985).

Each of the eight participants was asked to work out, under think-aloud instruction,
3-6 drafting tasks which contained non-trivial geometric problems. Figure 1 shows
two examples of such tasks. The participants worked in front of a computer using the
drafting program they commonly used. Their utterances (while thinking aloud) were
tape-recorded, and their hand-sketched and computer drafts were also recorded. The protocols were literally transcribed and segmented using easily applicable criteria of pauses between thoughts and the timing of each segment was measured.

**Task 3.** From a CAD you have imported a shape representing a 5 mm thick metal plate to be milled.

**Task 6.** On your CAD you have got a drawing, like shown below, representing two separate pieces to be machined. Your task is to find out whether you should machine two copies of the same piece or should you machine two different pieces.

> Your task is to find out whether the plate was designed as a perfect rectangle.

---

**Figure 1.** Two examples of tasks used for verbal protocols.

**ANALYSING THE PROTOCOLS AND RESULTS**

Of the eight selected participants one was not able to think aloud. The other seven participants solved altogether 32 geometric problems. The recorded protocols gave rise to 2843 segments, 773 of which were excluded from further consideration because were not directly related to the solved problems (e.g. comments on saving files to the computer disk). The analysis proceeded along two directions: a qualitative analysis of the solutions of the tasks, based on clustering techniques, and a quantitative analysis of the protocols, which is described below.

---

**Figure 2.** The assumed processes in reasoning.
The quantitative analysis of the protocols has to be considered to be exploratory because of the small number of observed tasks and because of the fact that the participants were purposefully selected. In the analysis two elements were considered: 1. the cognitive processes during the problem solving, and 2. the context (school mathematics or computer-drafting) to which the participants were referring while solving the tasks. The cognitive processes were analysed using a cognitive model, based on Saxe’s (1991, p. 16-23) description of cognition. Figure 2 shows a simplified schema, derived from the model. The related categories used for coding the protocol segments are listed in Table 1.

<table>
<thead>
<tr>
<th>Category</th>
<th>Description of segments</th>
</tr>
</thead>
<tbody>
<tr>
<td>Context</td>
<td>Referring to the problem at a meta-level, e.g. any reference to drafting or school-learning activity, tools, artefacts, conventions, or social relations.</td>
</tr>
<tr>
<td>Ignored</td>
<td>Making statements related to the problem but not to the solving process, e.g. students' utterances solicited by experimenter for clarification.</td>
</tr>
<tr>
<td>Orient</td>
<td>Looking for a goal or method; stating given, observed or inferred facts; quoting facts or methods without relating them to the worked task.</td>
</tr>
<tr>
<td>Select</td>
<td>Selecting, declaring, naming a goal or method with the expressed intention to work on it or to consider it as a possible direction of work.</td>
</tr>
<tr>
<td>Execute</td>
<td>Executing a method either mentally, on paper or on computer.</td>
</tr>
<tr>
<td>Validate</td>
<td>Checking whether the selected goal or method would lead to the desired result, e.g. expressing arguments, questions or confirmations about the correctness or appropriateness of a goal or method.</td>
</tr>
</tbody>
</table>

Table 1. Categories related to the assumed cognitive model.

The assumed cognitive model and the categorisation were satisfactory in the sense that the segments could be reliably coded and reasonably followed the flow from Figure 2. For example, the segments from the Orient category were followed by another Orient segment in 61% of cases, by a Select segment in 15% of cases, by an Execute segment in only 6% of cases and by a Validate segment in 3% of cases.

Another categorisation of the segments of the verbal protocols, shown in Table 2, was related to the important issue of whether participants, in solving a geometric problem in a drafting context, were ‘reasoning’ in terms of school mathematics or in terms of contextual (drafting) activity. It was initially envisaged that it would be extremely difficult, if not impossible, to determine whether someone is referring to one or another context but this was not the case because there are concepts and operations in computer-drafting that are very unusual or not even meaningful in school-geometry context (e.g. setting the snap interval of the computer mouse – an important issue in defining geometric entities in computer-drafting) and vice versa (e.g. quoting a theorem or writing down an equation). However, in most cases the
segments are meaningful in both contexts (e.g. measuring a distance or drawing a line segment). It was fortunate that the participants were thinking aloud in Slovenian while the software they were using was in English, so that it was easy to identify segments that certainly referred to drafting commands on computer.

Table 2. Categories related to the context of thinking.

Here is a brief summary of the results of the (exploratory) quantitative analysis of the 32 geometric tasks. Recall that the tasks were solved by eight participants (one of which was not able to think aloud). The quantitative and qualitative analysis of the protocols (as well as other performances not considered in this report) indicated that the participants clearly split into three groups: the two expert practitioners (the WORK group), three students that avoided using advanced mathematics (the CAD group), and two students that showed a preference for applying advanced mathematics in drafting context (the GEO group). The unit of analysis used in comparing the three groups was the solved task. For each solved task the fractions of time spent in each category related to cognitive processes was computed (and similarly for categories related to contexts). To determine significant differences in the distributions of codes between tasks worked out in the three groups a one way ANOVA was performed for each code. The results are presented in Table 3. From the table it can be read, for example, that validation took on average 16% of time for the students from the CAD group, on average 13% of time for the students of the GEO group, and on average 21% of time for the participants of the WORK group. The value $p (p=0.297>0.05)$ indicates that in this respect the groups do not differ significantly. From Table 3 it is evident that the three groups do not significantly differ with respect to the assumed cognitive model. However, the participants from the three groups behaved quite differently regarding the context they referred to as they were solving the tasks.

Table 3. Average fractions of time per task spent by participants of different groups in categories related to cognitive model and the categories related to context of thinking.

DISCUSSION OF THE RESULTS

School mathematics in drafting context. In spite of the fact that in drafting activity procedures tend to be routinised and, for the sake of productivity, reduced to push-button operations, some students and practitioners use methods and reasoning patterns similar to those commonly found in school mathematics. A practitioner, for example, solved Task 3 (see Figure 1) by measuring the lengths of both diagonals: since they were not congruent, he deduced that the quadrangle is not a rectangle. Practitioners and some students also wrote down equations containing trigonometry functions or ratios related to similar triangles and tried to solve them. In general, the students from the GEO group and the practitioners from the WORK group did not hesitate to draw attention away from the computer drawing and to study the geometric properties of the figures. In contrast, the students from the CAD group, in general, tried to solve the problems by looking for appropriate computer commands. Though the tasks were set in computer-drafting context, some participants did not automatically stick to the computer-drafting practices.

The role of the context. The practitioners very sporadically mentioned anything about context. Altogether they spent only 1% of time on segments anyhow related to the contextual activity, this occurred mostly when they were stuck. The fact that the participants did not reason about the context at the beginning of the task (and similarly not at the end of the tasks) by itself indicates that they their way of working out geometric tasks was not based on mathematical modelling.

Though the participants spent very little time considering anything related to the context, the context played an essential role in solving geometric problems. The students from the GEO group evidently placed the task immediately (without even thinking about it) in school-geometry context, and similarly the students form the CAD group placed the tasks in drafting context. The students from the GEO group
spent significantly less time in drafting considerations (e.g. looking for an appropriate command, working on a command) and used more advanced mathematical ideas than the students from the CAD group. This indicates that, for students (novices), the context serves as a frame of reference in making sense of a task and in indicating the way of working out the task. Though the tasks were given in a drafting context, some students perceived them as ‘purely’ mathematical tasks to be solved with mathematical means, and some perceived them as drafting tasks to be solved with techniques specific to the used software or activity. Typically, the students from CAD group solved Task 3 by interactively rotating the figure to an almost horizontal position and reasoning about whether the line segments are parallel on the basis of the discontinuities of lines due to the resolution of computer display.

Expert practitioners regarded the context quite differently than the students. On one hand they had considered the broad context of the task – in solving Task 6 (see Figure 1) a practitioner, for example, asked whether the shapes have to be milled from inside or from outside and he mentioned what one should take care of when positioning the workpieces on the milling machine. On the other hand, though the practitioners claimed they had forgotten all mathematics they learnt in school, in solving the tasks the mathematics they used was much richer than even those of the students from the GEO group. They used trigonometry, wrote equations and made non-trivial deductions. This apparently paradoxical behaviour is perhaps due to two causes. First, the practitioners spent very little time on drafting considerations (see Table 3), for they used the software in a very fluent, almost automatized way. The fluency in managing the activity-related apparatus seems to be a necessary condition for ‘advanced mathematical reasoning’ in other activities. Second, compared to the students, the two participants used many mathematical ideas and procedures similar to those found in school classes even though they did not perceive these to be mathematical. I hypothesise that, as participants join an activity, their mathematical knowledge undergoes a transformation. Apparently, on one hand their visible mathematics reduces to some more or less routinized practices, but on the other they learn to relate school mathematics to the activity environment, how to ‘reason mathematically’ using the structural resources found in their activity and how to govern their mathematical thinking by the contextual activity.

**Individual differences in solving mathematical tasks in context.** One of the aims of the research was to point to different ways of using school mathematics and activity-related knowledge in solving mathematical tasks that occur in other activities. The most important differences in this respect have been considered above, but other differences between the participants from the three groups also emerged. Expert practitioners, for example, in solving harder tasks worked in parallel on two or more different directions, while the students commonly stick just to one solution. Another interesting trait of expert practitioners was to work on solutions for which they knew in advance to be only apparently correct. Usually they were able to use such solutions as a step towards the final solution. Such differences are probably due to the expertness of the practitioners.
FINAL REMARKS

This study indicates that when the use of advanced mathematical ideas in out-of-school practices is considered neither the radical situated view (according to which people work out tasks by relying on activity-related practices) nor the modelling paradigm (according to which tasks in activities are worked out by applying school-learnt knowledge) seem to be valid. Inexperienced students solve geometric problems given in an out-of-school activity by placing them in a context - which can be school mathematics as well as the contextual activity - and solve them according to conventions common to the considered context. For them, the context is, above all, a frame of reference for setting the meaning of the task and for setting the way of working out the task. As practitioners acquire expertise their school mathematical knowledge and mathematical reasoning appear to undergo a complex transformation which is not explained by either paradigm. Further research and different conceptualisations are required to describe mathematical thinking in (work) context (Noss, Hoyles & Pozzi, 1998).

WHY ARE WE DOING THIS?: A CASE STUDY OF MOTIVATIONAL PRACTICES IN MATHEMATICS CLASSES

Heather Mendick
Goldsmiths College, University of London

In this paper I argue that looking at the meanings that mathematics classroom practices have for learners and the subject positions that these make available are central to understanding who succeeds, who fails, who enjoys and who detests maths, and so who decides to continue studying it. I explore this using a case study of the, often overlooked, motivational strategies used in an AS maths class arguing that the stress on the exam, competitiveness and procedural work engaged in make it difficult for students to come to think of themselves as mathematicians and so unlikely that they will study the subject further.

Veronica Sawyer [1] has just marked the second homework of her new first year AS-level group [2]. The topic of the homework was completing the square although a lot of the errors occurred in the students' manipulation of fractions. As a result she decides to suspend the normal curriculum and spend an hour looking at prime factors, highest common factors, lowest common multiples and then the four operations on fractions. She describes this as a "very, very simple" topic "dealing with very, very basic things" and further as "babyish". The students progress through the work largely in silence and with few problems. Their teacher interrupts them at regular intervals to offer advice, call out answers, deal with queries and remind them how to deal with the operation rehearsed in the next set of questions. One particular student, Vicky is one of the first to complete the fractions exercises and has had no problems with it. This surprises her teacher who had commented at the beginning of the lesson that, given the mistakes Vicky made in her work, this lesson will be particularly useful for her. Mrs Sawyer asks her, "so it wasn't that that was the problem? What was it?" Vicky pleads ignorance and suggests that, "perhaps it was just a bad day". Mrs. Sawyer simply adds that it cannot be that because she has made these same errors twice, and the discussion ends.

This occurred during my observation of classes at a London college and struck me as typical of how, often in maths lessons, the assumptions of teachers about how maths is learnt cannot explain learners' behaviours. The teacher's conversation with Vicky indicates that she has assumed that the latter's inability to apply a skill (in this case, the manipulation of fractions) in one context (in this case, completing the square) indicates a general inability to apply that skill in all contexts, and one that could be remedied by decontextualised drill and practice of the given skill. In spite of a mounting body of evidence to the contrary, maths teachers continue to act as though they are 'delivering' transferable skills to students and, as in this case, disappear the parts of their lived experience that cannot be understood within such a model.

In this paper I highlight some of those disappeared features. I argue, drawing on insights from situated cognition, post-structuralism and psychoanalysis, that it is the
practices in which maths students and teachers engage, the meanings they give to them and the possibilities these make available for their own identity work [3] which provide a better model within which to understand who comes to succeed and who to fail in the subject and crucially why some people choose to continue with the subject and some reject it. I focus on the practices through which teachers, explicitly and implicitly, answer the frequently asked student question "why are we doing this?" since constructing a rationale for one's actions is a central part of identity work.

SITUATING THE RESEARCH: WHERE, HOW AND WHY?

The case study data used here are taken from an on-going project on gender and AS-level maths that combines classroom observations with student interviews at three sites: Grafton School, Sunnydale Further Education College and Westerburg Sixth Form College [4]. They focus on subject choice, since it is in participation, rather than in achievement, that significant gender differences remain in the United Kingdom. The starting point is the idea that subject choices are a public disclosure of identity, a way of telling people who we are and who we are not. As such, they are intimately connected to other aspects of our identity work: importantly gender, class and 'race'. This orientation to the project, together with my overtly feminist stance, guided the methodological and theoretical choices that I have made. In particular my methods involve the detailed discursive exploration of qualitative data and my theories aim to challenge the authority of mathematical knowledge and to politicise maths classes.

I interviewed 12, 13 and 18 students at Grafton, Sunnydale and Westerburg respectively during their AS course. Also, during Autumn 2001, I have observed two weeks of lessons in each of the classes attended by my participants. In this report I concentrate on some of the findings from my observations, looking in detail at Mrs. Sawyer's AS class at Westerburg. Westerburg is a college with about 800 ethnically diverse 16-19 year-old students and a mostly academic curriculum; it is always oversubscribed and so has a highly competitive entry policy. It has a large maths department, with over 300 students being taught advanced maths courses by six full-time and one part-time members of staff. In order to qualify for entry to an AS maths course students must have at least a grade B pass from the higher level GCSE examination, although occasionally exceptions are made [5]. I have drawn on my observations in Westerburg here, rather than those in Grafton or Sunnydale, because sixth form colleges are now the most common route through which young people gain AS and A-level maths qualifications. I chose Veronica's group because, of the four Westerburg teachers I observed, she was the one who most commonly invoked the requirements of the examination as an explanation for her teaching practices and so provided the most unambiguous message to students regarding the purpose of her classes. However, there were also more personal reasons for my choice. While Veronica is clearly a good and experienced teacher who cares a great deal about the young people in her classes she told me, "most of the [students with GCSE grade]
B’s fall by the wayside”. This statement troubled me more than any others I heard teachers say and I think that I wanted to look at the ways in which such an outcome could seem natural and unproblematic. Retrospectively, I suspect that the way I see her teaching style as the most different from my own was an unconscious motivation for my choice, since it makes my analysis less threatening to the identity work I do in constructing myself as a ‘good mathematics teacher’.

I was a participant in the classes I observed. However, my position was an ambiguous one and my participation differed from that of either the students or the teacher. I sat with the students, obeyed instructions from the teacher, took notes (although of course very different ones to the other students), and was occasionally used by students to subvert the teacher’s intentions. I also adopted some teacher-like practices: assisting students with their work, hanging out in the maths staff office, and even though I encouraged students to call me Heather I often found they addressed me as ‘Miss’. I took detailed field-notes that I wrote up within a day of the experience. I then worked through these notes identifying and classifying incidents according to themes that emerged from the data. I do not see the process of these themes’ emergence as one of my discovery of the intrinsic truth embedded within my data, as perhaps grounded theory approaches would suggest, but as one of creative invention on my part. Although this was a process of invention that often surprised me, what I noticed and how I understood it were influenced by my theoretical framework, so I will outline this before giving an account of the observations.

**SITUATING PRACTICE: MEANING AND BECOMING**

The weakness of the traditional, functionalist model of the transfer of skills within maths, highlighted by the mismatch between Veronica Sawyer’s expectation for the lesson and the actual outcome of it embodied in Vicky, was famously challenged by Lave’s (1988) study. Lave compared the near perfect performance of people she names ‘just plain folks’ on best buy calculations with their much weaker scores on a maths test covering the same numerical skills. Lave developed a different way of looking at learning to help her understand her findings, a perspective she calls situated cognition in which maths and learning are conceived of as social practices, taking place within communities, and learning is never context free. This is a significant shift for it recognises that although “people clearly do transfer ideas, feelings etc. from one context to another under all kinds of conditions...what they transfer is not always what we in education would like them to transfer” (Evans, 1998, p. 285). This approach displaces the power of maths; it is no longer seen as an absolute body of knowledge, but as something people do. Within this framework the opposition of abstract and concrete knowledge is viewed in terms of the socio-cultural practices within which the differently classified objects are learnt. The explanatory burden for problems experienced in teaching is shifted from the cognitive and the pedagogical to “issues of access, and...the transparency of the cultural environment with respect to the meaning of what is being learned” (Lave...
and Wenger, 1991, p. 104-5). If the ‘ability’ to perform a certain skill is tied to the context in which we are asked to perform it, this means that a variety of things impact on it, including the language and situation in which the task is framed, the physical environment, the actions of other learners and of the teacher, and the other experiences of the learner in which these are embedded. Evans (1998) work on adults’ mathematical problem solving points to the complex interweaving of desire and discourse out of which individual performances are constituted. I concur that:

In a given setting subjects in general are positioned by the practices which are at play in the setting and that a particular subject will call up a specific practice (or mix of practices) which may differ from those called up by other subjects, and which will provide the context for that subject’s thinking and affect in that setting. (p. 274, original emphasis)

So the meanings of the practices for those doing them are complex mixes of the structural, the environmental and the psychic, and hence are intimately tied to the way we talk about ourselves, that is to our identity work.

It is this research that situates my approach in the analysis that follows. I am seeking the meanings that students and teachers give to what they are doing in their classroom communities of practice. Thus, it is not what maths is or is not that matters but what it is constructed as being and as not being; the stories we tell about it; the discourses through which it is constituted (Walkerdine, 1998). And also the subject positions that these make available to learners, the way in which maths becomes part of their identity work. I start where Lave and Wenger do with what people do.

SOCIAL PRACTICE IN A MATHS CLASSROOM

The lesson described earlier in this paper was typical of the way students in this maths class generally work individually on repetitive exercises that practice set procedures, when they are not being taught didactically. Mrs. Sawyer’s decision to improve the group’s skills by going back to basics exemplifies the way she feels that maths has to be done in a particular order. In another lesson she comments that they are going to do all the operations on polynomials except for division. She explains that it would be a waste to tackle division before the group have learnt more techniques. This discourse of a hierarchy of knowledge in which she inscribes mathematics, renders pointless the doing of topics out of order. However, it exists in awkward relationship with the way in which different syllabuses and different textbooks put topics in very different orders. The fact that division of polynomials has shifted in the new AS course from the second to the first year, and the fact that at least one student has already covered this topic, provide further contradictions.

Within this hierarchy of knowledge some topics are located near the top of the scale, as ‘hard’ and others near the bottom, as ‘easy’. As the lesson described at the start further demonstrates Mrs. Sawyer often described the latter as ‘babyish’; this association with a younger state being carried through by their being labelled as
junior school or GCSE work. Such references draw on and fuel a series of parallel binaries in which ‘baby’ work is ‘easy’ and opposed to ‘grown up’ methods that are ‘hard’. These are gendered, with the masculine ‘hard’ also opposing the feminine ‘soft’, and classed, because certain aspects of middle-class ‘cultural capital’ are commonly taken as signifiers of mathematical maturity and ‘ability’.

In looking for meanings in maths classes many researchers have discussed the way that sense-making is absent from overly procedural, competitive maths lessons. Boaler commented on the maths classrooms that she had encountered:

It seemed to me that in most of them, it was as if there were a kind of check-in desk just outside the classroom door labelled ‘common sense’, and as the pupils filed into the classroom, they left their common sense at the check-in desk saying ‘Well we won’t be needing this in here’. (1994, p. 554, original emphasis)

In a later study Boaler (1997) reported that many students, but particularly girls, found their ‘quest for understanding’ frustrated by the fast paced, repetition of techniques that dominates top set maths pedagogy. Veronica Sawyer’s approach to the ‘quest for understanding’ is interesting. On a couple of occasions during exposition of demanding topic areas she substitutes belief for understanding, so for example her discursive framing of a topic shifts her from comments like “I know this is hard for an afternoon lesson” to “you’ve got to believe me, it’s not magic, you’ve got to believe me, I’m not fooling you”. Alternatively she often suggests that the quest must be deferred, “you’ve got to be patient with yourself when you’re learning”; understanding will result from time, effort, and hard work. This construction of understanding is used as a rationale for stemming the flow of student questions. However, I would argue that the most important difference between the ‘quest for understanding’ of the girls in Boaler’s study and the one that Mrs. Sawyer wants her class to pursue is its motivation. She makes clear that it is the examination that defines not only what understanding is needed, but also whether you have understood or not; an external authority replaces internally authorised sense-making.

The spectre of the examiner as a disciplinary presence in the classroom

As you would expect in all of the maths classes I observed there was some mention of the exam. However, the frequency and nature of such mentions was very varied. In Veronica Sawyer’s class the exam itself was discussed often and the teacher used many opportunities to describe exam technique. However, it was largely through the constructed figure of ‘the examiner’ that the exam made its presence felt. This examiner is sometimes a hard taskmaster (male labels/pronouns are used here advisedly) rigorously insisting on one form of answer over another and at other times a doddery old man who may find messy work “confusing”. The examiner guides the choice of methods as when Mrs. Sawyer instructs her students to score neatly through each term when expanding brackets so that the person marking your script can still see it and to write “comparing” when comparing coefficients in order “to
show off to the examiner that you're a logical person”. That the examiner is also the ultimate arbiter of right and wrong in the eyes of the students is clear from Imran and Saeed’s comments to me during a lesson on inequalities. When I point out to Imran that he has used = instead of <, he says twice “you know what I mean” and then shifts to “the examiner will know what I mean”. While Saeed, who gets the answer ‘–x<4’, wants to know how to get the answer at the back of the book. After I explain he wants to know (referring to his original solution) “will they mark that as right in the exam?” However, exams carry with them constant evaluation, not only against the requirements of the examiner, but also against each other. As Denscombe (2000, p. 370) found students recognised that exams offered “the prospects of success or failure which could be used as a ‘measure of the person’ on which to make comparisons with others”. Next I look at the way this process of comparisons was played out and encouraged in the classroom.

How do I measure up? Competition within the classroom

During the ten hours of lessons that I watched there were two short tests. These tests are clearly linked to improving student performance in the exam. However, competition seems to be a motivation over and above this. In both cases students are required to declare their marks in front of the rest of the class. Veronica also sustains a competition between this group and her parallel first year class, whom she describes as “my other set, my decision maths set, that you’re in competition with”. When several members of the group provide her with the correct answer to the product of $4x^3$ and $3x^2$ she praises them with the words “you’ve already beaten my other group” (who had offered the incorrect solution of $12x^6$). They are similarly praised for naming the most basic numbers as “positive integers” rather than “counting numbers” as her other group suggested. And in fact while the students are working individually and in silence on some test questions she describes the errors made by her other group as her reason for doing this test adding to me (but clearly audible to the whole group), “I just wanted to see if this lot could beat them”.

Veronica emphasises not only the differences between her groups but also the differences within them. For example, when I am recruiting students for interviews she several times encourages me to take some of them out of lessons explaining that there are a couple of people that I could take out now and it wouldn’t matter that they had missed a lesson. She draws on two discourses to explain these differences: ‘lack of preparation’, which is used to explain how some are doing less well, and ‘natural ability’, which is used to explain how some are doing better. Although not explicitly invoked to explain failure, the use of a discourse of ‘natural ability’ to explain success, necessarily carries with it the implication that lack of ‘natural ability’ contributes to lack of success. Yasser is an example of how these positions are lived:

Yasser is referred to by his teacher as “naturally able” and is clearly marked out as different. He is sometimes given different work to do and on one occasion is asked to teach the class his method for tackling quadratic inequalities. At first he tries to explain
his solution to her verbally, but this proves difficult so he suggests “shall I write it?”, to
which Mrs. Sawyer responds “please do”. When Yasser writes up his solution there are
many looks from students that combine amusement and bemusement. Imran declares
“that is so complicated, I’ve never seen that in my life” and next to him AJ has his hand
up, while Saeed says to his teacher “he’s clever isn’t he?”, then adding “he should do
further maths”. She agrees with him, “he should but he’s busy doing other things”. Saeed
asks her “why don’t you encourage him to do further maths?”, to which she responds
“I’ve tried, it’s his choice”. Yasser has now completed writing up not just his original
solution but also the graph that Mrs. Sawyer asked him for when his first approach
appeared obscure. AJ asks “what is that?”, and then repeats the question. Sanjay has a
furrowed brow and his hand up. Then Mrs. Sawyer steps in and goes
up to the board and
explains the graphical method while leaving up Yasser’s work because “it is worthy of
honour”. She further suggests that you could make sense of his diagram by putting
numbers in “but you’ve done it theoretically like a good pure mathematician”. Yasser is constructed here as a mathematician. However, the manner of this
construction as an esoteric being, a curiosity, “the spectre of mathematical ‘genius’”
(Bartholomew, 2000, p. 4), as Other, makes it more difficult for the rest of the group
to share this position. In concluding, I examine what positions are available to them
and the consequences for their identity work.

BECOMING A MATHEMATICIAN?

Learning “implies becoming a different person” (Lave and Wenger, 1991, p. 53) and
the 16 students in this class are all engaged in making themselves, in a creative
response to the constraints imposed by the situations in which they find themselves.
I have argued in this paper that Mrs. Sawyer’s classroom, in common with many
maths classrooms, is one where the motivations, the reasons given for doing maths,
promoted are not the intrinsic ones of pursuing a ‘quest for understanding’ or gaining
enjoyment from it; that is not ones that make available a position as a mathematician.
Thus in their identity work, in making sense of what they do and who they are, they
look for other motivations and positionings. They become rule followers, good or
bad students, ‘naturally able’, bottom or top of the class, among other things. But
above all, they become exam passers, where this goal is officially about progression
through the educational system and building a career. However, for students, exams
are not just to get jobs; they have a powerful impact on young people’s self-image.
That this is not recognised within classroom discourses creates conflicts for learners,
particularly those who previously saw themselves as enjoying maths, who often
come to see the maths that is on offer as incompatible with their identity work:

Where there is no cultural identity encompassing the activity in which newcomers
participate and no field of mature practice for what is being learned, exchange value
replaces the use value of increasing participation. The commoditization of learning
engenders a fundamental contradiction between the use and the exchange values of the
outcomes of learning, which manifests itself in conflicts between learning to know and learning to display knowledge for evaluation. (Lave and Wenger, 1991, p. 112)

NOTES

1. All names of people and schools and colleges have been anonymised.

2. This is a qualification taken after compulsory schooling, usually between the ages of 16 and 18.

3. Identities are unstable, contradictory, and multiple. Identities are the way we have of talking about ourselves, and are constantly being produced in our actions and our interactions with others; identities are always in process and never attained. However, the word 'identity' suggests coherence and completeness so I have decided instead to use the phrase 'identity work'. Stuart Hall in his work (see Hall, 1996) imbues the phrase 'identification' with similar meanings.

4. Sixth form refers to the educational phase involving 16-19 year-olds; Further Education denotes all post-16 education.

5. The GCSE is usually taken at age 16 and pass grades go from A* down to G, it can be taken at the three levels of foundation, intermediate and higher.

ACKNOWLEDGEMENTS

My thanks go to Leone Burton and Dennis Atkinson for their comments on an earlier draft of this paper, and the Economic and Social Research Council for their funding.

CERTAINTY BIAS AS AN INDICATOR OF PROBLEMS IN CONCEPTUAL CHANGE: THE CASE OF NUMBER LINE

Kaarina Merenluoto & Erno Lehtinen,
Department of Teacher Education, University of Turku, Finland

This paper presents an analysis of interaction between levels of answers and respective certainty estimations in a number concept test participated by pupils at upper secondary school. In the analysis four different profiles of interaction were found and they are explained by various pupils' characteristics (prior knowledge, achievement level in mathematics, gender and test effort). The results refer to significant differences in the sensitivity to the need for conceptual change and tolerance for ambiguity, which seem to be essential for a conceptual change.

INTRODUCTION

The crucial idea in the theory of conceptual change is the radical reconstruction of prior knowledge which is not adequately taken into account in traditional teaching. In educational contexts, mathematics is considered to form a hierarchical structure in which all new concepts logically follow from prior ones, which allows students to enrich their knowledge step by step. The transitions from the domain of natural numbers to the domains of more advanced ones, are often treated as a continuous growth of knowledge. From a cognitive point of view, however, they are better described as a radical reconstruction, because every enlargement requires fundamental changes in the previous thinking of numbers.

In previous research (Merenluoto & Lehtinen, in press; Merenluoto, 2001) about conceptual change needed in enlargements of the number concept, the majority of upper secondary school pupils had not restructured their prior beliefs on numbers in order to understand the concepts of rational or irrational numbers even on the preliminary level. The results refer to a mistaken transfer by the pupils from natural numbers to the domains of more advanced numbers. This suggests a low sensitivity by most of the pupils to the needed change in thinking the numbers. We explained these results with the theories on conceptual change (see Carey, 1985; Chi, Slotta, & de Leeuw, 1994; Vosniadou, 1994; 1999; Duit, 1995), which consider the relationship between the learners' prior knowledge and information to be learned as one of the most crucial factors in determining the quality of learning. In previous studies it has also been found that conceptual change involves not only change in specific beliefs and presumptions but also development of
metaconceptual awareness and consideration of metacognitive effects (Vosniadou, Ioannides, Dimitrakopoulou & Papademtriou, 2001; Limòn, 2001).

Hence in the case of numbers, the major obstacle in understanding the advanced concepts is the quality of students’ prior knowledge and beliefs on numbers. But there seem to be three distinctly different components in this obstacle, where the first component is cognitive, but the two others clearly metacognitive (see Flavell, 1987) and motivational (Pintrich, 1999).

From the cognitive viewpoint, the enlargements of the number concept require drastic changes in the very thinking of numbers. For example, the fundamental ideas of natural numbers, as the concept of a successor, are necessary for learning the notion of natural numbers. But in the domains of rational and real numbers the principle of a successor is not defined, but infinite successive division is possible. Thus some of these basic concepts are in serious conflict with the very character of both rational and real numbers (Sowder, 1992). Therefore in order to understand these concepts, a very profound change in thinking of numbers is necessary.

Secondly, small natural numbers and the concept of a successor seem to be among those special concepts which have a high unconditional certainty attached to them. This kind of certainty seems to be a result from innate cognitive mechanism relate to numeral reasoning principles (Gallistel, & Gelman, 1992) but also from the everyday experiences and the linguistic operations (Wittgenstein, 1969). It has a subjective nature with the feeling of self-evidence. Because these concepts seem self-evident, self-justifiable or self-explanatory, they easily lead to overconfidence (Fischbein, 1987). As such they might act as an obstacle for conceptual change or lead to mistakes and misunderstandings on more advanced domains of numbers. This is the case, when it does not even occur to the pupils that they need to rethink their knowledge and logic on numbers even though it would be necessary. In other words, the self-evident nature of this kind of certainty means that the students might have a low sensitivity to the need for a change.

Thirdly, because of the drastic nature of the needed change, the process seems to be related to pupils subjective experiences with mathematics (Merenluoto, 2001) and to their tolerance of ambiguity (Lehtinen, 1984; Stark, Mandl, Gruber & Renkl, 2002). Experiences in mathematics have been studied from many different viewpoints: In the analysis of feeling of difficulty in mathematics (Efklides, AkiLina & Petropoulou, 1999) the results suggest that these kind of feelings form a system of their own, which is mainly influenced by performance and cognitive ability rather than affective factors. The certainty estimated by the boys were more typical than those of the girls, which seemed to me more context-related. Certainty experiences in
mathematics have been studied also from the viewpoint of self-efficacy, self-awareness, self-regulation and math anxiety (Pajares, 1996; Schoenfeld, 1987). These studies are based on the assumptions that the personal confidence, which has earlier been experienced in mathematics has causal effects on the performance or certainty feelings later.

Thus we have a hypothesis that in process of a radical change in the thinking of numbers the students are forced to tolerate the ambiguity which comes from newly learned operations and characteristics of numbers while they do not yet fully understand the concepts.

The aim of this paper is to analyse the data from our previous research to find the factors referring to the sensitivity to the needed change in thinking of the numbers and to find the factors related to the tolerance of ambiguity.

METHOD

Subjects and procedure: The data used is from a number concept test, given to 537 students (mean age 17.2 years) from 24 randomly selected Finnish upper secondary schools (see Merenluoto & Lehtinen, in press). The students, who participated in the test after their first calculus course, were asked to estimate their certainty while answering the questions. In this estimation they were asked to use a scale from 1 to 5, where 1 meant that their answer was a wild guess, and 5 that they were absolutely sure, as sure as they know that 1+1=2. In this paper only the critical questions (table 1) pertaining to the density of the number line are discussed.

Scoring and variables: The performance in the tasks was measured with a 5-point scale, from 0 (no answer) to 4 (Table 1). The certainty scores were multiplied with 4/5 in order to set them to the same scale. Certainty bias: the task scores were subtracted from the certainty scores in each task. The negative values on this variable respond to uncertainty, the positive ones to overconfidence. Test effort: a percentage of answered items was calculated for every student. Achievement level in mathematics: students mark in mathematics was calculated as percentages from maximum. Group position: the group mean of achievement level in mathematics was subtracted from the respective pupils' mark in mathematics. The negative values refer to a group position below average, positive values to a position above average. Gender: there were 335 boys (62.4%) and 202 (37.6%) girls.

RESULTS

Identification of profiles: On the basis of interaction of the task scores (Table 1) with the respective certainty estimations, a cluster analysis was used and four different profiles were found. The general difference in the quality of
conceptual change is obvious in the profiles of the answers (Fig. 1), where there is a significant difference between the tasks 2 - 3 compared to the tasks 4 - 5. This difference is due to the quality of conceptual change. Although there were question about the concept of infinite divisibility (and limit) in all the tasks, it is possible to answer at a high level without making any notable change in thinking of numbers in tasks 2-3. Whereas it requires a radical change in order to answer, that the "next" or "closest" is not defined in Q or R. The different level of task scores was obvious in the profiles (Fig. 1) but the appearance of the difference was clearer in the certainty bias profiles (Fig. 2).

<td>100</td>
<td>100</td>
<td>74%</td>
<td>.40</td>
</tr>
</tbody>
</table>

Significant (p<.00) difference between profiles: ¹F(3, 525)=17.5, n.s. between profiles 2 and 3; ²F(3, 525)=16.2, n.s. between profiles 2 and 3; ³F(3, 534)=112.9; p<.001; ⁴F(3, 534)=53.2; n.s. between profiles 2 and 4.

For the pupils in profile 1 (n =135; 25.1%) the quality of answers and the estimated certainty level was low. They identified numbers only by their superficial features as whole numbers, fractions and decimal numbers. The profile is characterised by answers based on the logic of whole numbers, where there was a negative bias in certainty except for the tasks 2 and 4 where the word “fraction” was used instead of “rational number”. Their low level of answers suggest a low level of sensitivity for a need for change in thinking, which seems to be due to the serious deficiency in their prior knowledge about numbers. Their low level of test effort (Table 2) together with low estimations of certainty and low achievement level in mathematics suggest a low tolerance of ambiguity.

FIGURE 1. Profiles of the task scores, cluster means.
The profile 2 (n = 161; 29.9%), is characterised by a positive certainty bias in tasks which seemed familiar (tasks 1-2 and 4), but negative bias in task 3, where the set of numbers was referred to as "real numbers". They mainly used the logic of whole numbers in their answers and were sensitive to the difference in tasks 2-3 compared to the tasks 4-5 (Fig. 1), where the questions were very different (Table 1) compared to the ordinary questions they had been used to in school. This suggests a context-related tolerance of ambiguity. The level of answers refer to a low sensitivity to a needed conceptual change.

The profile 3 (n = 188; 34.9%), is characterised with systematic over-estimation of certainty. The levels of answers were significantly better than for the students in profile 2, but the difference in the certainty bias was still higher. This refers to a high context-independent tolerance of ambiguity, which is suggested also by their achievement level in mathematics and high test effort (Table 2). Their answers to the tasks, though they were better than in the previous profile, however, refer to a superficial level of conceptual change: to an enrichment kind of learning which in turn refers to a superficial level of sensitivity to the needed change. The difference between the profiles 2 and 3 has also a significant reference to the gender of the pupils.

The pupils in profile 4 (n = 54), who gave the highest level of answers to the questions, had a positive certainty bias in seemingly familiar tasks (2-3 and 5). But they were sensitive in their certainty estimations in more difficult tasks (4-5), where their explanations clearly referred to a more radical change in their thinking of numbers and the density of number line, compared to the

**FIGURE 2. Certainty bias profiles in the tasks, cluster means.**
pupils in the other clusters. This kind of change seemed to yield to a very significant difference in the certainty bias profiles between the profiles 4 and 3. The best answers had significantly lower certainty estimations because of the novelty of the ideas and radical nature of the change experienced. These students had a high sensitivity to the needed change, which was obvious in the quality of their explanations. Their achievement level in mathematics, their group position and high test effort refers to a high tolerance of ambiguity.

**CONCLUSION**

The results give a suggestion that the conceptual change is related to metacognitive and motivational aspects, which still needs further studies. The students in profile four had high sensitivity to the needed change combined with high tolerance of uncertainty, a combination which seems to be optimal for a conceptual change. These pupils had a quite high level of understanding of the density of the number line. Whereas the superficial level of sensitivity combined with the high tolerance of ambiguity seem to be restrictive to a more radical change and deeper understanding of the concepts. Their thinking of the density of the number line was based on operational thinking (making numbers more exact, adding decimals, etc.) without any references to the structural differences between the numbers. These students have an illusion of understanding and do not necessarily see any reason to strengthen their metaconceptual thinking. The majority of students (profiles 1 and 2) had serious problems in their prior formal understanding of numbers, which is an obstacle for their conceptual change also. Their thinking of the density of the number line was more or less based on thinking of whole numbers.

These results refer to the necessity to consider the metacognitive and motivational aspects in future research on conceptual change. They also suggest that process of conceptual change, altogether, is a complex and a gradual affair, which needs to be taken care of also when planning learning environments which support conceptual change.

THE THEORY OF LIMITS AS AN OBSTACLE TO
INFINITESIMAL ANALYSIS

Raquel MILANI  Roberto Ribeiro BALDINO
Master Degree Student  Volunteer Professor
Action-Research Group in Mathematics Education - GPA
Graduate Program in Mathematics Education
UNESP, Rio Claro, SP, Brazil

ABSTRACT

This paper reports on a study aimed at determining how students would respond
to an introduction to intuitive infinitesimal ideas once they were granted that these
constitute legitimate mathematical knowledge. During six meetings a group of four
freshmen in a calculus course for physics students worked on the basic ideas of
calculus, including the second fundamental theorem, with the support of CorelDraw
zoom. Following a method of data collection used by Sierpinska [1987], we asked the
students to make a demonstration to the whole class. We report on the outcome and
discuss the theoretical implication in terms of Bachelard's concept of epistemological
obstacle.

INTRODUCTION

The pioneer work of Abraham Robinson [1966], granting that infinitesimals are
a legitimate mathematical notion, generated a new branch of mathematics, called non
the sake of the readers who need a briefing on these ideas, we reprint the following
excerpt, whose range and conciseness we have not been able to improve.

"The concept of infinitesimal, of an "infinitely small" quantity, has met a variable
fate along history. Banished by some, used in heuristic but circumspect ways by others,
the infinitesimals until very recently, did not have a right of citizenship in mathematics,
moreover after the 19th century analysts introduced in the differential and integral
calculus, via the ε-δ, the cannon of rigor that came up to our days. Of course, the
physicists and engineers persisted in their intuitive usage of infinitesimals but the
mathematician knew that all this could (and should!) be replaced by a rigorous discourse
evacuating all notion of an actual infinitely small" [Hodgson, 1994:157].

The endeavor of 19th-20th century mathematicians to get rid of infinitesimals has
created: 1) an abyss between mathematics and its uses in other sciences and
techniques [Harthong, 1983]; 2) the need to supply information to non-specialist
mathematicians, introducing them to elementary and intuitive ideas about
infinitesimals [Kossak, 1996]; 3) a problem for mathematics education, timidly
tackled so far, in spite of appeals to bring infinitesimals back to school [Harnik,1986,
Grattan-Guinness, 1991]. Keisler [1986] made an attempt to produce an infinitesimal

1 Research supported by CNPq.
calculus textbook launching the idea of infinitely powerful microscopes and lunettes to “see” infinitesimal and infinite numbers. Stroyan [1998] renews such an attempt, in a recent software-supported textbook, using infinitesimals but without naming them so. Bell [1998] develops nilpotent infinitesimals, more suited to interpret some passages of Leibniz, where \((dx)^2\) is not just an infinitesimal of higher order, but it is actually zero. Some teaching experiments are reported by Tall [1980a, b, 1982].

The following example illustrates how strongly limit conceptions are taken as the only legitimate mathematical interpretation and how strongly infinitesimal conceptions in the students’ culture refuse to die. Czarnocha et al [2001] investigate students’ conceptions about the definite Cauchy-Riemann integral. First they made clear a genetic decomposition, making explicit their structured set of mental constructions about the integral. This genetic decomposition is infinitesimal-free. Then they interviewed students and finally they adjusted their genetic decomposition according to the data collected. The students’ reported views are that “the limit of the Riemann sum is seen as the infinite sum of the rectangles of small width” or “of zero width” [p. 297]. However, the authors did not interpret this outcome as an emergence of an infinite-infinitesimal mental construction and insisted on a limit-conception interpretation: “rather than the limit of the sum of the areas of n rectangles the students state it as the sum of the limit of the areas of the rectangles” [ibid.].

Infinitesimal conceptions have been observed to emerge as epistemological obstacles in attempts to teach limits [Cornu, 1983, 1991, Sierpinska, 1987]. In these studies, infinitesimal conceptions were not asked for, but they emerged spontaneously from students’ speeches. Our basic research question is then the following: what if, instead of waiting for the infinitesimal conceptions to emerge, we stimulated them? What if the students became aware of the abyss between mathematics and its applications produced by the, now unfounded, discrimination of infinitesimals? Will such an awareness stimulate the transposition of the obstacle towards the understanding of limits or will it create new obstacles? In what sense is there an obstacle?

THE SETTING AND METHOD

On order to boost the political dimensions of our research we chose to do the experiment in a regular calculus classroom. We chose a freshmen 2001-course for physics students\(^2\) for whom the language of infinitesimals would be largely used in later courses given by the Physics Department. Since infinitesimals are not part of the calculus courses syllabuses, we expected that this choice would assure the legitimacy of the taught object so as to minimize the criticism from the colleagues from the Mathematics Department. We selected a group of four students willing to participate in the experiment and followed the method used by Sierpinska [1987]: during six videotaped encounters of two hours during class time but in a separate room, we

---

\(^2\) We received stimulus and support from the responsible teacher, Prof. Dr. Miriam Godoy Penteado, Graduate Program on Mathematics Education, UNESP, Rio Claro, SP, Brazil.
introduced the students to the intuitive basic ideas and a brief history of infinitesimals. In the last meeting, we asked them to prepare a demonstration for the whole class. We did not interfere in their preparation. In our country, students do not generally come in contact with limits in high school, and by the time of our first meeting, the teacher had not introduced them. Since these physics students do not take analysis courses, we made no attempts at formalization, neither defining hyper-real numbers via classes of sequences of real numbers [Lindstrom, 1988], nor providing axioms to decide the truth of propositions [Tall, 1982, Keisler, 1986]. The four participants received bonus in the course and the written mid-term had a question that could be answered optionally by limits or infinitesimals.

Our presentations used a CorelDraw zoom in the following instances: to visualize the merging together of a curve and its tangent line at the tangency point P, to visualize that curve and tangent appear as parallel straight lines at P+dx, and sin (dx), to visualize the difference between cos (dx) and 1, and to visualize the trapezium with parallel sides f(x) and f(x+dx) in integration. In all these cases we asked the students to foresee what would come out, before we showed them the zoom on the computer.

We introduced the sign ≈ to indicate "infinitely close to". The infinitesimal increment of the dependent variable was defined according to Leibniz and Robinson as df = f(x+dx) − f(x) and called as almost differential. We maintained f '(x) dx to the standard differential. The derivative was defined as what one gets from the infinitesimal quotient df / dx by neglecting the infinitesimal excess and retaining only the real part; it was interpreted as the constant of almost proportionality between df and dx, so that f '(x) was equivalently defined by df ≈ f '(x) dx. Several calculations were carried out. Here is an example:

\[
\begin{align*}
y &= x^3 = f(x) \\
dy &= (x + dx)^3 - x^3 \\
dy &= x^3 + 3x^2 dx + 3x dx^2 + dx^3 - x^3 \\
dy &= 3x^2 dx + 3x dx^2 + dx^3 \\
\frac{dy}{dx} &= 3x^2 + 3x dx + dx^2 \\
f'(x) &= y' = \text{re} \left[ \frac{dy}{dx} \right] = 3x^2 \\
\text{re}[3x^2 + 3x dx + dx^2] &= 3x^2
\end{align*}
\]

The chain rule was proved as an immediate consequence of the definition (box 1). The definite integral was introduced as the expression of the area under a curve in terms of an infinite sum of infinitesimal parcels. Once the students believed that the sum of the infinitesimal variations dF due to an infinitesimal partition of the domain interval [a, b] equals the variation F(b)−F(a) in the whole interval, the second
The fundamental theorem of calculus was proved in one line (box 2) and expressed in the statement: the area is the variation of a primitive.

\[
\begin{align*}
    h(x) &= f(g(x)) = f(u) \\
    u &= g(x) \\
    dh &\approx f'(u)du = f'(g(x))g'(x) \, dx \\
\end{align*}
\]

QED.  

**Box 1**

\[
\begin{align*}
    dF &= \frac{dF}{dx} \\
    F'(x)dx &= f(x)dx \\
    F(b) - F(a) &= \int_a^b f(x) \, dx \\
\end{align*}
\]

QED.  

**Box 2**

**DATA OUTCOME AND COMMENTS**

In a pilot study, we had asked the class of the year 2000 for a written report on the naught point nine classical question. We got 16 equalities, 16 “less than” and 5 “less than or equal to” answers, but only one evoked a limit conception, though in imprecise terms: “this number may be written as limit, then we should have \( \lim_{x \to 1} x = 1 \). So, among the properties of limits, this number may be considered as being 1, because it gets closer and closer to 1”. The remaining justifications, either of = or <, did not differ qualitatively. They indicate that the notation has a strong appeal to concept images [Tall & Vinner, 1981] through categories such as: 1) **process**: “closer and closer to”, “the number 0.999... tends to infinity and it becomes so close to 1 that...”; 2) **negligible difference**: “...becomes so close to 1 that one may say that this number has the same value as 1”, “because experimentally, this number is rounded off”; 3) **the unthinkable**: “they are so, so close that... they may be considered as equal”; 4) **physical sense**: (from the 2001 study:) “depending on where you are going to use it, you may consider them as equal, but in fact they are not”, “(used) in a rounding off, in a measure, you put 1 to facilitate understanding”; 5) **infinitesimal**: “because there is a gap of \( 1 \times 10^{(-\infty)} \)”; “it will always be less than 1 because in spite of tending to 1, a number will always fail to spot it as equal to 1”; (from the 2001 study:) “be as close as they can be and the difference as small as it can be, one is always greater”. Every calculus teacher should, be aware that such are the spontaneous conceptions of their students if s/he is committed to teaching limits.

In the first 2001 meeting we asked whether the students had ever heard about infinitesimals and whether they recalled any word, phrase or figure related to them. We got answers such as: “I have heard of infinitesimals related to very small points. They are negligible points. Infinitely small points. They are related to infinite decimals. Small points that can be neglected in some calculations. I heard infinitesimal related to fractal, in the sense of something that tends to the uni-dimensional. It diminishes so much that it loses dimension. You may neglect them depending on your point of view, depending from where you look at them. (Pilot-2000 study:) It is something very small indeed, so small that you cannot imagine it, it tends to zero so small it is”. There is nothing new here, except the notion of fractal that looks like a nice teaching device.
We then continued the hyper-real line through the usual diagram and gave a provisional definition: An infinitesimal is a number smaller than any real positive number. We asked for examples. Here are discussion excerpts: “If you imagine a very small number, 0.000...1 it is always possible to put one more zero before the 1 and it will become smaller. It can be very close to zero but is not zero, so you can say that there are numbers that are even smaller than it”. Nobody thought of zero nor of negative numbers. We asked whether zero would be an infinitesimal. Three students agreed, but one argued: “If an infinitesimal is positive, than it is greater than zero, not equal to zero. So I think that zero does not belong in this classification”. The novelty here is the emergence of a concept image of an infinitesimal as a small amount of matter, like a particle, which would not make sense to think of as negative. Along these lines, Hanna & Jahnke ask: “What is the possible role of arguments from physics within mathematical proof, and how should this role be reflected in the classroom?” Hanna & Jahnke [1999:74].

After some calculations of derivatives, we asked the students how they justified dropping off infinitesimals. We got answers based on concept images such as: “The infinitesimal part is so small that it can be neglected. The infinitesimal in this case are not going to make much of a difference”. But we also got answers indicating retention of the formal concept definition [Tall & Vinner, 1981]: “The infinitesimals do no exist in the reals. When you calculate the derivative you take only the real part”. This kind of answer (the derivative is the real part by definition) was only received by the mathematics of 20th century and could not have been given by Newton and Leibniz to Berkeley, were they still alive by the time The Analyst was published. In the face of these two last answers, can we say that “we have the impression that students do not ascribe cognitive values to definitions, they seem to perceive them only as labels which are not relevant to mathematical work” [Furinghetti & Paola, 2000:345]? Or is this conclusion only valid when definitions and images differ considerably, which is the case of limits, but not of infinitesimals?

Here are some excerpts from the students’ discussion at the end of one of the meetings: “In physics we have to imagine the situation, we have to imagine what happens in a very small space, with tiny dimensions. The zoom helps. In the physics class the teacher also spoke about the zoom, taking an infinitely close view, but it was not clear for all the students”. They seemed to feel privileged for being able to understand the teacher. “In the infinitesimals you see the reality of the thing; you keep the sense of the approximation. In the limits you approach the thing; you do not see what is behind. You have to believe. (In the infinitesimals) we understand the part we are neglecting, we see it. In the limit, you don’t. In our calculus course, or even in any area, it would be more coherent to work with these ideas. It is interesting to see how this has developed, to show both sides. By studying the history you understand”. We think that this remark requires no additional comments. We intend to check these students next year to see if their esteem for infinitesimals persists.

From the classroom demonstration, we collect the following excerpts, many of them enthusiastic. “This part of the subject matter is very interesting, a totally different
universe. Sometimes you embark on a trip that leads nowhere. If you take a chronometer and record the time it takes for you to get home, you may notice that it will never leave zero”. (Students from the class: Zeno? Zeno! Some laughed.) “You start perceiving that numbers are infinite, and this makes a big difference. You start thinking about this universe of which the infinitesimals are a part. There is even a special set, the hyper-reals, in which the infinitesimals are included”. The students seemed to praise the existence of a “set” to lodge the infinitesimals; they felt that this made infinitesimals more legitimate. A student from the class asked: “Can you give an example of where you use such infinitesimals?” The answer: “You must be working with the hyper-reals. Consider extremely small particles in such a way that any variation could alter your result. If you are working with rays or with subatomic particles, maybe these infinitesimals will have to be included. If you are dealing with dilation, this infinitesimal could make a lot of difference. If you calculate the dilation coefficient of an iron bar, say the rails in a railroad, in the coupling of one bar to another, in the end it will make much of a difference in the dilation”.

Here we can note the mingling of mathematical, continuous, infinitesimal conceptions with the physical, discrete, subatomic reality. The total dilation was conceived as the integration of infinitesimal dilations as if matter were continuous. It is reasonable to conclude that the whole research process led the students to spontaneously enlarge their concept images so as to incorporate elements from the microscopic physical world among infinitesimals. This inclusion has already been praised by a researcher in quantum mechanics:

“We may regard the physicist who studies the macroscopic behavior of a phenomenon whose microscopic behavior is too complex for him, as a limited observer who cannot apprehend but the shadow of things. The microscopic behavior will be described by non-standard functions” [Harthong, 1983:1200].

On one hand, we may see that the inclusion may be praised as going in the direction recommended by Hanna & Jahnke [1999]. On the other hand, it may be criticized as leading to Bachelard’s obstacle of quantitative knowledge: “magnitude as a property of [physical] extension” [Bachelard, 1980:211].

CONCLUDING REMARK: THE THEORETICAL FRAMEWORK

Bachelard’s concept of epistemological obstacle has been evoked to describe the mode in which infinitesimal notions emerge in the learning of limits. The directive upon which we based our research is clearly indicated by the following “must”: “The construction of pedagogical strategies for teaching students must then take such obstacles into account. It is not a question of avoiding them but, on the contrary, to lead the student to meet them and to overcome them” [Cornu, 1991:162]. There have been many misunderstandings about the concept of obstacle. Errors indicate obstacles but obstacles do not reduce to errors nor to mere difficulties. We rely on a thorough reading of Bachelard who states:

“Errors are not only the effect of ignorance, of uncertainty, of chance, as espoused by empirist or behaviorist learning theories, but the effect of a previous piece of
knowledge which was interesting and successful, but which now is revealed as false or simply unadapted. Errors of this type are called obstacles” [Brousseau, 1997:82].

The difficulty resides in the “dialectical character of the process of overcoming an obstacle” [Brousseau, 1997:88] which stems from Bachelard: “In fact we know against a previous knowledge, destroying ill-formed knowledge, transcending what in the very spirit makes obstacle to spiritualization” 3. [Bachelard, 1980:14]. The emphasis here should be on the verb “to transcend”, in French “surmonter”, which is generally used in philosophy to translate the German verb “aufheben”, meaning to conserve-in-surpassing. Reading the excerpt from this dialectical perspective, the “destruction” acquires the meaning of transformation, of becoming, and the “ill-formed” refers to the surpassed basis of future knowledge.

It is falsifying the concept to say that the overcoming of an obstacle is a matter of making the original, insufficient, malformed knowledge disappear and replace it with new a concept which operates satisfactorily in the new domain. This distorted view of Bachelard’s concept supports the commitment that pervaded the twentieth century teaching of advanced mathematics: erase infinitesimals and write limits. This uni-dimensional view is unable to think of limits and infinitesimals except in terms of “either...or...”, whereas we say that both should be present. Robinson’s non standard analysis is not a return to Leibniz; it is a theory posterior and subjected to Hilbert-Weierstrassian rigor.

If it is clear how infinitesimals play the role of obstacles in learning limits; it is not so clear how the theory of limits creates an obstacle, in the precise sense of Bachelard, to the learning of the now rigorous infinitesimal analysis and its use in Mathematics Education. We hope that this paper takes one step toward bringing this question to the fore.

RELATION BETWEEN PROOF AND CONCEPTION:
THE CASE OF PROOF FOR THE SUM OF TWO EVEN NUMBERS

Takeshi MIYAKAWA
Laboratoire LEIBNIZ – IMAG – Université Joseph Fourier (Grenoble)

The aim of this research is to advance understanding of how mathematical knowledge functions in the proof construction, especially in its written outcome with a problem in algebra. The theoretical analysis allows us to explain some reasons of students' proofs and their tendency obtained by a case study. The first result is that the difficulty of constructions of mathematical proof is due not only to the algebraic competence or proof conception, but also to the mathematical knowledge.

INTRODUCTION

In this paper we report some finding from an analysis of students' proofs in algebra taking into account mathematical knowledge at stake. The aim of this research is to advance understanding of how knowledge functions in the proof construction, especially in its written outcome. This is to know which relation may exist between the mathematical knowledge involved and the nature of proof.

Our research question comes from the recent study about proof conceptions by Healy & Hoyles (1998, 2000). These authors found, from their grand survey in the Great Britain with a statistic method, students' proof conception in algebra that proofs constructed by students follow an empirical approach or a narrative style rather than a formal one although most students are aware of their limitations (2000, p.396). The authors discussed that this problem was due to the lack of algebraic understanding for the proof (2000, pp.425-426). We share the idea that this is one of the possible reasons, but we consider that this is not the unique one. We develop this point in this paper by focusing on the mathematical knowledge. We intend to evidence the role played by students' conception of the mathematical notion (not proof conception) in their proof construction and learning as well.

We take for our analysis the proof problem of sum of two even numbers already studied by Healy & Hoyles. We partially replicate this study (on a smaller scale) and show how one can interpret the data gathered.

THEORETICAL FRAMEWORK

Proof

To characterise or classify students' approaches to proving, some research results have already been presented: proof types of Balacheff (1987), proof schemes of Harel & Sowder (1998), characterisation by the structure of reasoning (Duval, 1991), "proofs that prove" and "proofs that explain" of Hanna (1989), etc. In this paper, we adopt as a theoretical framework, the proof types of Balacheff (1987) from "pragmatic proof" to "intellectual proof", more precisely four types of proof –
"naive empiricism", "crucial experiment", "generic example", and "thought experiment" – and "mathematical proof" (also called "formal proof"). We expect this choice to be relevant in order to characterise the relationship between the nature of proof and that of knowledge. In fact, to characterise these types of proof Balacheff takes into account not only the nature of the underlying rationality and the language level, but also the nature and the status of knowledge (1987, p.163), which is the most important point of view in our analysis.

Conception

To identify and differentiate students' knowledge of even number involved in their proofs, we adopt the notion of conception. Conception is a didactical tool for modelling the students' knowledge in problem solving situations. It reveals the plurality of the possible points of view on a same mathematical object, it differentiates the representations and related methods, and emphasises their more or less good adaptation at the resolution of such and such class of problems (Artigue, 1990, p.265). In our analysis, we pick up aspects as the operators which are used to solve a problem, and the language which is also important from the perspective of proof characterisation[1].

The conceptions of even numbers we can identify, considering operators appearing in schoolbooks or in students' proofs are following. From C2, we can get out three operators by the concept of divisibility or multiplicity. C3 is an algebraic one.

C1: Even numbers end by 0, 2, 4, 6, or 8.
C2: Even numbers can be divided by 2, or the result of the multiplication of a whole number by 2
   C21: Even numbers can be divided in two identical parts.
   C22: Even numbers can be decomposed 2 by 2.
   C23: Even numbers have 2 as a factor.
C3: Even number can be expressed by \( a = 2p \) (\( p \): whole number).

ANALYSIS OF THE POSSIBLE PROOFS FOR EACH CONCEPTION

By this analysis we intend to construct a framework for discussing the data obtained during the observation. We try to construct several different proofs from "pragmatic" to "intellectual" involving the conceptions we have presented. This analysis allows us to locate or to characterise students' proofs, and also to identify the relation between the conceptions of even number in the proof. Concerning the representations used to express proofs, we pay attention to the operational one[3], that is, the representations on which computations or transformations can be carried out. In fact, the natural language is often used in the formulations of proof, but we should often take care to distinguish it from the operational one.

List of proofs

C1: Even numbers end by 0, 2, 4, 6, or 8.
Naive empiricism (numerical): \( 2 + 4 = 6, 4 + 8 = 12, 6 + 8 = 14, 12 + 24 = 36 \).
Crucial experiment (numerical): I take arbitrary two even numbers. $188 + 76 = 264$.

Generic example (numerical): With two even numbers: 18 and 24. $18 + 24 = (10 + 8) + (20 + 4) = (10 + 20) + (8 + 4) = (10 + 20 + 10) + 2$.

We can do this for any two even numbers.

Thought experiment (natural language): Even numbers end by 0, 2, 4, 6, or 8. The last digit of number of sum of two numbers is calculated by the sum of their last digit of numbers. So the sum of two even numbers ends also by 0, 2, 4, 6, or 8.

Mathematical proof (numerical): The proof is same as that of thought experiment but with the table 1.

**$C_{21}$**: Even numbers can be divided in two identical parts

Naive empiricism (numerical): $4 + 8 = 12 = 6 + 6, 6 + 8 = 14 = 7 + 7$, etc.

Crucial experiment (numerical): I take arbitrary two even numbers. $188 + 76 = 264 = 132 + 132$.

Generic example (numerical): With two even numbers: 12 and 18. $12 + 18 = (6 + 6) + (9 + 9) = (6 + 9) + (6 + 9) = 15 + 15$. We can do this for any two even numbers.

Generic example (graphical): $:: + ::::: = :: :: :::: :$ (separate horizontally). We can do this for any two even numbers.

Thought experiment (natural language): Even numbers can be divided in two identical parts. So, if you add each divided part of two even numbers, the sum can be also expressed by two identical parts.

Mathematical proof (algebraic): $\forall a, b$: even number, $\exists p, q \in \mathbb{Z}$ s.t. $a = p + p, b = q + q$. $a + b = (p + p) + (q + q) = (p + q) + (p + q)$.

**$C_{22}$**: Even numbers can be divided 2 by 2

Naive empiricism (numerical): $4 + 8 = 12 = 2 + 2 + 2 + 2 + 2 + 2, 6 + 8 = 14 = 2 + 2 + 2 + 2 + 2 + 2$, etc.

Crucial experiment (numerical): I take arbitrary two even numbers. $188 + 76 = 264 = 2 + 2 + ....$

Generic example (numerical): With two even numbers: 4 and 8. $4 + 8 = (2 + 2) + (2 + 2 + 2) = 2 + 2 + 2 + 2 + 2 + 2$. We can do this for any two even numbers.

Generic example (graphical): $:: + ::::: = :: :: :::: :$ (separate vertically). We can do this for any two even numbers.

Thought experiment (natural language): Even numbers can be divided 2 by 2. So, if you add two numbers divided 2 by 2, the sum can be also expressed 2 by 2.

Mathematical proof (algebraic): $\forall a, b$: even number, $\exists p, q \in \mathbb{Z}$ s.t. $a = 2 + 2 + \ldots + 2 (p \text{ terms}), b = 2 + 2 + \ldots + 2 (q \text{ terms}). a + b = (2 + 2 + \ldots + 2) + (2 + 2 + \ldots + 2) = 2 + 2 + \ldots + 2 (p + q \text{ terms})$.

**$C_{23}$**: Even numbers have 2 as a factor

Naive empiricism (numerical): $4 + 8 = 12 = 2 \times 6, 6 + 8 = 14 = 2 \times 7$, etc.

Crucial experiment (numerical): I take arbitrary two even numbers. $188 + 76 = 264 = 2 \times 132$.

</table>
Generic example (numerical): With two even numbers: 12 and 32. $12 + 32 = 2 \times 6 + 2 \times 16 = 2 \times (6 + 16) = 2 \times 22$. We can do this for any two even numbers.

Thought experiment (natural language): Even numbers have 2 as a factor. So, if you add two numbers having 2 as a factor, the sum have also 2 as a factor.

Mathematical proof (algebraic): $\forall a, b: \text{even number}, \exists p, q \in \mathbb{Z} \text{ s.t. } a = 2 \times p, b = 2 \times q. a + b = 2 \times p + 2 \times q = 2 \times (p + q)$.

$C_3$: Even number can be expressed by $a = 2p$ ($p$: whole number).

Mathematical proof (algebraic): $\forall a, b: \text{even number}, \exists p, q \in \mathbb{Z} \text{ s.t. } a = 2p, b = 2q. a + b = 2p + 2q = 2 (p + q)$.

What we can expect from this analysis

Distance between the conceptions: $C_1$ tests all the cases, $C_2$ and $C_3$ show structure

We can point out some differences between $C_1, C_2,$ and $C_3$ by analysing each type of proof from a mathematical point of view. $C_1$ pays attention to numbers or the representation expressed by the decimal system[4] and observes all the sums of last digit of numbers between 0, 2, 4, 6, and 8 (exhaustive). In this case, the structure of even numbers or their sum is not evidenced. On the contrary, $C_2$ and $C_3$ do not focus on specific numbers, but the structure of even numbers, of their transformations, and of their sums, and the proofs are constructed by showing them.

Whereas we gave a proof based on a generic example with $C_1$, this example is not for sums of numbers chosen among \{0, 2, 4, 6, 8\}. In fact, $C_1$-proofs except naive empiricism and crucial experiment can be separated in two phases. The generic example showing the structures intends to establish the first phase "the last digit of sum of two numbers can be calculated by the sum of each last digit of numbers". The second phase consists of showing that the sums of two digits between \{0, 2, 4, 6, 8\} end by one of the same digits. Thus $C_1$ cannot give generic example for a whole proof, although $C_2$ can. This division in two phases also shows a gap between pragmatic proofs having only one phase and more intellectual proofs. In fact, not limiting at this example of two even numbers, it's not easy for the students to shift from a mere judgement to eliciting the structure of a mathematical notion.

Besides, we can also find that $C_2$ and $C_3$ have a very close nature. In fact, $C_{21}$ divide into two identical parts ($p + p$), $C_{22}$ divides $2$ by $2$ ($2 + 2 + \ldots + 2$ ($p$ terms)), and $C_{23}$ has $2$ as a factor ($2p$). And these "2" appearing in $C_2$ can be seen as "2" of "2p" in $C_3$. Thus we consider that there is not a big obstacle in passing from $C_2$ to $C_3$. On the contrary, $C_1$ where only the last digits are important is very different from $C_2$ and $C_3$. From these points of view, we can find that the distance between $C_2$ and $C_3$ is smaller than between $C_1$ and $C_2$.

Three elements relying on each other: conception, representation, and proof type

Among the different proof types we have presented, the construction of some proofs is a little probable. For example, $C_2$-naive empiricism and $C_2$-crucial experiment. Almost everybody would use $C_1$ when they are asked to judge whether the given
number is even or not (ex. Is the number 243992 even?). It's enough to verify the last digit of number and very easy and simple. On the other hand, judging a large number by C2 requires a great and hard work. As the naive empiricism and the crucial experiment require this simple judgement, if the students have a proof conception of these types, it's obvious that they take C1. Thus, we could state that more relevant or effective conception exists according to the choice of a proof type.

On the contrary, we can also state that the choice of a proof type depends on the "available conception"[5]. As C2 already shows the structure of even numbers, this conception facilitates the construction of a generic example. And it's very obvious that nothing but a mathematical proof can be constructed with C3.

As concerns the language, the representation used in a C1-proof is likely to be numerical since C1 focus is always on the last digit expressed by the decimal system. Thus, even if students have algebraic representation as a modelling tool, it will be difficult for them to produce an algebraic mathematical proof if they have not available a relevant conception (in our case, C2 or C3). In other words, if the available conception for students is only C1, it is unlikely that they will construct an algebraic proof. On the other hand, the possible representations with C2 could be numerical, graphical, algebraic, and the natural language, because C2 doesn't always focus on the digits like C1. And, only the algebraic representation is used for C3. This key role of language is not new. However what is remarkable is that it's not always the algebraic representation which is necessary to construct a mathematical proof. The most relevant one for a mathematical proof depends on the mobilised conception. Therefore, if the intention of teacher is to make students to construct an algebraic proof, he has to design a situation which "disqualifies" C1 but favour C3.

The graphical representation that appears to be a rather easy way to present the structure of a number and a given operation, is only plausible under C21 and C22. We suggest that this representation may be used with the intention to make more "visible" the structure (like "proof that explain" of Hanna (1989)). On the contrary, one can remark that the representation impacts the choice of a proof type. Let us take C2 as an example. If one use only the numerical one, the possible types of proof are naïve empiricism, crucial experiment, and generic example. With natural language, only thought experiment, with graphical one, generic example, and with algebraic one, mathematical proof.

THE RESULTS OF A CASE STUDY

Observation

To get data about proofs constructed by students, we have proposed a questionnaire to 37 students of 9th grade (aged almost 14 years) from Grenoble area in France. The students were just asked to make a proof for the sum of two even numbers: "Is the following statement is true or false? Prove your answer. «When you add any two even numbers, your answer is always even»". We didn't present examples of proofs to students like in the study made by Healy & Hoyles (2000), because the aim of our
observation is to get some data in France and to characterise their tendency and their possible reasons. In France, the proof learning begins progressively from explanation or justification at the 6th grade and is taught mainly in relation to deductive reasoning at the 8th grade in geometry.

Results

We have classified students' proofs depending on the conceptions and the types of proofs (table 2). The criteria of this classification are following:

*Naive empiricism*: proofs based on few cases, only some sums are shown.

*Crucial experiment*: these proofs consist of a statement that describes the use of large numbers like "with two large numbers", "take arbitrary two numbers", or large numbers explicitly used comparing to others, even if it is not stated.

*Generic example*: these proofs consist of just one case that is specifically analysed and this analysis attempts to show the structure of even numbers and their treatment.

*Thought experiment*: such proofs attempt to show the structure of even numbers and their transformation or computation with natural language.

These proofs can not always reach a complete achievement. Some proofs in which we were not able to identify a related conception, are classified to the column "other". And the line "other" of proof type is for the case where the statement "the sum is even" is taken as a hypothesis (circular argument), or where students evidence their conceptions but don't show any idea of a proof. We couldn't find C21-proof or C3-proof. As regards the operational representation, only one student used the natural language (C23-thought experiment). Very few students used the algebraic representation (2 C23-mathematical proofs and 1 C23-other). No student used the graphical one. And all the rest took the numerical one (hence 33/37). Whereas the observation method was not same, we couldn't remark, as Healy & Hoyles (1998, 2000), that students used narrative argument for their own approach.

Much more than half of the students (24/37) produced a C1-proof, most of them (20/24) based on a naive empiricism or a crucial experiment. And proofs of these types were only based on C1. We consider two mutual reasons of these frequencies following our theoretical analysis. First, proof conceptions of students remain in the types of naive empiricism or crucial experiment, like Healy & Hoyles stated, so they take C1 that is useful for these types. The proof types precede the conceptions. Second, the conception C2 is not available to students, so they take C1 which lead to these types of proof. The conceptions precede the proof types. In this second reason, it is not same what they "know" about a tool as they can use it as own tools. For example, Maud's proof (figure 1) shows two conception: "the even numbers go two
by two" (C22) and "they always end by same digit" (C1). But the conception used in
the given example is only the later. With these two reasons, we cannot explain why
they cannot give intellectual proof. We consider that this is due to the different
characters between the proof types. As we have mentioned in our analysis of the
possible proofs, there is a gap in the proof structure between the first two types and
the others: the former has one phase and the latter has two phases. Among these
reasons, none relates to the lack of algebraic knowledge, that is, even if students had
algebra available, they could not construct an algebraic mathematical proof with C1.

Only one seems a proof based on a generic example (figure 1). We have classified this
proof as a generic example, whereas the treatment of last digits was not shown. In
this proof the second phase (exhaustive sum) was implicit. Maud would think the
second phase was too evident. On the contrary, all C1-mathematical proofs were
proof by exhaustion and the first phase was always implicit, that is, students would think the first phase was too evident. This point gives evidence of difference what must be proved between students.

C22-proofs were always based on a generic example (4/4), and none of them were
naive empiricism or crucial experiment. A reason would be that C22 is relevant to
showing the structure which leads to a generic example and useless for naive
empiricism and crucial experiment. However, none of these students could construct
a mathematical proof. Three reasons may be offered to understand this. First, the
lack of algebraic knowledge as a modelling tool. Second, their proof was always of
the type "generic example" and C22 is relevant in this case. Third, a lack of method
for applying algebra to the expression "2 + 2 + ... + 2". In fact, students are not
used to an expression like "a = 2 + 2 + ... + 2 (p terms)". So, we could also suggest
that C22-mathematical proof is little probable as a student's proof.

Concerning C23-proofs, while the total number of these proofs is not great (5/37),
any of them were not based on naive empiricism, nor crucial experiment, nor
generic example. For the former two types of proof, the reason would be same as
C22: C23 is useless for verifying whether a number is even or not. But why no
generic example? We consider that this fact distinguishes the nature of C23 from that
of C22. The reason would be that algebra as a modelling tool is easy to apply with
C23, or the generic example of C23 is not enough to persuade for students.

CONCLUSION

In this paper, we have presented a study of the relation between proof and
conception, in the case of the problem taken from Healy and Hoyles. In the
mathematical analysis of possible proofs, we have shown that the proof character
(exhaustion, demonstration evidencing a structure, or another types of proof) would
be changed by several conceptions which are possible with a mathematical notion.

In the case study, we got the data of students' proofs and their tendency, and explained them with the results of the theoretical analysis. This would be one response to the results obtained by the study of Healy & Hoyles (1998, 2000). For example, it would be not only the problem of algebra (representation) or of proof conception (proof type) that students could not construct mathematical proof, but also that of conception on a mathematical notion (in our case even number).

For the perspective of mathematical proof learning, our study also showed the necessity to design a situation where students could mobilise more pertinent conception or which enable to shift from a conception to more pertinent one. The mathematical knowledge has a crucial role there.

NOTES

1. This point is similar to the two elements of the formal definition proposed by Balacheff (2000) who models a conception with a quadruplet (P, R, L, Σ) in which: P is a set of problems; R is a set of operators; L is a representation system; Σ is a control structure.
2. We didn't separate "divided by 2" and "multiplied by 2", because they have the same sub-conceptions.
3. In the French literature, Duval (1995) calls this representation "semiotic register".
4. C_i is not applicable if numbers are given in the trinary system or odd number system.
5. "Available conception" means in this paper the conception or the operator that is not only known but also which can be used by students.

INVESTIGATING THE INTERPRETATION OF ECONOMICS GRAPHS

Carlos E. F. Monteiro
Mathematics Education Research Centre, Institute of Education – University of Warwick

Several studies in cognitive psychology have investigated the development of mathematical knowledge in cultural practices. For example, some authors have investigated situations where people deal with economic issues, which refer to quantitative relations and mathematical concepts. Print media use graphs to give information about economic topics, e.g., variations of the rates in inflation, and wages. This study investigates the ways in which economists and business people, who subscribe to magazines and newspapers, interpret such graphs dealing with economics. The aim of the study was to identify how the background of the interviewees and the specific aspects of the graphs influenced the interpretative situation. Analysis of the data raised issues related to the teaching of graphing.

INTRODUCTION

Several research studies in cognitive psychology have investigated the development of mathematical knowledge in daily professional activities (Schliemann, 1995). Generally speaking, three aspects could be noted in the majority of those studies. First of all, the participants have limited school experience. Secondly, those studies approach specific mathematical concepts and procedures (e.g., arithmetical operations, area calculation, etc). Finally, these studies indicate that subjects competently solve mathematical problems in their work practices.

Similarly, this paper reports a study that investigated cognitive processes pertaining to the utilization of mathematical knowledge among professionals in an everyday activity. However, in contrast to the studies described above this paper approaches a topic that has been little explored within the Psychology of Mathematical Education: the interpretation of graphs in print media. In addition, the present study investigated the activity of interpretation among professionals with high levels of schooling.

Carraher, Schliemann & Nemirovsky (1995) argue that individuals with limited school experience do not have a general difficulty in working with symbolic representations because everyone uses symbols whenever they think and communicate. On the one hand, these authors remark that in interpretative situations a graph could be defined as an instrument to express the ideas of the person who interprets it. On the other hand, they acknowledge that a person with a limited schooling level would not work out all the issues involved in a graph.

1 CNPq – Brazilian governmental institution, funded this study. I thank Luciano Meira (Federal University of Pernambuco) for his supervision in this study, and Janet Ainley (University of Warwick) for comments on drafts and for contributing to the ongoing discussion of graphing.
In the light of such discussions, this paper investigates how individuals with specialized competence could interpret media graphs. Would their interpretations be refined? Could professionals with a background in the utilization of graphs realize a more complete interpretative approach?

THE INTERPRETATION OF PRINT MEDIA’S GRAPHS

Even in the ‘strict sense’, the word ‘interpretation’ means more than the perception of information. The interpretation of graphs is not an isolated activity. It should be considered as part of a Data Handling process that is a human activity in which people can explore information and construct knowledge.

Therefore, interpretation is more complex than observation. The person needs to make relationship between data and needs to make inferences about the information (Shaughnessy et al., 1996).

Referring to the relations between data and people, Gal (forthcoming) differentiates two kinds of context. When people read newspapers or watch TV, they should be called ‘data consumers’. On the other hand, when they interpret and report their own findings and conclusions, they could be denominated ‘data producers’. In spite of this differentiation, a same person might be consumer and/or producer, depending on his/her context.

The context of use of graphs is an important aspect in understanding interpretative processes. For example, readers of print media and students in the classroom have qualitatively different contexts for the interpretation of graphs. Consequently, different meanings could be attributed to interpretation when it involves specific participants and particular settings.

In contemporary society, graphs are frequently used as sources of information in the news media. In this context, the graphs illustrate journalistic arguments for different topics, and could emphasize and/or disguise data (Meira, 1997; Ainley, 2000).

Figure 1: graph reprinted from a Brazilian weekly magazine.
Figure 1 provides an example of a media graph that was published in a report about the consequences of Real Plan (Brazilian government’s current economic policy). The title is: “Prices have fallen again; Inflation measured by FIPE” (Economics Research Foundation in Brazil). The graph displays information related to a period of 14 months, but it presents just 7 indices that correspond to peaks and troughs. The choices of figures presented and the omission of some months labelled were deliberately used to emphasise the main theme of report.

Figure 2: graph reprinted from a Brazilian weekly magazine: “the value of children: monthly benefits for two children in some countries (US$)”.

Another example of a media graph is shown in Figure 2. On the top of the ‘feeding bottles’ there are figures for each country, and on the bottom there are the names of countries. Belgium’s bar is a complete feeding bottle. The graph presents partial pictures, which symbolize France, Germany, and Italy. Brazil’s value is just shown through the feeding bottle’s tip. Finally, there is not any piece of a picture for United States’ zero value.

The feeding bottles used in graph were ‘adornments’ used to illustrate the topic (Meira, 1997). On the one hand, those visual resources could be a distraction from the interpretation process. On the other hand, the feeding bottles, as extra-mathematical components, might be a symbolic source related to “the value of children”.

In the following sections we present the design, results, analyses and conclusions of a study which investigated the processes of interpretation of such media graphs among specialised professionals. This study aimed specifically to explore how the interpretations of media graphs could be influenced by specialized background of readers.

ECONOMISTS AND BUSINESS PEOPLE INTERPRETING GRAPHS

The final research design of this study was based on the analyses of pilot interviews with several professionals (e.g. secondary school teachers, engineers, researchers). The analyses of pilot interviews mainly provide reflections about the relationship between the background of interviewees and their familiarity with the theme of graph. We decided to focus on economic topics because these were frequently shown
in the media. The economic theme was also very important during the period of data collect, because recently Brazil had moved from high inflation levels after a governmental economic plan.

Among several specialized professions related to economics issues we chose research economists and businessmen/women. The economists have a ‘data producer’ routine, which include production, analysis and reporting of economics data. Those economists frequently construct, use and interpret graphs. The businessmen/women also produce and analyse data related to their work. However, rarely they construct and use graphs in their work routines.

Two groups of eight interviewees were formed. All participants were daily readers of print media, and subscribed to at least one newspaper and one magazine. Therefore, all of them were ‘data consumers’. In addition to specific professional routines, these groups were differentiated by academic background and age (See Table 1).

Table 1: Background of two research groups.

Each participant interpreted seven graphs, which were published by two national magazines and one local newspaper. This paper only refers to data from two graphs (see Figures 1 and 2).

In interview, two types of questions were asked. The questions called ‘general’ were asked at the beginning and at the end. After of first question, the researcher asked more specific questions, which attempted to investigate interviewees’ understanding related to particular aspects of each graph presented.

ANALYSIS OF INTERVIEWS

The interpretations related to the first general question were called ‘initial approaches’, and the answers resulting from other questions were called ‘specific approaches’.

**Initial approaches**

The analyses of ‘initial approaches’ demonstrated that there was a tendency towards discursive and extensive comments. We could distinguish three categories of ‘initial approaches’. The first one was characterised by comments which related to data that came from the graph. The majority of interviewees demonstrated this kind of strategy (59%). The following exchange is an example of this category:

Researcher:  What could you notice from the reading of this graph? [See figure 2]

Businesswoman: [after reading the title, subtitle and labels] It is in dollar. Isn’t it? ...Right...It means that in the United States...Here there isn’t any benefit for two children!
Researcher: The graphs shows that, isn’t it?

Businesswoman: It is... At least... I don’t know if I am wrongly interpreting. [Reread the title]... It is for two children, it is not for one, either for three. For two...
[Reread the names of countries and corresponding figures]... I didn’t really know this aspect!

In her initial approach, the Businesswoman tried to establish relations between the data shown by the graph. We can note that her surprise at values for the United States provoked a rereading of the graph.

Another type of discursive strategy was characterized by interviewees talking extensively about the theme, but basing their analyses on their previous knowledge and experiences rather than on quantitative information presented in the graph. Approximately one quarter of the interviewees (26%) were placed in this category.

A third type of strategy identified was that interviewees approached the quantitative information more directly. They made approximations and estimates, and/or they made written calculations and used calculators. The frequency of these strategies was low in ‘initial approaches’ (15%). The following extract shows an example, in which the interviewee utilized a formula to compare the relations between the values of benefits in each country in figure 2.

Researcher: What could you notice from the reading of this graph?

Economist: ...Have you cut something here? Because this graph is not explicative (...). I understand that (...). The benefits in France, Germany, Belgium, and Italy, are very, very much higher than the benefits in Brazil. In the United States there is not benefits [for children]. You can realize the following calculation [using a calculator, talking aloud] 222 / 8 = 2775%. It means that the benefits in Belgium are 2275% more than the benefits in Brazil. Or the benefits in Belgium are 28.7 times higher than in Brazil. The benefits in Italy are 6 times higher than in Brazil.

His procedure provided a more accurate approach to the quantitative information from the graph. Afterwards, he explained his strategy that could be represented by following expression:

Higher value – Least value = W x 100 = comparative percentage

Least value

Specific Approaches

The analyses of interviewees’ answers to specific questions only generated two categories: comments from the graphs’ data (50%), and approximations and estimations, and/or written calculations (50%).

However, the analyses of frequencies of interpretations developed from each specific question revealed particular tendencies. For instance, all the interviewees utilized the
strategy ‘comments’ to answer the question: ‘what would the number 8 mean?’ (Figure 2).

Researcher: What would the number 8 mean?

Businesswoman: So... The benefit would be for one child? But, here it is US$8, isn’t it? It shows US$8, but this value is an average, isn’t it? Because, I know that on the commercial sector [my] the employees earn 7.5 per each child[ she referred to Brazilian money = Reais]. It is very few!

Researcher: On the commercial sector is?

Businesswoman: On the commercial sector are 7.60 [Reais] per child! Here, it is showed US$8 per two children, isn’t it? ... Per two children. I also think that it is the average of all the professions. I have heard that they really pay very well (referring to European countries).

The Businesswoman drew on her experiences as employer, and her general knowledge about social policies, when she was answering the specific question. In spite of these references to her expectations about the figures, she analysed the data from graph.

In contrast to the frequency of answers from the benefits’ question, nobody developed extensive comments from the inflation’s question: ‘Which period had the faster speed of increase of inflation, in Jan-April/1995 or in May-July/1995?’ (Figure 1). The analyses of protocols indicated that all interviewees answered through approximations and estimative, and/or calculations. The following extract gives an example this strategy.

Researcher: If we will compare these two peaks [Jan-April/1995 and May-July/1995], which is the faster increase?

Businessman: Well... If I will trust the drawing... Because it does not have number for that I can calculate [Referring to May of 1995],... Is that from May to July? Its inclination is bigger!

Researcher: If will you trust the drawing?

Businessman: Well... Looking to the drawing... It depends on... Would you like to know how much increasing between here and there? [Referring to May-July/1995] Or would you like to know the inclination?

Researcher: The speed.

Businessman: The speed here is bigger [May-July/1995].

Researcher: Do you see it just because the inclination?

Businessman – Exactly! I know that the speed is derived to the distance here. Then you look to the inclination to know what is more quickly increasing.

The Businessman’s approach was more strictly related to the data from the graph. His calculations were associated with specific features from the graph.
This specific question had some peculiarities. Firstly, the question asked was connected with the comparison between two periods. In general, the other questions involved comparing two particular values. Secondly, the graph did not present all the numerical values for the calculation asked. The interviewee had to estimate the percentage of May/1995. Thirdly, the concept of speed could not be applied for percentage values of inflation. The suitable procedure should be the comparison between the average increasing percentages on each period. But, this calculation was not possible because the graph did not present all monthly percentages.

We researched the real values in each month displayed by the inflation graph, and we found that the period of highest increasing was between May and July of 1995. In spite of the absence of all necessary numerical values, 25% of interviewees correctly answered the question. But, the more frequent answer was the period between January and April (44%).

The variability of specific questions and of the levels of complexity could be possible causes of particular tendencies of interpretation of interviewees. It could be argued that the specific question related to the benefit graph was more open than the specific question for the inflation graph. This argument might be simplistic, because, for example, the same structure of question was used with the interviewees when they were interpreting another economics graph. In that case, 31% of the interviewees made strategies of approximations, and estimative. Thus, we believe that the analysis of the whole body of data is important to understand these particular results in specific questions.

A second cause could be connected with the type of graph: the benefits graph might be simpler than the inflation graph, partly because it presents ‘adornments’ that could make it most accessible. However, our analyses did not show any relation between pictures shown and ‘facilities’ or ‘distractions’. In general, the feeding bottles were an initial attraction, but that it did not ‘help’ or ‘confuse’ the interpretation process.

On the contrary, real interpretation could be more difficult for the benefits graph than for the inflation graph because it requires the reader to know other information related to several areas. When the researcher asked about the necessity of other data, the majority of the interviewees affirmed that this was necessary, for example to know something about the cost of living in each country.

CONCLUSIONS

Our initial hypothesis was that familiarity with the use of graphs and academic background could be important elements which would influence the interpretations. However, analysis of the data collected from the whole study does not show any particular patterns suggesting differences between the two groups of interviewees in the ways that they interpreted the graphs.

Firstly, we could emphasis that the familiarity with the theme of graphs is not itself a facilitative aspect. The familiarity needs to be immersed in meaningful relationships.
between the interpreter and the graph. In other words, the importance of familiarity is not a pre-established aspect that independently happens.

Secondly, the academic qualification of the interviewees is one part of their background. The economists and businessmen/women are also citizens, consumers, fathers and mothers, electors and so on. From multi-background, interviewees brought their beliefs, desires, and knowledge about everyday situations to their interpretation. Therefore, the interpretation of graphs demands more than a specific competence for perception of information.

On the other hand, we could remark that the generic mobilisation of knowledge is not enough. Even 'data producers' like economists also need to engage in a context, in which the mathematical relationships could become explicit. In our study, the specific questions prompted the interviewees to approach the graphs in more detail, becoming aware of the mathematical relations involved. For example, our analyses demonstrate that specific questions provoked a decrease in generic approaches.

In the contemporary society, the school is a context in which processes of teaching and learning related to graphs are developed. Specifically from our data analysis, we may infer that it is important to consider the planning of didactic sequences with graphs, which provide the mobilisation several types of knowledge, and that construct bridges between previous experiences and the formal aspects of mathematics present in graphs.

References

This paper discusses mathematics education as a contribution to the development of democratic competence. As a feature of democratic competence, the concept of critical consciousness is examined and some results of a study involving students' work within a First Calculus Course are presented.

EDUCATION FOR CITIZENSHIP

As Constant (1998) states, «the job of citizen cannot be improvised». Thus the citizen must be educated. Educational institutions are most often indicated as being the place of such education, but the meaning and content of education for citizenship have been understood in different ways. For some, education for citizenship takes place in a specific academic subject, in which students learn about the rights and obligations of the citizen, the rules which establish who is authorised to take collective decisions and which processes are to be used. For others, this type of education is transversal: it is to be found across the board of academic subjects and involves the development of capacities which are indispensable to self-determination and autonomy (Hall et al., 1998). The work presented in this paper falls within the latter context.

CRITICAL CONSCIOUSNESS

If the democratic citizen is a presupposition of democracy, democratic competence is also an indispensable condition for the democratic citizen to behave as such. In this paper it is considered that democratic competence has, essentially, three components: critical consciousness, sustained and sustainable action, and co-operation.

According to Freire (1975a), critical consciousness is the ability that each individual must have to «understand the reality which surrounds one and situate oneself within the social context in order to intervene in this context in a conscious and creative manner» (p.33).

It is critical consciousness that allows us to understand that the political, social and economic conditions in which we live are not immutable, and that we can participate in changing them, that we can participate in the making of history. But in order to do this, we must begin by understanding what is happening with ourselves. Thus a primary component of critical consciousness is the capacity to identify the dispositions (Skovsmose, 1994) which shape our convictions, our attitudes, our behaviour — it is the awareness of our own system of values, it is the capacity to find a justification for our actions and judge the rationality of them.
To recognise that systems of values and codes of conduct which we thought to be a personal creation, are, in fact, culturally induced can be liberating and can constitute a stimulus for change and a factor of understanding of others (Brookfield, 1987).

Critical consciousness involves, therefore, a reflective dimension – critical reflection – which results in a change in the way we see ourselves, the way we see the world and the way we see ourselves in the world. Or, as Freire (1975b) said:

“(...) people begin to understand, critically, how they are in the world with which and in which they find themselves” (p.102).

In the words of Broughton (cited by Brookfield, 1987, p.18), imagining and exploring alternatives involves «the capacity to generate mentally a structure of possibilities standing beyond the empirically known world of the here and now». Creating and exploring alternatives is another aspect of critical consciousness that leads to methodical doubt – to «reflective scepticism» (Brookfield, 1987, p.21). It is this doubt which questions, for example, whether the fact of a given social structure having remained unaltered for a certain period of time is synonymous with its worthiness and inevitability. It is this scepticism which is revealed in the calling to question of information sources or even universal rules.

THE PEDAGOGICAL PROJECT

The pedagogical project, from which the small sample of the students’ work analysed here originated, is a curricular development project whose aim is to develop democratic competence within the context of mathematics education at the same time, obviously, as acquiring mathematical knowledge and skills.

The students involved were in the first year of a degree course in Management and the work was undertaken in Calculus classes. The author of this paper was both the teacher and the researcher.

In what concerns the mathematical content it was decided to keep to the items originally stipulated in the Calculus syllabus. Mathematical applications and real problem solving were selected to provide a context in which to approach mathematical concepts. Applications and problems were chosen so as to encourage reflection and to elicit sustained opinions about topics which affect Portuguese and/or world society. Ethics and the exercising of power were, then, the backdrop to the topics chosen: ecological issues – global warming, the treatment of waste, the preservation of biodiversity; problems of personal responsibility – drug use, AIDS; population increase and the exhaustion of natural resources; problems of ethics in companies. Cooperative group work was preferred as modus faciendi. The students participated in the organisation of the course in the following aspects: definition of the assessment model and choice of topics for the piece of work each group had to develop and present. The students’ receptivity to the type of work being developed was evaluated
by gathering their impressions/opinions at three different points in the semester: at the end of the fourth, ninth and fifteenth weeks.

ABOUT THE RESEARCH PROJECT

The duration of the research project was one semester - the length of the course module in which it was undertaken. A qualitative/interpretative methodology was used. Two types of data were collected: (1) students' written reports; (2) students' impressions/opinions regarding the work they were carrying out. The work assignments collected for the sample came from five groups of students, randomly selected from the ten groups formed in the class.

The research project was developed around the following questions: (a) to what extent does mathematics education contribute to the development of a democratic competence? (b) in which ways can mathematics education and democracy be connected through mathematical contents? (c) how are the nature of problem situations and the nature of classroom culture relevant to the ways in which democratic competence is acquired?

This paper presents the analysis of a sample of data collected. It addresses a particular piece of an essay produced by a group of students on one of the activities proposed.

ANALYSING A SAMPLE OF EMPIRICAL DATA

The sample analysed here comes from an assignment which was set as follows:

In the 1960's the population of the Antarctic Blue Whale was reduced to such a low level that the rapid extinction of the species was forecast. However, under the influence of an International Commission for the Protection of Whales, measures were taken which permitted the population to increase to around 10,000 in just 10 years. By 1994, their numbers had reached around 50,000.

We assume that the mathematical model which expresses the population variation of the Antarctic Blue Whale between two consecutive years is the function $h(x)$, analytically defined by:

$$h(x) = 0,000002(-2x^3 + 303x^2 - 600x)$$

where $x$ represents the population of the current year, in thousands of whales [1].

Write an essay analysing the problem of whale hunting in economic, ecological and political terms.

The students from group C began by carrying out an analytical study of the function $h(x)$. They then identified the minimum viable population level, the carrying capacity and the maximum sustainable yield, thus giving ecological content to the study. Next they attempted to construct a graph and it was here that the first problem arose.

Students: To make a graph of the function, we used the Excel programme and obtained the following graph (fig.1).
Due to the scale, the graph does not show the values found in the study of the function. So we decided to construct a new graph, with the actual population varying between zero and three thousand (fig.2).

By ascribing values between zero and three to the population, the graph already shows that the function is negative between zero and two, and the minimum found for \(x=1\) can be seen perfectly.

This critical attitude of the students regarding the product of the computer stands out; not only for the critical attitude in itself, but also for the confidence they reveal in their own work. Students often trust the efficiency of technology above their own and it is not uncommon to see them re-doing a correct piece of work so that it will agree with the results given by the computer. The students quoted above, however, are convinced of the correctness of the results of their study and try to identify the discrepancy between the graph supplied by the computer and their own expectations about the behaviour of the function.

![Figure 1](image1.png)  ![Figure 2](image2.png)

Further on, the students introduce new information, combining it with the values supplied about the actual population size:

Students: At the beginning of the 20\(^{th}\) century, large regions of whales were discovered in the Antarctic. Each summer, numerous whale-hunters and factory ships headed South. Thousands of whales were killed and processed in the floating factories.

Whaling was at its height between 1925 and 1960. In the 1960's, the number of blue whales was so small (we do not know the exact number) that the International Commission for the protection of whales took its first protective measures. Due to these measures, within 10 years the population reached 10,000 and in the beginning of the 1990's it stood at 50,000, that is, in 20 years it had grown five times.
And, surprisingly, the criticism of the numbers obtained:

Students: However, if we consider the reproduction function, instead of the variation function, we do not get these results.

Let us see how they reached this conclusion:

Students: As the population variation function between two consecutive years is $h(x) = f(x) - x$ where $x$ is the population in a given year and $f(x)$ is the population in the following year, we can determine $f(x): f(x) = h(x) + x$.

In the case of the blue whale it will be $f(x) = 0.000002(-2x^3 + 303x^2 - 600x) + x$.

Reconstructing the function $f(x)$ is a simple operation. Attributing values to $x$ and obtaining the corresponding values $f(x)$ is a trivial activity. Less so is the manipulation of the function so as to produce the values of the population in an interval of time, since this involves creating a recursive sequence in which the first term, $u_1$, is $f(a)$, with $a$ chosen randomly, the second term, $u_2$, is $f(f(a))$, that is $f(u_1)$, ..., $u_n = f(u_{n-1})$.

The results of the work of these students are shown below:

Students: The values we obtained from Excel were the following:

As can be seen, if the population variation function were that, the population twenty years after reaching 10 thousand (year 1) would be around 11,000 (year 21). The value of 50 thousand whales could only be reached 178 years later, as can be seen from the spreadsheet calculations:

In assigning the piece of work on the blue whale, the researcher had been less rigorous than the students and had not proven that the true numbers concerning the blue whale populations and the values obtained with the proposed function actually coincided. Tomastik was consulted again, where it was verified that the values obtained by scientists regarding the carrying capacity and the maximum sustainable yield did indeed coincide with the values obtained by applying the function. The minimum
viable level was unknown. But what had led the author to suggest a model of population variation that gave such different results to those observed empirically? The researcher had an idea of what may have happened, but she was not the only one. In fact, during the discussion of the assignments in the classroom, and in the face of group C's discovery, a student from group G suggested that there could have been a mistake and the function should perhaps have been:

\[ h(x) = 0.00002(-2x^3 + 303x^2 - 600x) \]

that is to say, an extra zero had been introduced in the factor in evidence.

This student thus showed a perception of the effects of multiplying by 10, the multiplicative parameter, on the behaviour of the function. Group C understood and accepted the proposed alteration and immediately went ahead with the modification of their calculations. And there, after 20 years, was the five-times-as-big population:

Having accepted the idea that the function needed to be altered, which aspects of the study of the function should be re-examined? And which characteristics maintained? The discussion was taken up again in the different groups.

Coming back to group C's report, the students also analysed the problem from the economic point of view:

Students: Whale-hunting is a highly lucrative business (...)

And they juxtaposed this with an ecological vision:

Students: Yet despite generating wealth, this activity threatens biodiversity and the balance of the ecosystem, as the extinction of the whales would break the food chains (...)

However the local situation is not forgotten:

Students: (...) in zones like the Azores, it was an activity with a long tradition and, as it was artisan in character, it would hardly have put the survival of the whale population in danger (...)

Finally, they concluded:

Students: (...) the countries which do not condemn and therefore do not apply laws and coercive measures to combat the capture of whales (...) should change their attitude, indeed they should be conscious of the true implications of this
problem and transmit to their citizens the message that they should not compromise the future of generations to come.

CONCLUDING REMARKS

From the strictly mathematical point of view, the students developed skills in the analytical study of functions and acquired competences for the interpretation of reality, in view of the relevant aspects of the population variation function. But besides the skills and competences they applied in the analysis of the problem it is the actual situation – in the broad sense – which guides the students towards certain procedures, leading to a better understanding of the mathematical concepts involved. In fact there is a reciprocal influence: mathematical knowledge helps the understanding of reality, but reality 'demands' certain mathematical procedures and gives sense to the concepts.

The analysis of the problems posed by whaling cannot be reduced to the «conscientization» (Freire, 1975a, 1975b) of the established reality. The knowledge of the dynamics of populations constitutes a prospective knowledge which should orientate practices. These should not be subordinated to economic interests, but rather be governed by an ethic of responsibility. It is in the balanced management of ecosystems that these students focus their attention and the maintaining of biodiversity as a value in itself is as important to them as the warning of ruptures which could affect the quality of life of future generations, if not their actual survival.

It is also noteworthy that, for these students, there is no room for dogmas or for “untouchable” experts. Things are not what they are because “that’s what it says in the book” or because “teachers say it is so” [2]. With all the naturalness of those who have learned to think about things, rather than submit themselves to a supposed truth, they detect a contradiction, propose an explanation and correct the author of a book and the teacher who placed blind trust in it; and they do it in an environment and context in which this has become a legitimate, permitted and even structuring process.

As regards group C’s use of the computer, some observations would seem to be pertinent. The group used the computer with two different aims in mind: firstly, to create a clearer, well-presented graph of the function; secondly, to avoid having to carry out fastidious calculations themselves. The first objective was initially thwarted because the first graph did not faithfully represent the behaviour of the function. And this is, in fact, one of the negative aspects of a purely technological approach, when the computer users have no idea or expectation of what they should obtain. In the case under analysis, the students had previously carried out a complete study of the function. That is why they proceeded with a localised study to produce an amplification of a part of the curve representing the function. On the other hand, the huge potential of the computer is shown in the work that the students did to verify the affirmations about the size of the whale population. It is unthinkable that without the computer the students could have taken their work in this direction, so great being the number of operations they would have had to do. The same could be said regarding the
work carried out in the classroom, i.e. the alteration of the function’s parameters. Once again, it is evident that technology should be considered a vehicle of cognitive development, a tool which promotes autonomy, an instrument which can stimulate an investigative attitude (Moreira, 1989).

The «reflective scepticism» shown here in questioning the sources of information was, at other times, also evident in the contestation of universal rules.

Adopting an idea, adhering to a cause, assuming a practice is not something which comes from a spontaneous enthusiasm, but from a period of questioning, analysis and reflection during which its value or legitimacy is established.

In such social and political dimensions, mathematics education has a crucial role to assume but the conditions for the development of citizenship arising from mathematics classrooms have to be created. That is a job that cannot be improvised either.

NOTES
[2] The expressions in inverted commas occur frequently, in other contexts, in the discourse of students to justify procedures or affirmations.

Abstract: The present paper is part of a more extensive study whose essential objective is to identify and analyse mental images that are constructed by students during mathematics learning process. In particular, it is one's intention to analyse the role that these images play in the realization of a mathematical task and to understand the origin of their development.

In this work, two mental images are analysed; these images are evoked by a 10th grade student while solving a task on the roots of a quadratic function. The origin of the identified images will be discussed while considering the use of a graphic calculator.

INTRODUCTION

The concept of function, considered by many investigators as one of the most important mathematics concepts, has acquired a central role in mathematics school curriculum (e.g. Ponte, 1984; Dubinsky & Harel, 1992). In spite the different didactics approaches suggested to introduce this concept - some years ago, this was done using a more algebraic perspective and, now, it is taking place using a perspective that values global understanding of the concept, considering all of its representations, with an emphasis on the graphic one, and making the most of the new technological potential (e.g., Eisenberg, 1992; Sfard, 1992) - it still seems to maintain its complexity in what respects the teaching-learning process (e.g., Sierpinska, 1992).

In fact, there is evidence that highlights the proliferation of mental images developed by students (e.g., Bakar and Tall, 1991; Resnick, Schwarz & Hershowitz, 1994; Ruiz Higueras et al., 1994) during the concept's learning process. These images and/or conceptions - rich probably due to the multiplicity of representations that the concept involves and the level of abstraction that those representations require for their understanding - might be idiosyncratic or be directly related to the approach context used (e.g., Eisenberg, 1992; Monk, 1992).

However, students' imagery does not appear exclusively connected to this concept and many investigators have dedicated their work to its study because they believe that it plays an important role in the learning process of mathematics (e.g., Clements, 1981, 1982), in the activity of "making sense of mathematics" (e.g., Dörfler, 1991, 1995; Presmeg, 1992; Reynolds and Wheatley, 1992; Solano and Presmeg, 1995) or in the development of mathematical reasoning at all levels (e.g., Thompson, 1996).
In this article, a broad perspective of imagery will be used - in which an image is "much more than a mental figure" (Thompson, 1996) - associated to the theory\(^1\) of mathematics meaning construction proposed by Dörfler (1989, 1991, 1995).

Dörfler elaborates his theoretical perspective on the construction of mathematical meaning based on the notion of the image schemata. According to this author, an image schema is a set of cognitive interactions with, and cognitive manipulations of, a concrete carrier (an object as model, a material model or just an imagined one, a drawing, a graph or other representation of a mathematical concept...) that allows an individual to obtain a personal meaning of the concept in question. The concrete carrier does not represent the concept; it only serves as a referent for the individual - it is the cognitive activity developed with and on the referent that allows for the concept to be "present cognitively and mentally" (1991, pp.21) to the individual. In this way, the same carrier may serve different image schemata corresponding to different concepts and, conversely, the same concept may allow for various image schemata based on different carriers - it all depends on what constitutes the main focus of the individual's attention and on the properties, relationships or transformations that this person constructs.

As a cognitive process, the image schemata is idiosyncratic and can not be shared by the individual and his/her speakers; only the carrier can be used in the communicative process and it is here - the communicative process - that subjective deviations are corrected (negotiation of meanings) and socially normalised carriers are supplied (Dörfler, 1991).

The mathematical meaning, according to Dörfler (1991, 1995), has a predominant holistic aspect that corresponds to the pertinent image schemata for the respective concept\(^2\). Each mathematical concept may allow for, as previously stated, various image schemata, based on different concrete carriers, and each adequate image schemata constitutes, for the individual, a mathematical meaning of the respective concept. This meaning, which derives from the set of image schemata and the respective concrete carrier, serves as a basis for the individual's memory and other cognitive functions such as, for example, argumentation and logical inference (Dörfler, 1991).

In what concerns the specific context of mathematical learning, this author defends that "the cognitive manipulation of mathematical concepts is highly facilitated by the mental construction and availability of adequate image schemata" (Dörfler, 1991, pp.20), in view of which the teaching of mathematics should privilege this

---

\(^1\) A theory essentially based on the notion of Johnson's (1987) and Lakoff's (1987) image schemata.

\(^2\) The author refutes the idea according to which the mathematical meaning of a concept is constructed accumulatively from basic particles whose meaning is predefined or previously understood (the Bourbakist school is an example of this construction).
construction and availability. As it is not possible to construct pertinent image schemata without adequate concrete carriers and, also considering that these are acquired through appropriate fields of experience, Dörfler suggests that mathematics teaching should constitute, in its entirety, a good field for experience. Not only will this situation offer an accessible set of normalised concrete carriers - as potential referents for mathematical concepts - but, also, it will basically orient individual construction and appropriate development of image schemata, without which mathematics learning only restricts itself to "the formal, rule-guided manipulation of symbols without referents" (1991, pp.22). He also defends, so that an adjustment of individual schemata can take place to socially normalised patterns, the continued use of image schemata that explicitly have, in a conscious form for the individual's understanding, the way in which they were constructed. For the conscious construction of image schemas in this context, he proposes protocols of actions and processes (1989, 1991).

In this present piece of work, part of an interview will be analysed. It seems to illustrate the existence of idiosyncratic images that interfere, in a decisive way, with the solution of a mathematical task. In particular, the way that two mental images are used is analysed; these images were evoked by a 10th grade student while solving a task on the roots of a quadratic function. The idiosyncrasy of one of the identified images is discussed, thus trying to establish its origin. The influence of the use of graphic calculators in the development of that image will be speculated.

DATA PRESENTATION AND ANALYSIS

The excerpt that is presented is part of a more extensive interview elaborated for a presently on-going investigation project.

The student, Alice (15 years old), is a 10th grade urban secondary school student. She likes maths and she does not easily give up when she finds tasks difficult.

The interview, which is semi-structured and task-based, consists of essentially two moments: (a) a moment during which the student tries to explain and illustrate how many roots a polynomial function of the third degree has; (b) a second moment in which the student argues that a quadratic function has always two roots. In the present article, the arguments presented by the student during the second moment will be analysed (the first moment was reported elsewhere).

The analysis of this moment in the interview reveals the existence, in the student's way of thinking, of two images of "roots of a function": a visual image associated to the

---

3 This first moment consists of two phases inserted by the analysis of the roots of the quadratic function; this is, the analysis of the quadratic function roots appears during the explanation of the cubic function roots: the student tries to explain that a cubic function has one, two or three roots (first moment). This explanation is interrupted so that the root of a quadratic function may be analysed (second moment); the cubic function is approached again to systemize the roots (conclusion of the first moment).
graphic representation of a function - 'the roots are the points of intersection of the graph with the xx axis'; a non-visual image where she tries to establish connection between specific mathematical vocabulary - 'if it is of the third degree, it has three roots, if the second, it has two'. These two images coexist and are evoked throughout the interview.

Roost of a quadratic function⁴: Alice's arguments

(...)  
Interviewer: So, the second degree has always two roots?  
Alice: Hum. Yes.

Interviewer: Can you give me an example?

The student draws the example in figure 1 - she begins by representing the axis, she draws without hesitation, from left to right, and highlights the points of intersection of the graph with the xx axis.

At this moment the investigator, trying to explore the stability of the idea 'that a quadratic function always has two roots', suggests the application, to this parabola, of a translation associated to a vertical vector. The student accepts the suggestion and draws the new situation (figure 2).

![Figure 1. Second degree function with two roots.](image1)

![Figure 2. Translation applied.](image2)

Interviewer: How many roots are there?

Alice: Also two... there are two; it's zero here [she indicates the origin of the coordinates] b'cause it's tangent... two.

Interviewer: And what if we apply another translation associated to a vector of greater length...

Alice: Down more?

Interviewer: Yes. How many roots will it have?

During the first part of the interview, when explaining the roots of a cubic function, the student arrives at a conflicting point where, on the one hand, she affirms that a cubic function has one, two or three roots while, on the other, she states that 'if is of the third degree, it has three, if of the second, it has two'.
Alice: Ahh, it'll probably have the same [she pauses a few seconds - she looks at the paper and, with the pencil close but above the paper, she makes some gestures above and below the yy axis; she lightly sketches a point on the yy axis and draws a part of what would be the new parabola, she does this so lightly that you almost can not see it (figure 3)]. But I don't know if it's still a second degree. Is it?

Interviewer: What do you think?

Alice: The form is, ... of a quadratic function. [She pauses] Hum. I don't think so. It's zero only here [she indicates the vertex of the third parabola that she did not actually draw] I don't think so [pause] but these [referring to the second and third parabolas] come from this one [she indicates the first parabola], they're written from this one and this is a quadratic function [she points to the first], this one... I think... is too [indicating the second] and this one...logically should be [she pauses for a few seconds during which she looks at the paper. She shakes her head negatively and state]...Maybe it is. [She giggles].

The interview continues to explore the possibilities in determining the roots of a function, when it is defined by an equation and not by its graph, but the student is unable to do so. During the dialogue, another graph appears (figure 4) and the student is once again asked to analyse this function's roots.

![Figure 3. Enlargement of part of the third parabola.](image)

![Figure 4. Another example of parabola.](image)

Alice: (...) there's always root, but... [she pauses for a few seconds] we can adjust here the graph [she moves her open hand along the yy axes] we make a translation...if we put the vertex here...[she indicates the xx axes]...it'll have a double root.

The student's hand movement seems to imply that it is possible 'to adjust the axis' in such a way as to make the quadratic function always have roots, as if it were possible

---

5 It is notorious to see how much the student wants the quadratic function to have roots to the point where the parabola's vertex is considered a root.
to physically hold the parabola and place it in a new more adequate position, in relation to the axis, so that the graphic could intersect the $xx$ axis.

The student continues to think about the parabola and tries to find an argument that will allow her to accept the fact that a quadratic function may not have roots without contradicting her non-visual image. She tries to explain how, even after having stated that a quadratic has always two roots (and she continues to believe it is thus), it is possible to obtain a graph that does not intersect the $xx$ axes.

Alice: *It could if... it can be written through this one here, ...if it is the result of a translation of a function...that has, that has...roots. This one is written through this one here above...[she points to figure 2, the second parabola]...it will be written...if it's the result of a translation, I think so.*

What the student seems to be trying to explain is that a quadratic may not have roots if it is the result of a translation applied to a quadratic that does; in other words, if the expression that defines it can be written from the expression of the original quadratic, associating to it the corresponding translation calculations. For this student, a translation does not seem to be an application that transforms a parabola into another parabola but, rather, something that allows for the moving of the parabola to another place: the parabola is always the same one, and since it is possible to put it in a convenient place so that it can have two points of intersection with the $xx$ axis (or one tangent point), then any quadratic has, always, two roots.

**DISCUSSION**

The following discussion is based on a preliminary analysis of the data.

This episode seems to reveal the student's preference for her visual reasoning component, in this specific task, given that every time she is asked to supply an example, she does so using the graphic representation. This preference, reported, for example, by Norman (1992) but contrary to what other investigators have given accounts of, may be related to the fact that the graphic component was initially the most explored representation within the study of functions in the classroom (even though the quadratic function had been systematically focussed as a whole, which allowed for the interaction of the various representations) or, still, the continued use of the graphic calculator and, some times, of the computer.

The two evoked images of the 'roots of a function' - a visual one associated to graphic representation of a function, *'the roots are the points of graph intersection with $xx$ axis'*; and, the other, a non-visual one related to specific mathematical vocabulary terms, *'if it is of the third degree, it has three roots, if of the second, it has two'* - coexist throughout the task appearing to take on a similar level of credibility for the student.
The visual image, 'the roots are the points of graph intersection with xx axis', is a standard image introduced by the teacher (and, also, by school textbooks) to help with graphic interpretation of a function.

The non-visual image, 'if it is of the third degree, it has three roots, if of the second, two', seems to be idiosyncratic given that no other subject involved in the study has referred to it. It also appears to have assumed a role of 'uncontrollable image', in Presmeg's (1992) and Aspinwall's et al. (1997) sense, given that it is maintained even when confronted with evidence to the contrary, and it overlaps the visual image not letting the student irrefutably accept the fact that a quadratic function may not have roots.

The origin of this non-visual image seems to be associated to a third one that interferes, in a direct and determinant way, with the task's resolution. For the student, a translation is not an application but 'a vehicle of transportation' that allows for the moving of the parabola in such a way that it may preserve one of its characteristics: to have always two roots.

This third identified image - one of translation seen as 'a vehicle of transportation' - might be connected to the kind of, and writing used in, some exploratory tasks, in the study of function families, using graphic calculators; for example: "Use your graphic calculator to study $a$ and $b$ parameter variation effect in functions of type $f(x) = ax^2 + b$. What happens to the graph when parameter $b$ is altered?" Answers to a proposal of this type usually appear as, 'the function graph has suffered a translation associated to the vector...' or 'the parabola suffered a displacement of ... units'. In this specific case, phrases such as 'the function graph suffered ...' or 'the parabola suffered...' may lead students to develop images such as the one evoked by Alice. (This point needs further investigation.)

ON THE PATH TO PROPORTIONAL REASONING  
Wanda K. Nabors  
The University of North Carolina at Charlotte

Four seventh grade students participated in a constructivist teaching experiment in which manipulatives within a computer microworld were used to solve fractional reasoning tasks followed by tasks that involve concepts of rate, ratio and proportionality. Through a retrospective analysis of video tapes, their thinking processes were analyzed from the perspective of the types of cognitive schemes of operation used as they engaged in the given problem situations. One result of the study indicates that the modifications of the students' available schemes of operation when solving the fractional reasoning tasks formed a basis for the cognitive schemes of operation used in their solutions of tasks involving rate, ratio and proportionality.

This paper focuses on Michael, one of four seventh grade students who participated in a study involving a constructivist teaching experiment as proposed by Steffe and Thompson (2000). In this study manipulatives within a computer microworld were used to solve fractional reasoning tasks and tasks that involve concepts of rate, ratio and proportionality.

BACKGROUND AND RATIONALE

It is commonly accepted among mathematics teachers and educators that reasoning involving the concepts of rate, ratio and proportionality proves to be difficult for most students. Because of the critical role that proportional reasoning plays in a student's mathematical development, Lesh, Post and Behr (1988) describe it as a watershed concept. That is, they refer to it as a cornerstone of higher mathematics and the capstone of elementary concepts. Thus, it is logical that there has been considerable research centered around these concepts that are embedded within multiplicative reasoning. The results of a study by Lamon (1993) indicate that before students proceed in using the formal representation of proportions and in using the cross-multiply-and-divide algorithm, they should be given extensive experience in exploring tasks involving multiplicative situations. One of the findings of Tourniaire and Pulos' (1985) review of the literature was that further research was needed in exploring the elementary proportional strategies and the problem context with its relationship to proportional reasoning acquisition. Studies by Thompson (1994) and Behr, Harel, Post & Lesh (1992) can be seen to be directed towards answering this call. Kaput and West's (1994) research can also be viewed as an answer to this call. The results of Kaput and West's (ibid.) study is used extensively in the study on which this paper is based.

The work in these former studies has included attempts to interpret the nature of concepts involved in proportional reasoning from the adult's perspective. The
Research in the present study (Nabors, 2000) is an attempt to clarify the nature of the students' concepts while engaged in such reasoning through producing cognitive models of students' mathematical reasoning from the students' perspective, thereby enriching former research. The cognitive schemes used to describe the mental operations and constructs of the students are based primarily on work by Steffe (1992, 1994), Sáenz-Ludlow (1990) and Olive (1996).

METHODOLOGY AND THEORETICAL PERSPECTIVES

A constructivist teaching experiment as proposed by Steffe and Thompson (2000) was considered to be an appropriate methodology for the study because this type of teaching experiment was originally designed to formulate explanations and models of students' mental constructions based on intensive interaction between the researcher and the students. The theoretical underpinning of such a methodology is that of constructivism as perceived by Ernst von Glasersfeld (1995). In this epistemological perspective, knowledge is viewed as not being passively received but actively built up by the cognizing subject.

Four seventh grade students were selected from two general math classes through the use of a written pretest and a 20 minute interview (Nabors, 2000). The students' responses were categorized according to Kaput and West's (1994) levels of proportional reasoning without instruction: (1) Coordinated build-up/build-down processes, (2) Abbreviated build-up/build-down processes using multiplication and division, and (3) Unit factor approaches.

In this study, these levels were interpreted through the use of the scheme theory mentioned previously. During the study the students used computer technology available in the computer microworld referred to as "TIMA: Bars" (Olive, 1996). In this microworld, the manipulable objects are rectangular regions that the student can make by clicking and dragging the mouse. The computer microworld provides a setting for the task situations that helps to discourage the students' use of school algorithms in their problem solutions. The physical hardware used to record the data collection consisted of the following equipment: a camcorder, a computer, a converter, a digital video mixer, a VCR and two television monitors. This technology enabled the researcher to work unassisted while collecting video and audio data.

THE CASE OF MICHAEL

The objective of the pretest and the subsequent interview is to explore the level of proportional reasoning each student seems to possess at the beginning of the experiment. The pretest is composed of seven problem situations covering the topics of money exchange, recipe formulations, mixtures, magnification and work which are consistent with those found in former research in which proportionality is being investigated among middle school students.
Pretest Results.

Michael’s written results of the pretest indicates that he possesses Level I (Kaput and West, 1994) proportional reasoning operations. That is, he used additive reasoning in his attempts to solve the tasks. Therefore, in an effort to further investigate his potential proportional reasoning, he is given a problem in which a hook is placed on one pole and he is asked to indicate where a hook should be placed on a second pole so that there would be a proportional relationship between the hooks and poles. Michael understands that there is a need to maintain a constant ratio between the hooks and poles. Thus, in spite of the additive nature of his responses to most of the tasks, there are two important insights that his responses on the pretest illustrate. They involve his awareness for comparing units for the calculations in the tasks involving recipes and in his recognizing the need for maintaining a constant ratio in the pole problem during the interview. Due to the importance former research gives to units in the area of rate, ratio and proportion, (Lamon, 1993; Kaput and West, 1994), these insights lead to the categorization of Michael as being one of the two stronger reasoners in the study. That is, he had available schemes of operation that characterize Kaput and West’s (1994) Level II proportional reasoning before instruction.

Part I: Fractional Reasoning.

In Part I of the teaching sessions, Michael was asked to solve tasks involving fractional reasoning by using manipulatives within the computer microworld: Tima: Bars. (A bias going into the study was that the fractional reasoning involved in the tasks in Part I would be sufficient for the reasoning involved in the tasks in Part II of the study.)

Michael quickly learned to use the actions of the microworld. The first task involved the construction of a bar that would be 3/4ths of a given bar. Michael partitioned the given bar into 4 equal parts and used the computer to dis-embed 3 of the four parts to get the new bar.

Figure 1

This was accomplished with no hesitation and illustrated, at the very least, the use of a partitive fraction scheme. “The partitive fraction scheme is regarded as an initial fraction scheme since it is here that the child begins using standard fraction words while working with partitive units.” (Tzur, 1995, p. 135) Michael knew he could iterate 1/4 three times to get 3/4 or iterate it four times to get the whole. This task was also given to show that the whole is not destroyed through this operation. Thus, a whole-to-part concept (Sáenz-Ludlow, 1990) could be shown or promoted through this task. The next task presented Michael with strong perturbations: The given bar is 5/7 of another bar. Make the other bar.
This task was given to test for and/or promote reversible operations. That is, in order to make the required bar, one needs to be able to 'see' or think of the other bar as being made of 7 sevenths. Then one needs to see the given bar as being made up of 5 of those sevenths.

M: The other bar is 5/7 of this one? (A typical response.)
T: No, the given bar is 5/7 of another bar.

Michael first partitioned the given bar into 5 vertical pieces and then partitioned the same bar into 7 vertical pieces. It is possible that he was trying to see the other bar as if it were superimposed on this bar; trying to see both bars at the same time. The resulting partition did not consist of equal parts, so he erased the bar. Then he partitioned a new bar into 7 pieces, copied it and pulled out 2 pieces of the new bar and joined it to the copied bar. Realizing that it did not give him what he wanted, he erased everything and made a new bar and pondered it for several minutes.

T: Can you picture both bars in your mind... at the same time?
M: Yeah.
T: Which one is bigger?
M: The second one.

Michael then made and partitioned a bar into 5 parts. Next he made a bar that appeared to be two sections longer. I interpret these actions to indicate that he knew the second bar would be two parts longer, but couldn’t make the connection of how to make it exactly the right amount longer. So I gave him another problem with numbers representing more familiar ‘parts of wholes’; that is, the given bar is 3/4ths of the second bar. Again, he tried to follow the same procedures and finally said: “I don’t know…”. It appears that he was unable to make a modification of his existing schemes in order to solve the task. I went back to more familiar parts of wholes and instructed him to make a bar from the given bar knowing that the given bar is one half of the bar he is to make. At this point Michael copied the given bar twice and joined the two new bars to get a correct second bar. To get the second bar in this case does not require any kind of partitioning of the given bar. He just doubled the first bar by copying and joining. He had to realize that two halves make a whole. I then asked him to make a second bar given that the first bar is 2/3rds of the second bar. This time, without hesitation, he copied the given bar, partitioned the given bar into 2 equal pieces, pulled out one of the sections of the given bar and joined it to the copy to represent the requested second bar. (See next page, figure 2.)

M: Is that it?

Michael had constructed a correct solution, but because he still asked if it were correct, I was not sure that an accommodation, a modification of a conceptual structure in response to a perturbation, had been made. Next, he attempted the task dealing with 3/4ths. He made a bar, partitioned it into 4 parts, pulled out one part and joined it to a copy of the given bar and turned to me as if for approval. I read the problem again,
and without realizing it, emphasized the 3 in 3/4. Michael said: “Oh.” He then partitioned the given bar into 3 parts, copied the bar, pulled out one part and joined it to the copied bar. He commented: “Now, I get it.” At this point an accommodation had taken place because he was able to assimilate the situation into his existing scheme of adding a part of the given parts to make a whole composite unit.

Figure 2

I hypothesize that Michael had modified his part-to-whole scheme to include viewing the whole given bar as a part of another bar. Up to this point he had viewed a whole bar as a whole composite unit from which he could pull out a part. In order to check to see if learning, “a permanent modification of a conceptual structure in response to perturbation” (Steffe and Wiegel, 1996, p. 496), had taken place, I gave the following task:

A given bar is 5/3rds of another bar. Make the other bar.

With an extremely surprised, puzzled look, he asked:

M: Five thirds?!
T: Yes.

This requires a huge conceptual leap in that not only are reversible operations involved, but the given bar is greater than a whole. With little hesitation though, Michael made a bar and partitioned it into 5 parts, pulled out 3 parts and turned to me as if for verification. (See figure 3.)

Figure 3

It is my hypothesis that Michael’s correct solution to this task indicates that he reorganized his iterative fraction scheme to include reversible operations. He reasoned that 5/3 could be obtained by iterating 1/3 five times and 1/3 iterated three times would be 3/3.

The previous exercises were given primarily to determine the availability of reversible operations with fractions. It appears that Michael did not have such operations available at first, but was led to develop them through reverting back to a situation in which assimilation and accommodation could take place. According to Glasersfeld (1995, pp. 62-63), “...cognitive assimilation comes about when a cognizing organism fits an experience into existing sensorimotor or conceptual structures it already has.” In this case, Michael was familiar with doubling and halving and with parts of wholes. I interpret his responses to indicate that he possessed a unit fraction scheme (Sáenz-Ludlow, 1990) which allowed him to consider both whole-to-part and part-to-whole
relations. I hypothesize that his reversible operations were basically brought forth through the use of his partitive fraction scheme. But more than this, he was dealing with fractions such as 5/3 which represents the meaning of fractions beyond the part-of-a-whole concept. Thus, his partitive fraction scheme was modified to include a unit fraction scheme and an iterative fraction scheme which allowed him to extend his fractional reasoning to include operating with fractions representing more than a whole.

Michael was able to solve the remaining tasks in Part I of the study tasks without significant perturbations. He (as the other students) did experience difficulty in naming the different fractional parts of consecutively constructed bars. For example, the task of making a bar, constructing a bar that is 1/4 of the given bar and then constructing another bar that is 2/3 of the one just made, caused perturbations in terms of naming the fractional value of the new parts. He viewed each newly constructed bar as an entity unto itself and not as a fractional part of the previous bar, etc. I hypothesize that Michael was working in his zone of potential construction (Steffe, 1992) because he could name the fractional parts when reminded after each construction, that each new bar was constructed from a previous bar.

**Part II: Word Problems.**

The word problems presented in Part II of the study are generally considered, from a school math perspective, to involve reasoning that involves concepts of ratio, rate and proportion. An analysis of Michael’s attempts to solve one such problem in terms of the schemes he used in his solutions is given here.

**Work Problem:** Adam can mow the grass of a rectangular field in four days. Jim can mow the same field 12 days. How many days would it take Adam and Jim, working together, to cut the grass? (Task adapted from Abramovich, 1996).

Michael immediately made a bar and then made two copies of it. (See figure 4.) Each bar represented the field of grass to be cut or the whole job. One bar was partitioned vertically into 4 parts with each part representing the amount of grass Adam could cut in one day. The second one was partitioned vertically into 12 parts with each part representing the amount of grass Jim could cut in one day. In both cases, he viewed the whole field (the whole bar) as a composite unit or whole. In the first solution Michael set up a three-to-one units coordination scheme, a 3-to-1 ratio, between the parts of the bars. This indicated to him that it would take Jim 3 days to cut the same amount of grass that Adam could cut in one day. Next he made a one-to-one coordination in which he matched one day’s work of Adam with one day’s work of Jim, three consecutive times. This ‘used up’ three of the vertical parts in the bar representing Adam’s work. The last part of Adam’s bar is recognized as the part of the field that Jim cut, thereby indicating that it takes three days to cut the field when working together.
Michael's solution to the work problem involves a 3-to-1 units correspondence scheme to indicate the amount of work performed by one person in each day. From the perspective of school math, it might be said that he illustrated the concept of rate when he talked about the amount of work per day. From the perspective of this study, rate was defined as: a reflected abstracted constant ratio (Thompson, 1994). I hypothesize that Michael was viewing the 3-to-1 ratios as static ratios involving a comparison of invariant quantities. That is, he had yet to view the constancy of the ratio from the viewpoint that the ratio would remain constant regardless of variation of quantities being compared. His reasoning did not demonstrate this level of abstraction.

DISCUSSION.

Michael left the experiment possessing more sophisticated fractional reasoning operations available to him than when he entered the experiment. My conjecture is that one of the reasons he was able to conceptualize problem situations that had previously involved constraints for him on the pretest is because he was first met at his level of reasoning and understanding. Next he was placed within mathematical situations which promoted the reorganization of his present schemes of operation to form operations that allowed for solutions requiring more sophisticated schemes of operation. His solving of all of the written tasks on the post test, which were similar to the tasks on the pretest, appears to be a byproduct of the increased sophistication of his available operations. With this being said, it is my hypothesis that Michael had still not demonstrated proportional reasoning from a Piagetian perspective. For Piaget (Inhelder, B. and Piaget, J., 1958), proportional reasoning involves a relationship between two relationships, a second order relationship. This entails a form of mathematical reasoning that involves a sense of co-variation and of multiple comparisons. For Michael (as with the other participants) proportional reasoning was still at the stage of involving the comparison of static ratios.

Gender and Written Mathematical Communication
Miriam Amit and Dorit Neria
Ben-Gurion University of the Negev, Israel

Abstract

This research study deals with the connection between two central topics in mathematics: communication and gender. The study examines the connection between gender and achievement, communication types and communication quality. The findings are based on analysis of 164 9th grade students’ answers to problems that demanded communication of reasoning, explanations and justifications. The results of the study challenge previous research, as not only were no gender differences found in achievement, but also no tendency was found for girls to communicate verbally more than boys. These findings demand further study on the value of verbalized communication, particularly before policy makers modify high stake tests that are meant to be in the interests of implementing affirmative action for the advancement of girls in mathematics education.

Background

In research literature dealing with gender differences in mathematics, it is agreed that no gap exists in achievement at the elementary school level. However, gaps in favor of boys, begin to manifest in middle school. These gaps grow as the students grow older and are most prominent at the very high levels of achievement (Leder, 1990). In Israel, gender differences in mathematical achievement have been found at all ages (Amit & Movshovitz-Hadar, 1989; Ministry of Education, 1996; TIMSS-R, 2000).

The source of differences in test results is not unequivocal and depends on the content and structure of the exam and type of items. It has been found that boys surpass girls in exam items having to do with geometry and problem solving, particularly those given within the context of everyday life. Boys have higher achievement when the problem solving demands strategies that have not been taught in school. The gaps, in favor of the boys, become more significant as the degree of difficulty in the exam items is greater. The girls surpass the boys’ in exam items dealing with calculations, algebraic manipulations and in problems having to do with abstract mathematics. Girls have higher achievement also when solving exam items similar to those appearing in text books (Seegers & Boekaers, 1996; Wang & Lane, 1996; O’Neil & McPeek, 1993). Despite the above, in an analysis by Hyde, Fennema & Lamon (1990), no gender differences were found at middle school classes in anything relating to verbal problem-solving.

In psychology, differences between boys and girls in verbal ability are regarded as an established fact. For example, in tests for verbal ability, it was found that already at the age of 10-11, the girls reached higher achievement than the boys. Those gaps were found in the varying aspects of verbal ability: vocabulary, reading comprehension, writing and speech flow (Halpern, 1986). Despite the above, in an analysis by Hyde & Linn, (1988), it was found that the intensity of the differences in verbal ability was so small that it may be considered nil.
Pomplun & Capps, (1999) argue that some of the gender differences stem from the test structure itself. Hence, boys have higher achievement on multiple-choice tests while girls have higher achievement in open-ended problems. What makes this argument stronger is that the American SAT exams where there has been a gap for many years in favor of the boys, but when a verbal element of essay writing was added to the test, the gap between the boys and the girls decreased significantly (Willington & Cole, 1997).

Mathematical tasks based on open-ended problems have the potential for the students to show a variety of mathematical comprehension and communication levels. Even regular problems, taken from textbooks, may “turn into” open-ended problems by adding a demand to explain and justify the answer, and therefore cause the students to develop and use mathematical communication. (Cai, Jakabcsin & Lane, 1996). The information obtained from the process of writing and its product comprise a diagnostic tool for the teacher and makes it possible to identify misunderstandings and assessing the degree of the student’s comprehension of materials that have been studied (Pugalee, 1998).

We assumed that verbal ability may improve mathematical communication and problem solving, particularly where verbal reasoning is required. Based on this assumption and on research literature, we hypothesized that we shall find significant difference in achievement and communication between boys and girls; this hypothesis, however, has not been confirmed.

Methodology

This research study examined gender differences in achievement and in mathematical communication modes which students used in their answers to problems that required explanation, argument or justification. In particular, we examined the connection between gender and:

1) level of achievement (correctness of answers);
2) the type of written mathematical communication;
3) the quality of written mathematical communication

The type of written communication referred to the representation through which the students chose to explain their answers. This is based on the perception that the mode of representation is the external expression that reflects the solution processes of mathematical thinking. The quality of communication referred to soundness of the mathematical justification, that is, whether the justification is based on correct mathematical argumentation and whether it consistently and completely supports the solution presented by the student (Cia, Magone, Wang & Lane, 1996).

Setting and instruments

The research instrument comprised of three problems from a regional test in mathematics to given 5,928 ninth graders in 73 schools in the southern district of Israel in February 2000. The test items were put together by the Ministry of
Education – as part of evaluation of a 3-year intervention project. The students being tested were asked to answer 46 problems referring to varying areas within the ninth grade mathematics curriculum. About half of the items were multiple-choice or short constructed response ones, and half of them were open-ended problems (to different degrees of “openness”).

For this research, three problems, whose solutions the students were asked to explain and/or justify, were chosen. This requirement obligated the students to select a communication method suitable for expressing mathematical ideas and arguments. In the instructions on how to answer, the students were told they could use any method they wished for justifying their answers.

The first problem dealt with an optimization situation: finding the most worthwhile condition for purchasing a product offered by two companies. The students were asked to mark the correct answer and then to justify their choice. The problem was a non-routine one and was new to the students.

The second problem dealt with rate of change. This problem seems to be a routine open-ended problem, like those appearing in ninth grade textbooks. But it was new to the students to be asked not only to give a verbal answer, but also to explain their answer.

The third problem was in geometry and dealt with the relation between area and circumference. This problem was hypothetical – the students were asked to deal not only with the given situation, but also with a hypothetical change, a process that requires deep understanding of the subject. The problem was formulated as a multiple-choice question in which the students were to choose the correct answer and, afterward, to justify their choice. The integration between the closed items and the demand to explain and justify the answers, turns the problems into open-ended problems and makes it possible to examine mathematical communication.

It is important to note that neither the teacher nor the students being knew, at the time of the exam, that part of the tests would be researched. This fact increases the authenticity of the answers.

Method of Analysis
The analysis of the students’ answers was according to three criteria: the correctness of the answer, the type of communication and the quality of mathematical communication.

- The correctness of answers: The students’ answers were checked with regard to their correctness, regardless of the type of explanation or its quality. The scale included: right answer, wrong answer and no answer.
- Types of communication which the students chose, were sorted according to their representations: verbal, numerical, algebraic, diagramatic.
- Quality of mathematical communication: This ranking reflected the quality of the explanation or reasoning given for the answer. The score was on a scale of: 0 = no explanation up to 3 – complete explanation that communicates effectively...
and presents supporting arguments which are logically sound and complete. This ranking method is based on Cai, Jakabcsin and Lane (1996).

The above method was tried out in a pilot study, and underwent refinement. The emphasis on checking communication quality was on the nature and quality of mathematical communication and not on the verbal/linguistic ability of the student. There are likely to be situations in which the explanation is impressively formulated but not supported by mathematical knowledge. In such a situation, the communication quality will be ranked as low quality. On the other hand, it is likely that a mathematical explanation is correct while not formulated properly because of spelling mistakes and/or language errors. In this case, the communication quality will be ranked as high.

Results

Comparison of Test Scores

For the sake of generalization, the test scores of the study population were compared with the scores of the entire examinee population, as rendered by the Ministry of Education. There was no significant difference between the mean score of the two populations; Study population mean score 67.08; Examinee population mean score 65.19; t-test result t (163) = 0.99

There were no significant differences between the girls' achievement and the boys' achievement in this test as indicated in Table 1.

Gender and correctness of answers:

Answer correctness was divided into three categories: correct answer, wrong answer and no answer. An \( \chi^2 \) test was implemented to the connection examine between gender and correctness of answers: No significant connection was found in any of the problems between gender and answer correctness. The distribution of answer correctness and the results of the \( \chi^2 \) test are presented in Table 2.

Gender and type of written communication:

In the optimization and in the rate of change problems, no significant connection was found between the type of communication mode and gender. In the problems of area-circumference, the distribution of the different communication types and the few students who used algebraic representations, statistically prevented the use of a $\chi^2$ test, but it may be seen that the distributions of communication types for boys and girls are alike. The distribution and the result of the $\chi^2$ test are presented in Table 3.

Gender and the quality of written communication

In the problem of optimization and in problem on area-circumference, there was no significant connection between gender and the quality of mathematical communication. In the problem on the rate of change, there was a significant connection, favoring girls, between gender and the quality of mathematical communication. The distribution of the quality of written mathematical communication by gender and the results of the $\chi^2$ test are presented in Table 4.

Discussion and Recommendations

Reform in math education puts emphasis on writing in mathematics as a communication instrument meant to develop mathematical reasoning and for assessment (NCTM, 1989, 2000). This study examined the quality and type of written mathematical communication modes of 164 ninth-grade students from five high schools in southern Israel. The analysis was derived from answers to problems
within a regional exam. The first problem was a non-routine optimization problem. The second was a routine rate of change problem in which a requirement for justification was added. The third problem was a non-routine one in geometry, in which one chosen answer had to be justified. We selected open-ended problems, requiring explanation and justification, because they enable students to manifest a variety of levels in mathematical comprehension and communication.

Specifically, in this paper we present connections between gender and (1) correctness of answers, (2) type of mathematical communication that referred to representations and (3) quality of mathematical communication that referred to reasoning.

Some of the results of this study go in line with previous research findings, while some challenge previous ones. In the current study, there were no gender differences found at the achievement level on the entire exam, nor in answer correctness to problems that were investigated and analyzed. These findings go well together with the general trends closing the gender gap (Hyde & Linn, 1988), but contradict other studies where gender differences were indeed found (O'Neil & McPeek, 1993; TIMSS-R, 2000). A possible explanation for this result may be attributed to the nature of the population being studied. The gender gaps reported in the research literature are not only age-dependent, but are also dependent on learning level: Among college bound students, gaps appear already in the 7th grade, while among students who are not college bound, these gaps appear in the 11th grade (Hyde et al, 1990). Students in this study were 9th-graders learning in heterogeneous classes, of which about 40% will be bound for academic studies (college bound) and about 60% for non-academic studies. Based on previous research, it is reasonable to assume that among the majority of the study population, the differences will arise at a later stage.

Surprisingly, in the current research, no connection was found between gender and the type of communication mode, particularly in the verbal mode. Yet in previous research as well as tests, that explicitly required verbalization, a verbal advantage had been found among girls (Amit & Movshovitz-Hadar, 1989; Leder, 1990; Halpern, 1986; Amit, 1988; O'Neil & McPeek, 1993;). It may have been expected that these differences would be reflected in the choice of communication type, and that girls would tend to use verbal representations more than boys. However, in the three problems investigated, no connection was found between gender and type of representation that were chosen as a means of communication.

A possible explanation for this rests on a trend of closing the gap in verbal ability in favor of the girls, to the point where it may be said that it does not exist (Hyde & Linn, 1988). However, if verbal ability indeed still exists, another possible explanation is that despite there being girls with higher verbal ability, they do not tend to use this ability when there is no explicit demand for it. That is, girls do not naturally transfer the relative advantage they have in verbal ability for the area of mathematical learning.
This assumption was further supported by the analysis results, where the girls surpassed the boys in the quality of communication for the rate of change problem. In the optimization and area-circumference problems, no connections were found between the quality of written mathematical communication and gender. The rate of change problem was distinct from the other two, in that it was completely open-ended, without an interim state of multiple-choice or constructed response that was in the others. In order to be ranked into “communication of good quality”, the students were asked to answer the problem fully verbally, to reach verbal conclusions and then to justify them well. It is likely that in a problem of this type, where there is an explicit demand for verbalization, the girls’ advantage in verbal ability was expressed. Girls produced fuller explanations of their reasoning, and therefore their quality of communication was graded higher. These findings are similar to the ones reported by Lane, Wang & Magone (1996).

Closing Recommendation

This research study challenges a number of conventions regarding the gender differences in mathematics education. No evidence was found in support of previous widespread reports, that at the age of 15, boys’ achievement surpasses that of girls. This study reinforces some others that claim the closing of the gender gap. However, the intriguing finding is that no tendency for girls to choose communication modes based on verbal representations was found, although girls have an advantage over boys in verbal ability.

Those who determine education policy, who are interested in advancing girls’ achievement in mathematics education, tend to integrate more and more verbal communication opportunities into the tests with the assumption that this will comprise a reformation preference for girls. This assumption, which finds no support in the above study, needs to be considered cautiously, and further research in this direction is required.

WHAT FACTORS INFLUENCE THE FORMATION OF TEACHERS' PROFESSIONAL COMMUNITIES AND WHY SHOULD WE CARE?

Susan D. Nickerson and Judith T. Sowder
San Diego State University

We describe a large-scale urban school initiative aimed at teachers' professional development with the goal of increasing teachers' mathematics content knowledge and helping them improve their practice. Believing that the formation of professional communities of teachers is crucial in supporting teachers trying to implement changes in their practice, the initiative provided opportunities for the formation of site-based supportive communities. Professional communities developed at some sites and not at others. We describe the factors, institutional and individual, in the formation of teachers' professional communities.

The administration and teachers working in a large urban school district in the United States have embarked on a massive reform of mathematics instruction in the district’s schools. This reform includes extensive professional development from a local university. The coursework, site-based support, and daily shared professional development time is intended to facilitate teachers’ sustained growth in content knowledge and practice. Somewhat serendipitously, this reform effort has offered extensive opportunities for research on teacher change. One aspect of our research, which we report on here, focused on the nature of the site-based communities in which these teachers participate. What aspects of these teachers' professional lives influenced the development and nature of these professional communities?

THEORETICAL PERSPECTIVE

We see this question as important because we adopt an interpretive approach that views the practices of the teachers as situated within their professional communities and in the schools and school district in which they work. In adopting the situative perspective, we focus on the reflexive nature of the settings of teacher learning and teachers' different kinds of knowing (Cobb & McClain, 2001; Putnam & Borko, 2000). Our working hypothesis is that teachers' practices develop within a community and that local contexts can play a crucial role in teachers’ beliefs, knowledge, and conceptions of effective pedagogy (cf. Franke & Kazemi, 2001; Kyriakides, 1998; McLaughlin & Talbert, 2001). We see the development of a teacher's identity as a mathematics teacher as situated within communities. Other studies (Adler, 1996; DeFranco & McGirney-Burelle, 2001; Talbert & Perry, 1994) suggest that departmental and school-based communities in which teachers participated were a fundamental part of their development of identity as teachers of mathematics. Franke & Kazemi (2001) suggest that the existence of a professional
community may be even more critical in supporting experienced teachers learning to teach in new ways.

THE SETTING

Our study took place in a large urban school district. The superintendent had developed a broad-based plan to increase student learning in literacy and mathematics, and had in fact been able to obtain large amounts of funding from private agencies to carry out this unique plan. One component of the plan was to assure that all students in grades four through six were taught mathematics by teachers prepared to do so. To begin this work, the eight lowest performing schools in the district were allowed to hire 32 additional teachers to their staffs, with the understanding that these teachers would teach only mathematics (three classes each 90 minutes long), that they would have 60-90 minutes each day together for professional development time, and that they would take university coursework that would help them obtain a deeper understanding and ability to teach appropriate mathematics. For the most part, teachers who sought out these positions did so because they enjoyed teaching mathematics. All teachers were experienced; about half were bilingual in Spanish and had a credential for teaching bilingual children.

The university mathematics specialist professional development program for the teachers consisted of 12 semester hours of coursework designed specifically for the needs of the teachers. The 6 semester hours of mathematics were taught by experienced instructors with master's degrees in mathematics and familiarity with the elementary school mathematics. The 6 hours of mathematical pedagogy courses were taught by two teachers-in-residence (TnR) who were master teachers from the school district with prior experience in high-poverty culturally diverse schools and prior experience as providers of professional development. The pedagogy courses focused on children's thinking about mathematics, teaching second language students, curriculum implementation, and pedagogy.

As a result of their extensive coursework as a cohort, we would expect these teachers to have theoretically shared patterns of discourse developed over time. This 'community of discourse' would have been further supported by their interactions with the two teachers-in-residence who, in addition to teaching courses, provided extensive on-site assistance in pedagogy. The teachers-in-residence each worked with four schools, visiting them each week to plan with teachers, to observe, and to discuss what had been observed. These meetings were often focused on a need that had been identified by the teacher. The period of time designated each day for professional development provided an opportunity for reflection with the teacher-in-residence. Also, the university mathematics instructors worked closely with the teachers-in-residence and frequently visited teachers in their classrooms and assisted them with the many problems inherent in teaching from new textbook materials to poorly prepared students, many with little understanding of English.
In our analysis we use the construct of a teachers' professional community as defined by Secada & Adajian (1997). According to this definition, a **professional community** is a group of people with a shared purpose and a common base of technical knowledge. Its members are accountable to each other in achieving their goals and their practice is open to review in what is known as deprivatization of practice. Secada & Adajian further described what distinguishes teachers' professional community by operationalizing this construct along four dimensions: (1) shared sense of purpose, (2) co-ordinated effort to improve students' (mathematics) learning, (3) collaborative professional learning, and (4) collective control over important decisions affecting the mathematics program.

In this report, we focus on two of the eight schools participating in the first year of the mathematics reform initiative because they provide examples of the factors affecting the formation of teachers' professional communities. Our data corpus included field notes of the TnRs and researchers and informal interviews with teachers. It also includes the written reflections of the teachers as they responded to journal prompts and a survey. We documented changes in teachers' mathematical content knowledge as measured by pre- and post-intervention instruments and their self-reporting of confidence levels for various content areas.

**THE CASE OF TWO ELEMENTARY SCHOOLS**

We will call the two schools Harbor View and Palm. Harbor View had five mathematics teachers in this program, Palm had four. Both schools had a high percentage of second language students. At Harbor View 63.3% were English learners and at Palm 73.3% were English learners. However, Harbor View students were Spanish-speaking (62.5%) whereas the Palm students were more multi-lingual (only 44.5% were Spanish-speaking). Three of five mathematics teachers at Harbor View and two of the four Palm mathematics teachers had teaching credentials for teaching bilingual students. Mathematics teachers at Harbor View averaged 14.9 years of teaching experience; Palm teachers averaged 9.75 years teaching. Four of the five teachers at Harbor View and two of the four teachers at Palm had prior professional development. The professional development time given to these teachers was left for the teachers to structure, except when they were visited by university or school staff.

There were no significant differences in the two groups of teachers' reported confidence levels in teaching different content areas at the beginning of the school year. For the purposes of this discussion, we characterized teachers as weak, sufficient, or strong in mathematics content knowledge. Harbor View had two mathematically strong teachers and three were sufficiently strong in mathematics. Palm had two mathematically strong and two mathematically weak teachers.

We found that, according to Secada's & Adajian's (1997) description, the teachers at Harbor View aligned well along the four dimensions of a teachers' professional community while the teachers at Palm did not. The eight sites varied in the extent to
which the teachers formed professional communities, with these two schools representing, to some extent, the extremes. We discuss them along each of the four dimensions.

Shared sense of purpose
Harbor View teachers developed a shared sense of purpose. Their reflections express a collective desire for their students to be prepared for later life. They discussed instilling children with the desire to learn and giving Latino children an opportunity in later-life situations. Their discussions revolved around what they could do as teachers to provide students with the opportunity to learn. At Palm, teachers espoused a goal of having the students understand mathematics. In their reflections, their stated goals are more diverse, such as getting the students to work independently and enabling students to solve problems in novel situations. They did not share common goals nor did they discuss how individual goals were to be met.

Co-ordinated effort to improve students' mathematical learning
The two sites differed in their use of time together. Harbor View teachers made a conscious effort to work together. They arranged their physical office space to facilitate their working together by arranging their desks to face one another in a large circle. The Palm teachers displayed no conscious effort to work together, and arranged their desks so that two of them faced a wall and two faced each other.

The TnR and the Harbor View teachers reported using their professional development time planning together prior to teaching and reporting on successes and failures of their previous classes and what modifications could be made for revisiting the topic. They also looked at and discussed videotapes of each others' teaching. As the year progressed they spent time looking ahead to prioritize topics with standardized tests and with the next year's curriculum in mind. The university mathematics instructor visiting the site reported that the teachers needed less assistance with mathematics content and spent their time discussing teaching mathematics.

In contrast, the teachers at Palm reported using their professional development time to report on successes and failures and learning content from each other or from the university mathematics instructors. They did not discuss teaching solutions to failed lessons. The TnR made several references in her field notes to her efforts to move the professional development time discussions during her visits beyond a discussion of what the students cannot or were not willing to do to what the teachers could change in their practice.

Collaborative professional learning
Collaborative professional learning describes how well and closely the teachers work together to learn about and improve their instructional practices as related to mathematics. Hargreaves (1994) distinguished between a collaborative culture and contrived congeniality. Collaborative culture is spontaneous, voluntary, development
oriented, pervasive across space and time, and unpredictable. At Harbor View, teachers initiated discussions, informally in smaller groups, and sought opportunities to work together outside of the space of their professional development time to improve their instructional practice. The teachers observed one another’s practice, both by visiting each other's classrooms and viewing videotapes with the videotaped teacher, and toward helping one another improve on teaching practices.

Contrived congeniality, as defined by Hargreaves, makes working together a matter of compulsion such as in mandatory peer coaching and when teachers are "persuaded to work together to implement the mandates of others". At Palm, teachers spent little time together except when mandated by the presence of on-site assistance. The discussions at Palm tended not to focus on planning but on sharing and reporting of experiences and on students’ shortcomings. They did, however, report having helped each other improve on teaching practices. Furthermore, the Palm teachers expressed a view that they were implementing district mandates and reported feeling that their "hands were tied".

**Collective control over important decisions affecting the mathematics program**

Harbor View teachers made grade-level decisions on content to be taught. They were willing to deviate from the adopted curriculum as needed to meet their shared goal of preparing underachieving students for their later life experiences, including students' success in school in subsequent years.

Palm teachers felt a lack of control over decisions affecting the mathematics program. The vice-principal and the principal both sought out the TnR on separate occasions to express concerns about the mathematics instruction being given to students, and particularly about students’ need for direct instruction. The TnR was told that parents and classroom teachers requested that more homework be assigned. In a subsequent meeting with the TnR, the mathematics teachers expressed a desire to give more homework but frustration that they were limited by the "no adaptations, no supplementing" rule of the district mathematics office. Palm teachers predominantly adhered to the curriculum as given until one teacher made the decision to use materials from the same curriculum two grade levels below the grade level of the students she was teaching.

One mathematics teacher at Palm faced the problem of working in the classroom of a teacher who had classroom rules and procedures that were not aligned with those of the mathematics teacher. In October, the TnR and the mathematics teachers met with the classroom teacher and the principal to talk about ways to make the rules and procedures ones that both teachers would find suitable. They had some common ground but were unable to align them. There were constant problems with students—in February a mathematics teacher at Palm reported that a student had threatened to kill her. There was no action taken against this student though, by school district policy, the student should have been immediately suspended.
In sum, Harbor View teachers articulate a shared sense of purpose, demonstrate a co-ordinated effort to improve students' mathematical learning, collaborate to improve their practices, and exercise collective control in decision making. Palm teachers could not.

**DISCUSSION & CONCLUSIONS**

The shared professional development time was intended to allow for co-operative planning amongst teachers at a site. Hargreaves (1994) described a three-year initiative intended to develop co-operative planning among school staff by providing additional preparation time. Yet, among the findings cited were that "...increased preparation time did not necessarily enhance the association, community, and collegiality among teachers. Time itself was not a sufficient condition for collegiality and community." (p. 131). So, why, under what could be identified as ideal conditions for the formation of communities that support teacher growth, did some groups of teachers form professional communities at their site and others not?

We identified several factors that seem to account for the differences in development and strength of teachers' professional communities at the school sites:

- the relationship the mathematics teachers had with the school administration and other classroom teachers,
- the respect for and access to the knowledge of other mathematics teachers,
- the presence or absence of a teacher leader,
- the mathematical content knowledge of the teachers and their reported comfort level when teaching mathematics, and
- the teachers' familiarity with the culture and language of the student body.

We discuss how these factors are related to the dimensions that distinguish teachers' professional community. One factor we identified as critical in the formation of teachers' professional communities was the nature of the relationship with the school administration and other classroom teachers within a school. In our eight schools, we saw a difference between the relationship between teachers and the administration at schools where the mathematics teachers were drawn from the site versus recruited from another site. Although these two school sites had all new staff, the Harbor View principal hired first, thus taking and being able to choose and select the best combination of teachers applying for the positions, whereas Palm teachers were selected last by their principal. Additionally, the shared professional development time was scheduled for the beginning of the day at Harbor View, reflecting the principal's commitment to the initiative and its success. The professional development time at Palm was shorter because of other responsibilities given to these teachers, and was scheduled for the end of their day. The Palm school administrator's questioning of the mathematics teachers' teaching and the classroom teachers' wanting to assign more mathematics work contributed to the lack of
collective control Palm mathematics teachers had over important decisions related to the teaching of mathematics.

A second factor was the respect for and access to the knowledge of other mathematics specialists both at their sites and beyond. "Knowing what others know, what they can do, and how they contribute to an enterprise" is one of Wenger's (1997) indicators of a community of practice. A Harbor View teacher said, "I feel the strongest support [for change in my practice] came from the daily staff development we have at Harbor View. . . . We have a level of trust to be able to discuss what went wrong and what could be done to correct a lesson." At Harbor View, each mathematics teacher has an area of expertise and others knew and respected and took advantage of the expertise of others. In contrast, Palm teachers did not share their expertise. Technology was also a factor in the quality of communication with those outside of school site. Harbor View teachers regularly used e-mail and the electronic bulletin board for the mathematics and pedagogy class. Palm teachers did not have access to e-mail and the Web. These constraints affected the degree of collaboration possible.

The presence or absence of a teacher leader was another key factor in the formation of a teaching professional community. The teacher leader can be a positive or a negative force and can play a fundamental role in shaping the shared sense of purpose. In this case, a Harbor View teacher with her experience with the California Mathematics Project led the co-ordinated effort to improve students' mathematical knowledge. No one stood out as a teacher leader at Palm.

The fourth factor we identified was the teachers' content knowledge and reported comfort level around teaching the content. This affected their collective control over decisions. Harbor View teachers felt empowered to alter the curriculum. Palm teachers did not feel that they could. Though two teachers at Palm were strong in mathematics content knowledge, two were quite weak. Their conversation around improving practice was limited by their mathematical understandings. This contributed to their feeling a lack of control over decisions affecting the mathematics program.

Last but not least, familiarity with the culture and language of the student body was a factor in two ways. In Palm's case, a multi-lingual environment and vast cultural differences in the student body affected teachers' co-ordinated efforts and shared sense of purpose, whereas Harbor View teachers shared a vision of empowering Latino children and were able to begin working together toward meeting their goals. Palm teachers struggled with classroom management issues late into the year. As documented in studies of beginning teachers, until issues of classroom management have been resolved a teacher feels as if he or she cannot move on to other considerations, such as design of instruction. Their image of 'self as a teacher' needed resolution before the focus could be turned outward (Kagan, 1992).
Given our hypothesis that teachers' practice develops within community, we examined factors that seemed to affect the development and strength of teachers' professional communities at their sites. These factors were related to both the institutional setting and the individuals. As teachers participated in the larger professional community of mathematics specialists and the school communities, endeavouring to teach in new ways, their settings and changing identities co-contributed to the nature of the site-based professional communities.

A STUDY ON THE ROLES OF "OTHERS" IN LEARNING:
FROM THE CASE OF CHARACTERS METHOD,
A NEW WAY TO LEARN MATHEMATICS

Hiro Ninomiya
Ehime University, Japan

In this paper, the social aspect of mathematics learning, especially the concept of "Others" is examined. The three types of "Others" in the learning environment are identified, and a framework of learning, "Reflexive Writing Activity", which consciously emphasizes the existence of "others", is presented. Moreover, one type of learning method in this framework, "Characters Method" has put into practice for some implications. In conclusion, Reflexive Writing Activity is not only the effective learning method, but also the aims of mathematics learning which is helpful for both knowledge-understanding and the rich-fruitful learning environment.

INTRODUCTION

From the script of TIMSS video study, one characteristic of Japanese mathematics lessons is described as follows.

Problem solving comes first, followed by a time in which students share the solution methods they have generated, and jointly work to develop explicit understandings of the underlying mathematical concepts.

In this script, we can find the importance of "students' sharing" or "jointly work", which might be the same ideas to social affairs or so-called Cooperative Learning. In the previous studies, Bishop(1985) points out the importance of "social construction of meaning". NCTM(1989) asserts "Mathematics as Communication", and Artzt & Newman(1990) examines "Cooperative Learning". Yackel et al.(1990) indicates the "Student-Student Interaction". It seems that mathematics learning is not just personal affairs any more, but the social activities which are conducted not only by the learner her/himself but with others. In this paper, social aspect of mathematics learning is focused on, and the roles of "others" in the learning environment is examined. In order that, one of learning methods, "Characters Method", which makes students much easier to be aware of "others", has put into practice, and some implications are discussed.

THEORETICAL FRAMEWORK

Lave & Wenger(1991) regards learning as "increasing participation in communities of practice", or "participation in social practice"(p.49). It says;

Activities, tasks, functions, and understandings do not exist in isolation; they are part of broader systems of relations in which they have meaning. These systems of relations
arise out of and are reproduced and developed within social communities, which are in part system of relations among persons. The person is defined by as well as defines these relations. (p.53)

Legitimate peripheral participation is far more than just a process of learning on the part of newcomers. It is a reciprocal relation between persons and practice. This means that the move of learners toward full participation in a community of practice does not take place in a static context. The practice itself is in motion. Since activity and the participation of individuals involved in it, their knowledge, and their perspectives are mutually constructive, change is a fundamental property of communities of practice and their activities. (pp.116-117)

From the same standing point, Saeki(1995) mentions the concept of others. It defines two kinds of others. One is the others who relate to the person her/himself just as mere classmates. In this case, the others’ learning never affect to the person her/himself. Of course they might be friends, but learning mathematics is totally the personal affair and nobody never relate to others’ learning. Saeki(1995) describes such learning environment as “They-World”, because every relation between classmates in their learning is the third personal. She/he is in the same classroom, but what I am learning is not her/his business and what she/he is learning is not my business. In this paper, such kind of others are regarded as “Third Personal Others”. Students tend to be Third Personal Others under the environment of knowledge-transmit type classes.

The other concept of “others” is in the environment of situated learning. As Lave & Wenger(1991) mentions; “Activities, tasks, functions, and understandings arise out of and are reproduced and developed within social communities, which are in part system of relations among persons”, others in such learning environment play very important roles to the learning of a person her/himself. Saeki(1995) describes such learning environment as “You-World”, because every relation between students in their learning is the second personal. What you learn is very important for my learning, and what I learn is also important for your learning. Everyone is in the same learning community and appreciates each other. Student-student interaction, or cooperative learning will be the integral part of such learning community. In this paper, such kind of others are regarded as “Second Personal Others”.

Further more, Hirabayashi & Shigematsu(1987) explains the concept of metacognition on the analogy of person, “Inner Teacher”, which means it works as if there is a teacher who warn to the student within the inside of her/himself. This analogy seems to be very effective to understand such internal operations. Not only metacognition but reflective thinking, metaknowledge, or affective issue are also essential internal operations which play important roles in learning mathematics. Since such internal operations can be regarded as a person who is in the inside of the learner her/himself, the term of “First Personal Other” is provided in this paper. Another way to say, First Personal Other are another self, who watches the learning activities of the self and makes some internal operations.
It is obvious that the ideal learning environment makes classmates to be the second personal others rather than the third personal others. It is also important to notice that the second personal others are not just classmates but the essential source of each student’s learning. Moreover, first personal other should also play an important role in the ideal learning activities. We need to pay more attention to such internal operations. After all, it is crucial that learners should be conscious of both second personal others and first personal other, and put them to practical use for fruitful mathematics learning.

**METHOD**

Ninomiya (2001) proposes a framework of reflexive writing activities, which is a kind of writing that has reflexive interaction with both learner and class activities. Student writes reflexive writing from the viewpoint of either her/himself, second personal others or first personal other. Although reflexive writing is basically the reflection of learner’s own learning, she/he can never stop writing just the answer or her/his own solution. Students need to write more. Since students need to reflect their own solutions, some reflective internal operations are needed and students are encouraged to show them. However, sometimes it is hard for students to distinguish metacognitive or other internal affairs from cognitive operations, so the concept of first personal other is introduced to the students as another self. Students are encouraged to watch their own learning processes from the viewpoint of another self, and have another self make some comments toward their own learning as if they were told by teacher. Moreover, the ideas or comments from second personal others are also important for students’ learning. Because such ideas or comments are integral part of learning, students are also encouraged to show them.

In this way, reflexive writing is formed with (1) student’s own answer or solution, (2) ideas or comments from second personal others, and (3) comments from first personal other. The important point is that reflexive writing never ends with only one single statement. For example, when a student writes her/his own solution, she/he may also add to write some other ideas from second personal others afterward, and compare with his/her own. Making comparison, she/he may be aware of something which are metacognitive or other internal affairs, then she/he may be able to add some more comments from first personal other. Further, because of such comments, she/he can foster her/his own idea, and may get another solution. In such way, writing activity and student’s learning may develop their mutual interaction, and the nature of their relation is reflexive. Moreover, since every student is an autonomous participant in each class activity, her/his description is not a copy of the blackboard but her/his own learning process. However, watching the student’s reflexive writing, we can figure out not only how she/he promote her/his own learning, but also how the whole class activity progresses. Reflexive writing is a reproduction of the class activity, which is produced from each student’s viewpoint. From this point of view, reflexive writing is the reflection of
each class activity, and the nature of their relation is also reflexive. Summarizing, there are reflexive natures both in the relation between Reflexive Writing vs. student’s own learning, and Reflexive Writing vs. the whole class activity.

One of the best ways to promote Reflexive Writing Activities is “Characters Method”. In this method, some characters such as persons, animals, etc. are used on purpose, in order to let students be aware of the existence of Second Personal Others and First Personal Other. Each character becomes either student her/himself, Second Personal Others, or First Personal Other (another self). Because students can directly see the subjects of each comment, or they can distinguish who is talking which comment, “others” are easily intervened into the students’ own learning environment. During the instruction of Characters Method, teacher never force students to use characters, but just show how to use characters on her/his blackboard writing. Most of the students spontaneously imitate their teacher’s way, because they love to study in such a way. Although there is not special instruction for “Others”, students learn the importance of Others by themselves. The example of Reflexive Writing is shown as Fig.3 in the following paragraph.

RESULT

In this paper, 4th grade class (18 boys and 19 girls), in which students have been encouraged to learn with Characters Method, is investigated, and a case of one hour period class is examined. The topic of the class is “folding a piece of paper”. The outline of the class is shown in Fig.1, and the description on the blackboard is as in Fig.2. Also, two typical cases of Reflexive Writing are shown as in Fig.3 and Fig.4.

In this class period, the time of Reflexive Writing is set up twice, as after the Introduction and after the Wrapping up. After the Introduction, students are encouraged to write the task and the first impression. Then, they start their own investigation, or problem solving. Solving the task, they also write some Reflexive Writing for the reflexive interaction with First Personal Other. When the class discussion starts, they are encouraged to write some Reflexive Writing for the reflexive interaction with Second Personal Others, as well as with First Personal Other. During this period, they are expected to present their own ideas, to discuss each other, to write some Reflexive Writing with both First and Second Personal Others, and think again through their Reflexive Writings. Finally, they are encouraged to write some Final Remarks after the Wrapping up. Although there is very little time to devote only to Reflexive Writing Activity, students may write anything they want at any time during the class, and their Reflexive Writing become so fruitful.

DISCUSSION

First of all, a brief description of the students, Miku and Yoji, is presented, and their Reflexive Writings are investigated based on their learning behaviors.
Introduction (5 min.) presenting the task
Teacher picked up a piece of paper and begin to fold it.
T: How many lines are there when I fold once?
S: One line.
T: How about twice?
S: Three lines.
T: How about 3 times?
S: Seven.
T: 4 times, 5 times, 6 times, 7 times------, so how many lines will be there when I fold 7 times?

Reflexive Writing activity (2 min.)
Writing the perspective of solving the task

Problem solving by each students (10 min.)
Each student try folding a piece of paper.

Confirming the task (6 min.)
T: Don't you have any trouble?
S: It has become harder to fold. It is impossible to fold 7 times.
T: How can we manage it?

Presenting Yoji's idea (6 min.)
# of folding: 1 2 3 4 5 6 7
# of lines: 1 3 7 15 31 63 127

Yoji: Adding the next number to the #of lines, we get the next # of lines. Added number have become twice as big as previous one.

Presenting Yuri's idea (4 min.)
T: Where are these added numbers come from?
Yuri: They are the numbers of smell rectangles (rooms) when folding.

Comparison their ideas (5 min.)
T: How about you, Yoji? Is this same to what you have thought?
Yoji: No, this is different. I have folded the paper till I have got 16. Then, I found the number become twice as big as previous one when I fold one more time.

Presenting Ayu's idea (2 min.)
Ayu: The number of lines is just 1 smaller than the number of the room.

Summarizing students’ ideas (5 min.)
T: What are the numbers which have become twice as big?
S: Number of the rooms. The # of the room at the previous stage.
T: # of rooms (previous stage) \( \times 2 - 1 \) = # of lines

Wrapping up (3 min.)
Teacher briefly summarized today's class, again.

Reflexive Writing activity (4 min.)

Presenting several student's writing (1 min)
Two students read their own brief remarks.

---

Fig.1 The Outline of the Class

Fig.2 The Description on the Blackboard
How many lines will be there when I fold 7 times?

Yuri: +2 +4 +8 +16

the number of the room

Yoji: twice as big as previous

+16 → +32

Yuri’s idea and Yoji’s idea are different. But, it seems something relates.

Mm, I totally can not figure out. After all, how many are there???

1 line

3 lines

7 lines

15 lines

127 lines

After folding 7 times, there are 127 lines.

Fig. 3 Miku’s Reflexive Writing

I raise my hand for “over 30 lines”, but how can I figure out?

Final remarks

Though I did not mention in my explanation, I have also found that it becomes twice because the paper is piling on. Maybe the number of the lines will also become twice.

Fig. 4 Yoji’s Reflexive Writing

Miku is a student whose math ability is not so high. She used to have no confidence for mathematics, but when she knows Reflexive Writing Activity and start learning with this method, she has become to be confident of. Because she surely
understood the importance of Reflexive Writing Activity and started learning consciously with this method, she has been able to understand mathematics. Although she sometimes has hard time to understand classes, she has flexible and accepting attitude toward Others, and try to learn from every classmate.

In contrast, Yoji is a student whose math ability is very high and has strong confidence in his math ability. However, he believes that the value of learning is only the “correct answer”, and he never appreciates the “process” of the problem solving. He also values his rapidity of solving, and believes that the rapidity shows his high quality of math ability. Therefore, he understands neither the importance of Reflexive Writing Activity nor the importance of interactions with classmates. He is a type of the student who rejects “Others” in his learning process, because he seems to believe that he is the smartest student in his class and his solution is the best.

The biggest difference between Miku’s and Yoji’s writing is whether there are ideas or comments from Second Personal Others. This is due to the difference of how they appreciate Reflexive Writing Activity. Miku tries to deepen her ideas or understanding through the class discussion, by means of her Reflexive Writing. As mentioned above, her math ability is not high enough to solve the task in her alone. In fact, she made a mistake in her diagram of “folding twice”, and her First Personal Other expresses that she could not understand Yoji’s idea. However, her Reflexive Writing promotes her understanding, and it indicates the progress of her learning until she finally understands the idea and solves the problem. She could learn from Yoji’s, Yuri’s, and Ayu’s ideas through her own Reflexive descriptions. The comments from First Personal Other arrange her process of learning, and they clarify her own understanding. Finally, her learning becomes so rich and fruitful.

In contrast, Yoji indicates only his own ideas or comments, and never mention others; which means there is no comment from Second Personal Others and almost nothing from First Personal Other. Even though there are some characters in his writing, these comments are regarded as his own. Because of his rejecting attitude toward Others, he has missed some important ideas, although he was the first student who could get the correct answer in this class. He found the pattern in the number of lines, as the difference of sequence is powers of 2. He could get the right answer so quick, but because he values only the “correct answer” and never appreciates the “process”, he has not deepened his investigation more. He persisted in his own idea of “the powers of 2”. Because this is a very strong strategy for solving this task, he was very satisfied with getting this strategy and never examined the reason why “the powers of 2”. Because of his rejecting attitude, he could not accept Yuri’s idea and he missed the meaning of the difference of sequence, even though there was a description on the blackboard.

Comparing Miku’s and Yoji’s learning, there might be little difference on understanding the problems; however, the results of their learning are so different. Even though Reflexive Writing Activity is one of the learning methods, Reflexive Writing itself must be regarded also as the aim of math learning. Compare to Yoji,
Miku has greater ability to express in Reflexive ways. Although it may seem that their difference is whether they know how to use Reflexive Writing, we ought to regard it also as the “difference of the learning abilities”, which means that this is not only the evidence of her power in representation but the evidence of her learning ability. Because Miku has improved on her ability to express in Reflexive ways since she began to learn in Characters Method, her knowledge or understanding of mathematics have been also improved, shown as in Table 1.

Table 1 Miku’s Achievement in “Knowledge-Understanding”

Table 1 indicates not only Miku’s achievement but also the development of whole class learning environment since they started learning with Characters Method. The change of mean is the improvement of their knowledge-understanding score, whereas the change of standard deviation (SD) implies that those who was low score could improve their score a lot. It might be true that Characters Method is helpful in the improvement of knowledge or understanding, as well as in the rich and fruitful learning environment.

In conclusion, Reflexive Writing Activity is not only the effective learning method, but also the aims of mathematics learning which is helpful for both knowledge-understanding and the rich-fruitful learning environment.

Abstract
Twenty secondary school students (in Grades 9 & 11) were given two datasets to represent graphically – one with 10 pieces of numerical data, and one with 30. Students were more likely to represent the large dataset in an organised form than the small dataset. The more mathematically able students found it easier to organise the data than their less able counterparts. Grade level had no effect. Possible explanations for the results are explored and the implications for teaching and the curriculum are discussed.

Introduction
“A picture is worth a thousand words”
This old saying might explain why many people find it worthwhile to use graphs to represent data. However, just as the capacity of a picture to convey the meaning of “a thousand words” depends on the technical ability of the artist, so too, the capacity of a graph to communicate messages depends on the ability of the drawer of the graph to represent the data appropriately. This paper concerns the ability of secondary students to represent numerical data in a graph, and explores factors which assist students to organise the data before drawing the graph. The term numerical data refers here to counts or measures such as the number of pencils a student has, whereas categorical data refers to categories such as eye colour.

The ability to draw an organised graph is one in a suite of skills expected of all students according to recent curriculum documents. The Australian Numeracy Benchmarks (Curriculum Corporation, 2000) include the ability of primary school students to organise, summarise, and display information in graphs. Similarly, the National Council of Teachers of Mathematics Standards (NCTM, 2000) has highlighted the need for students at all levels to organise and represent data.

Research into children’s ability to draw graphs has included the development of a framework for statistical thinking by Jones, Thornton, Langrall, Perry, & Putt (2000) (Framework). The third construct in the Framework - Representing Data - is the main issue under consideration in this study, and incorporates constructing representations that exhibit different organisations of the data. As with the other constructs, four levels of thinking have been proposed for this construct. The levels are defined by statements describing students’ data displays in terms of the validity of a display when asked to complete a partial graph, and the degree of reorganisation of data when asked to produce a display. The evidence obtained in this study relates to the latter – the degree of reorganisation of data shown in the display.

According to the Framework, at Level 1 the student produces an idiosyncratic display that does not represent the data set. At Level 2, the student produces a display that represents the data but does not attempt to reorganise the data. At Level 3, the
student not only produces a display that represents the data but also shows some attempt to reorganise the data. At Level 4, the student produces multiple valid displays, some of which reorganise the data.

Research in the area of students' representation of data is not extensive, however a small number of studies provide some background for this study. Lehrer and Schaub (2000) investigated the process of data organisation with elementary school children in grades 1, 2, 4 and 5. They examined how these children developed and justified models to categorise (by grade level) drawings made by children in the same grade levels as themselves. Their results suggest that, at higher grades, children use more sophisticated strategies for organising data.

Nisbet (1999) examined the representations of categorical data generated by teacher-education students. The majority (99%) drew representations of the data showing some reorganisation of the data. However, the data was categorical, not numerical. Nisbet, Jones, Langrall & Mooney (submitted) analysed children's representations of categorical and numerical data. The study revealed that numerical data was significantly harder for children to organise and represent than categorical data. Children beyond Grade 1 can make connections between organizing and representing data when the data are categorical but generally not when the data are numerical. Whereas 60% exhibited Level 3 thinking with categorical data by reorganising the data, only 20% exhibited Level 3 thinking with numerical data. Two of the three Level-3 thinkers produced a tally table while the third drew a pictograph.

Another study (Nisbet, 2001) found that teacher-education students had similar difficulties with organising numerical data. All could produce an organised graph from categorical data, but only 19% could produce an organised graph from numerical data. For the latter, the majority of students merely drew separate bars for each individual piece of data without organising the data into numerical categories.

Why do more students find it difficult to represent numerical data in an organised way, compared to categorical data? It could be that the way to organise categorical data is obvious, but less obvious for numerical data. Maybe the need for organisation is not perceived to be great when there are only 10 items in the dataset. Perhaps, if the dataset was made larger, then the students would be more likely to see the need to organise the data, and subsequently draw an organised graph based on numerical categories. This proposition was the motivation behind the current study.

This study was therefore designed to test the hypothesis that if students were presented with two data sets, one small (say 10 items) and the other significantly larger (say 30 items), then the students would be more likely to draw an organised graph of the larger dataset. It was decided to conduct this investigation with secondary students as the statistical thinking of this band of the age/grade spectrum had not been investigated by the researcher. Students in Grades 9 and 11 were given the task of drawing two graphs – one for a small data set, and a second for a larger set. The Framework was used to evaluate the graphs produced by the students' organisations and representations of the data, and an interview protocol was...
employed to ascertain the extent of prompting required before students realised that
the larger set needed to be organised before it could be represented meaningfully.

Method

Participants

A sample of 20 students at a suburban secondary school was drawn from Grades 9 and 11 – eight students in Grade 9, six students from the Grade 11 Mathematics A classes, and six students from the Grade 11 Mathematics B classes. At the school, all Grade 9 students do a common mathematics course, but Grade 11 students can select either Mathematics A ("life-skills mathematics") or Mathematics B, a higher-level course which includes algebra and calculus. The latter however is recommended only for students who achieved highly in Grade 10 mathematics. Mathematics B students in Grade 11 are more mathematically able than their Mathematics A counterparts. The students were selected for this study by the Head of Mathematics such that a spread of achievement (high, medium & low) was included in all three groups.

Tasks

Participants were given two tasks. The first required them to draw a graph representing the information in the following scenario.

Ten students were asked about the number of novels they read during the term. These are their answers.

NUMBER OF NOVELS: 5, 4, 1, 7, 5, 0, 3, 4, 5, 6

Draw a graph which represents this data.

After the students had drawn their graphs, they were asked the following questions:

(i) What sort of graph did you draw? and
(ii) Why did you draw it that way?

The second task required the students to draw a graph representing this information.

Thirty students were asked about the number of CDs they bought during the year. These are their answers.

NUMBER OF CDs: 2, 4, 2, 7, 5, 0, 3, 4, 5, 1, 5, 4, 1, 7, 5, 0,
3, 4, 5, 6, 3, 4, 8, 6, 3, 2, 3, 4, 5, 6

Draw a graph which represents this data.

If a student had drawn an organised graph successfully, he/she was asked:

(i) What sort of graph did you draw? and
(ii) Why did you draw it that way?

If the student was experiencing difficulty in working out what to do, a protocol comprising a series of prompts was available, and the extent of prompting necessary for the student to embark on the correct course of action was noted.

1. How many students bought no CDs? How many bought 1?
   Does that help with your graph?
2. Could you fill in a table of values like this? (Show blank table of values as in Table 1)
3. Could you draw a graph with this table of values? (Show completed table of values.)

<table>
<thead>
<tr>
<th>No. of CDs</th>

<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>No. of people</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

If those prompts were not sufficient, then the student would be shown a graph of the data set (Figure 1) and asked the following question.

4. Here’s a graph drawn by someone else. What does it tell you?

![Graph](image)

Figure 1: Graph shown in Prompt 4.

Each student was interviewed individually away from any class distractions, and all interviews were audio-taped. The researcher also kept brief notes of the interviews. Sheets of graph paper, rulers, pens and pencils were supplied by the researcher, and all graphs drawn by the students were collected by the researcher for analysis.

**Results**

*Overview of results*
1. The effect of size of data set: With the small data set (10 items) most students drew graphs showing no organisation of the data. However, increasing the size of the data set to 30, lead more students to organise the data and draw a representation based on number of CDs rather than individual measures.
2. The effect of mathematics ability: Most Grade 11 students in the higher ability group (Mathematics B) were able to organise and represent the data in an organised way without any prompting. However, only one student in lower ability group (Mathematics A) completed Task 2 without any prompting. There was no similar ability effect for the students in Grade 9.
3. The effect of Grade level: Grade level had no effect on performance at organising and representing numerical data.

*Results in detail*
Increasing the size of data set lead more students to organise the data and draw a representation based on categories rather than individual measures. In Task 1, which had only 10 items of data the majority of participants (95%) did not organise the data, but without much hesitation, drew a bar graph based on the individual pieces of data – one bar for each person in the dataset, showing how many novels read (Figure 2).
According to the Framework, one student produced a response at Level 1 (Idiosyncratic), 18 students produced responses at Level 2 (Transitional), and one student produced a response at Level 3 (Quantitative). The response patterns were fairly uniform across the three groups of students.

(See Table 2)

</tr>
</tbody>
</table>

Only one student organised the data into categories, e.g. the number of novels read. The dependent variable in her graph was the number of people who read that many.

The pattern of responses was quite different for Task 2, which had 30 items of data (number of CDs bought by 30 people). In response to this task, 10 of the participants (50%) organised the data into categories without any prompting and drew graphs based on the how many CDs people bought. The other 10 participants required varying degrees of prompting before they realised how the data could be organised first and then represented graphically. Table 3 shows the number of students requiring prompts to represent the data in Task 2 in an organised fashion.

There was no significant effect of mathematics group, nor of Grade level. However, there was a significant difference between the Grade 11 Mathematics A students and the Grade 11 Mathematics B students \( \chi^2(2, N=20) = 6.67, p < .05 \) indicating an effect of mathematics ability. Students in Mathematics B produced organised data
representations with fewer prompts than students in Mathematics A. Interestingly, there was no similar ability effect for students in Grade 9. Of the four Grade 9 students who produced an organised graph without any prompts, two were A students (high achievement) and two were D students (low achievement). Further, the other four students who required two prompts to assist in organising the data were spread across the achievement spectrum – their results were A, B, C, and E.

**Discussion**

The effect of dataset size seems to imply that when students see the need to organise data they are more inclined to draw an organised graph. The nature of statistics vis-a-vis data handling comes to the fore when students are faced with a large dataset. Unfortunately, not all students understand how to organise the data in such situations.

What factors come into play in determining how well students are able to organise the data? This study showed that there was an ability effect demonstrated, but it evident in Grade 11 students but not Grade 9 students. The ability effect is quite understandable, but why only Grade 11 students? Either the levels of achievement allocated by the school for the Grade 9 students are not valid measures of their true mathematical ability, or the ability effect is more to do with mathematical processes such as categorising than passing standard mathematics exams. The study concluded that there was no age effect – Grade 11 students did no better than Grade 9 students. So it appears that performance at drawing organised graphs is related to some extent to a general mathematics ability rather than age.

Another factor relevant to some students’ difficulties in organising numerical data may be the mathematics curriculum in its various forms – the formal syllabus, the school work program, the intentions of the teacher, and students’ experiences in the classroom. Hopefully secondary students would have had extensive experience in collecting, organising and representing data over seven years of primary mathematics. The current state-wide Mathematics syllabus, which has been in official use since 1987, incorporates statistics from Grade 3 onwards. Topics include collecting, organising, and representing data with various forms of graphs – picture graphs, bar graphs, line graphs, histograms and circle graphs. However, most of the examples shown in the support booklets involve categorical data, and very few involve numerical data. With such an emphasis on categorical data in the syllabus, it would be of no surprise if teachers had a similar emphasis, giving students more experience with situations involving categorical data compared to numerical data.

Another syllabus-related issue is the approach taken by teachers in the teaching of statistics. At one end of the spectrum of teaching approaches is a mechanistic approach (Ernest, 1989) which implies teaching rules and formulae (e.g., for finding mean) and using data out of a text book. At the other end of the spectrum is a dynamic approach (Russell & Friel, 1989) in which students investigate an issue of interest to them by collecting, analysing and representing primary data. It could be that during the students’ school careers, most of their teachers have used the mechanistic approach in preference to the dynamic approach. In the mechanistic
approach, teachers would have given the students secondary data that are already grouped. Hence the students wouldn’t have had to think through the reorganisation step, thus missing a crucial stage of the data-reduction process. The author contends that if more teachers used a dynamic approach, and if an expanded range of techniques for data organisation was specified in the school curriculum and taken up by teachers, then students’ would find organising and representing data easier.

A number of other issues did arise from the study. The first issue concerns the participants’ choice of direction of axes in the process of constructing the graphs. Many hesitated over which variable was the independent variable and which was the dependent variable, especially in Task 2. In Task 1, most chose “students” as the independent variable and put it on the horizontal axis. Then they chose “the number of novels read” as the dependent variable and put it on the vertical axis, thus producing a series of vertical bars – one bar for each observation. (See Figure 1.) However, in Task 2, when faced with data that had to be grouped according to how many CDs were bought, many participants had difficulty in determining that “the number of CDs” was the independent variable and “the number of students buying that number of CDs” was the dependent variable. This apparent reversal of axes caused some difficulty for the number of students.

Perhaps this difficulty is associated with an inherent complication in the data-reduction process. In collecting the raw data, such as how many CDs people bought during the year, “the number of CDs” is the dependent variable – it depends on who you ask! However, when organising the data, “the number of CDs” becomes the dependent variable, and “the number of students” becomes the dependent variable: the number of students varies according to how many CDs they bought! The data have been transformed by the organisation process. Related to this complication was the choice between horizontal or vertical bars in drawing their bar graphs. For most, it was determined by the labels they gave the axes. If they wrote “number of CDs” on the horizontal axis, then the bars drawn were vertical. If, however, they wrote “number of CDs” on the vertical axis, then the bars drawn were horizontal.

Another observed difficulty was coping with zero – zero novels or zero CDs. Firstly, some students did not realise initially that zero was a legitimate piece of data, and that they had to allow for it in their organisation of the data. (In the Task 2 scenario, two people bought zero CDs.) Secondly, in representing the fact that two people bought zero CDs, the bar can’t be located at the intersection of the two axes – the vertical axis has to be located away from zero on the x-axis.

The last significant issue noted during the interviews was how helpful the table of values was to most of those who had difficulty initially in working out how to organise the data. Seeing a blank table of values seemed to “turn on the light” for them. They immediately knew what to do, filled in the table, and drew the graph.

A number of implications for teaching arise out of the results of this study. Firstly, it is clear that the formal syllabus needs to distinguish between categorical and numerical data, and to place more emphasis on situations involving numerical data. Categorical variables have their place in the early Grades but beyond the
middle-primary Grades, they should take a lesser role. Teachers then need give students greater exposure to organising and representing numerical data. Further, teachers need to highlight the process of organising and summarising data as a prerequisite to representing the data. Use of the term *summarising* as a key word could be useful for some students – it conveys one of the purposes of statistics! Secondly, the examples used by teachers should involve large datasets, with sample sizes of the order of 30 rather than 10, so that students are challenged to think about organising the data. Teachers should not waste too much time on drawing graphs based on individual measures; they should get onto organising the data e.g. rank ordering, grouping, and tabulating. During this procedure it would be beneficial for teachers to offer *scaffolding* to the students (Wood, Bruner & Ross, 1976) by talking through the processes and their reasoning behind the steps.

In conclusion, it is worth reiterating that a dynamic approach to teaching statistics would be the means of integrating all of these curriculum and teaching issues to improve students’ skills in representing numerical data.

WHAT DO SUCCESSFUL BLACK SOUTH AFRICAN STUDENTS CONSIDER ENABLED THEM TO BE SUCCESSFUL

Pentecost, M. Nkhoma
Technikon North West

Black South African students have a poor success rate in school leaving mathematics examinations. Attempts have been made to shift teachers’ practices from teacher-centredness to learner-centredness, in Black schools, in order to improve the situation. The attempts have failed to yield the desired results. This paper reports on the findings of a study that aimed at learning from students and teachers in Black schools, as to what classroom practices lead to success in school mathematics, in their impoverished context.

INTRODUCTION

An analysis by Blankely (1994) in Howie (1998:27) reveals that only 1 in 312 Black students entering the school system leaves with physical science and mathematics as final year subjects. In comparison, the corresponding figures for the other racial groups are: 1 in 5.2 Whites; 1 in 6.2 Indians, and 1 in 45.9 Coloureds.

Although the above quoted analysis is now several years old, in my experience as an educator in South Africa, there has been little improvement if any in the schooling of Blacks in South Africa. The poor performance of Black students has resulted in their inability to pursue careers that require one to have passed the school leaving mathematics examination. Tertiary institutions in South Africa have not yet found any other acceptable yardstick to use in selecting students. Whether school leaving examinations are a good reflection or not of students' capability, nevertheless, they still continue to be the only instrument used for selection.

IN SEEKING A SOLUTION

Fingers have been pointed in all sorts of directions to demand an account for why Black students do not do well in mathematics. It is acknowledged that through apartheid policies there has been poor human and material resourcing amongst Blacks. One area that gained prominence in mathematics education circles in South Africa, and with the new democratic government, is teachers' classroom practices (more specifically, the methodology of teaching).

Even before the democratically elected government came to power in 1994, attempts had been made to try and improve classroom practice amongst Blacks. This is because what goes on in the classroom is believed to influence greatly the learning gains of students.

When it was impossible to convince the apartheid government to improve the lot of disadvantaged Black communities, Research and Development units in Mathematics and/Science Education based at universities and independent NGOs in the 1980s, intervened in the teaching and learning of mathematics and science. A National Audit
by Arnott and Kubheka (1997:54) revealed that, there were at least 36 NGO programmes in Mathematics and Science aimed at teacher up-grading throughout the country. These programmes are essentially designed to meet the need for in-service training of teachers already in the field. The aim of the NGOs is to shift teachers' classroom practices from teacher-centredness to learner-centredness.

Studies and observations on the effectiveness of the intervention programmes in Black schools have yielded findings including:

1) There were no sustainable changes in the teachers' classroom practices that is, from teacher-centred to learner-centred (Harvey:1999).

2) There are problems if classroom practices are seen not to be directly related to improving results in the existing examinations (Kitto: 1994).

3) What is possible in the developed world with adequate supply of human and material resources may not be possible in Black South Africa (Brodie:1998).

4) In the absence of support it might be wise to limit educational reform to developing the quality of existing teacher-centred teaching methods through improved resourcing, rather than attempting a radical shift in underpinning pedagogy (Harvey:1999).

The findings on the effectiveness of intervention programmes in Black South African schools including those summarised above gave rise to my study.

PURPOSE OF STUDY

The study focussed on Black students, in tertiary institutions, who have been successful in school mathematics, and their teachers. The aim of study was to learn what classroom practices students and teachers find enabling and which lead to success with reference to the South African Curriculum. Secondly, my study attempted to learn from students and teachers how those practices are carried out in a manner that is meaningful to them in their own social contexts, and why it is meaningful to them. This is against a background of intervention programmes that simply labelled teachers' classroom practices as "teacher-centred" therefore bad, and in need of changing. A shift to learner-centred classroom practices by teachers is accepted, by the interventionists, as one way of improving the success rate of Black South African students.

FINDINGS FROM THE STUDY

In the study successful Black students were asked what classroom practices helped (enabled) them and which particular teachers have been effective in teaching them mathematics.

Data gathering was preceded by a questionnaire completed by 480 students from two tertiary institutions. This was followed by individual interviews of a few selected students. From the student interviews, 14 students and 14 teachers were finally selected. Five of the students were taught in Black rural schools whilst the rest (9
students) attended schools in townships. Townships are residences formerly designated for Blacks close to the cities. Generally, they have better infrastructure when compared to the Black rural schools. Following the students' interviews, teachers were first interviewed and then observed teaching.

The study followed a grounded theory approach, where categories and themes emerged from students and teachers own responses. The following practices were cited by students and teachers as enabling: Extra classes; Friendly to us, open to us, created a good environment; Provided extra resources; Working in groups; Preparedness in class; Used Practical examples; Availability; Encouragement / Motivation; Active participation; Language used in class; Homework; Tests; Competition. Other than these practices above, my study also established the challenges that students and teachers face in the teaching and learning of mathematics. This throws some light as to why the suggested practices are critical to students' success. For this paper, I have chosen only to elaborate on two categories namely, extra classes and active participation as a sample of my findings.

**Extra classes**

The extra classes were conducted at different times depending on the circumstances of teachers and students. For those that took place in the school, only two teachers conducted them in the morning before classes began, one teacher created space in the school timetable to have extra classes. The rest were conducted in the afternoon during study time or free periods. Other extra classes are those conducted on Saturdays and during school holidays. The duration of the classes ranges from one to two hours. The frequency of classes was from 2 to 4 times a week.

Activities in extra classes are different from those in normal classes, between 08:00 and 14:00. The morning sessions are dominated by teaching and some class work whilst the afternoons are dominated by group work and discussion. This description of activities in the different sessions does not mean that there is no discourse in the morning sessions. My class observations showed that the majority of morning sessions had students asking questions and teachers responding. The discourse, in the afternoon sessions, is between teachers and students and mostly between students themselves. Few observed classes had vigorous discussions in morning. This somehow explains the sweeping generalisations about classroom practices in Black schools, because if class observation is done only in the morning, and for a short time, one would simple claim that meaningful dialogue between students and teachers hardly takes place in Black schools. There are however some setbacks to this practice in that not all the students are keen on these extra sessions and that, as my study has documented, they are mainly common with grade 12 students in the year when they write school leaving examinations.
For reasons why the extra classes were critical to success in school mathematics both teachers and students frequently cited the following points, which are generally learner-centred:

- Morning sessions do not allow much time for discourse as they are short and teachers hurry to cover the heavy syllabi
- Students struggle with concepts and extra classes provide students with an opportunity to catch up where they feel left out. Students struggle because they lack some basics which were supposed to have been learnt in earlier grades
- Provides students with an opportunity to teach each other
- Provides an opportunity for discussion and where the teacher simply supervises as students practice sums
- Students are exposed to different approaches to manipulations of mathematics, especially for extra classes conducted during holidays and weekends where the teachers are different. Here, students meet others from different schools. In some cases it is the very same teacher that takes students during the week
- Students have more practice of problems/sums as they learn from each other
- Provides opportunities to handle difficult tasks

From the above discussion it is obvious that opportunities get created in Black schools, with some teachers, where teachers elicit their pupils understanding and then develop concepts from there.

**Active participation**

Other than giving pupils a lot of tasks, in the form of homework or class work, some teachers promoted active participation by asking students to come to the board during morning sessions. Students volunteer or are randomly asked to come to the board to do sums. This was usually after a homework had been assigned the previous day. There was only one case where coming to the board followed after students had been exposed to a particular mathematical concept.

The chalkboard is usually divided into four parts or less. Whilst the students are writing solutions the teachers took the opportunity to check whether students have done the homework. After students finish the writing of solutions on the chalk board, the teacher together with students discuss the solutions, line by line. One teacher, even showed the allocation of marks for each solution. Where there were problems or misconceptions the teachers in my study embarked on re-teaching by going back to some basic mathematical concept(s) that throw light into the task at hand. In the discussions that ensured as solutions are checked students actively participated. In the mathematical discourse, that occurs, teachers were able to elicit pupils meanings and
understanding and then building upon them. An ideal situation would have been where a teacher elicits the meanings and understandings of students in a one to one basis but I found this practice to be one of the closest ways that teachers could get to pupils' meanings and then building upon them, given the large numbers and other social constraints in Black schools.

DISCUSSION

There is no doubt/debate about the significance of learner-centredness. Numerous studies have shown learning gains, on the part of students, where classroom practices leaned towards learner-centredness. However, an argument arises when the status of learner-centredness in teaching and learning is raised to the level of a panacea, especially in Black South African schools. Not only that, but a problem also arises when it is presented as the only way in which teachers' classroom practices may developed (improved) in order to lead Blacks learners to success in South African school mathematics. This ignores, as my data has revealed, that rich experiences for learners can also be provided, by teachers, in a way that enables students to succeed in school mathematics in Black South Africa. These classroom practices that can be casually characterised as teacher-centred and therefore bad for any learning to take place, by those who have not taken a closer look at them.

At the centre of the argument is a lack of an interpretation or clarity, of how the concept of learner-centredness can be meaningfully implemented in Black South African secondary schools. Several studies in South Africa cited earlier have revealed that there have been no sustainable changes in Black teachers' classroom practices when attempts were made to impart the concept of learner-centredness.

Although the same South African studies record teachers showing an interest and appreciation of the concept of learner-centredness, however, teachers later resort to the same old practices. This dilemma of non-sustainability is not unique to Black South Africa, which can be classified as part of a developing world. A review of existing literature reveals a need, amongst researchers and education practitioners elsewhere, to define and elaborate on the meaning and implications for practice of successful "progressive" classroom practices such as learner-centredness, in the developing world. I must, again, state here that learning gains associated with progressive practices are supported by research in the developed world, for example, Boaler (1997) compared two schools in UK and found that there was an improvement in learning gains amongst students whose teachers implemented practices that leaned towards learner-centredness.

CONCLUSION

It is not beneficial to stereo-type classroom practices into, simply, teacher-centred therefore bad, and learner centred therefore good. Even classroom practices that appear learner-centred, in how they are organised, for example students working in
groups, can be a failure depending on what goes on in there. On the other hand rich experiences can be provided in practices that appear teacher-centred. Dewey (1902/1975) in Liping Ma (1999: 153) sums it all up when he states that,

"...it is easier to see the conditions in their separateness, to insist upon one at the expense of the other, to make antagonists of them, than to discover a reality to which they belong."

My study has begun to lay a base to which learner-centredness and teacher-centredness belong to in the Black South African situation.

THE CONSTRUCTION OF COMMENSURATE FRACTIONS

John Olive
The University of Georgia

This research took place in the context of a 3-year constructivist teaching experiment. The report indicates how Joe and Patricia, two 9-year old children, were able to construct what we are calling a commensurate fractional scheme, whereby composite fractions (e.g. 6/24) of a composite unit can be renamed as fractional quantities in their simplest form (and vice-versa). During the second year of the experiment both children constructed an iterative fractional scheme with which they could produce both common and improper fractions as iterations of a unit fraction. They also constructed an equi-partitioning scheme for composite units (a “partitive division” scheme). Commensurate fractions emerged through a coordination of these two schemes and recursive partitioning.

THE CONSTRUCTIVIST TEACHING EXPERIMENT

The research reported in this paper is part of an on-going retrospective analysis of videotaped data from a three-year constructivist teaching experiment with 12 children (Steffe & Olive, 1990; Steffe, 1998). A team of researchers began working with the children at the beginning of their third-grade and continued through the end of their fifth grade year in a rural elementary school in the southern United States.

More than 600 video-taped teaching episodes were conducted during the three years of the teaching experiment. Pairs of children worked with a teacher/researcher using specially designed computer tools (TIMA) (Olive, 2000a). The major hypothesis to be tested was that children could reorganize their whole number knowledge to build schemes for working with fractional quantities and numbers (the rational numbers of arithmetic) in meaningful ways. This reorganization hypothesis (Olive, 1999) contrasted with the prevailing assumption that whole number knowledge is a “barrier” or “interferes” with rational number knowledge (Behr et al., 1984; Streefland, 1993).

Previously Reported Results.

In my report for PME-25 (Olive, 2000b) I presented evidence for Joe’s construction of an iterative unit fractional scheme that enabled him to construct common and improper fractions as iterations of a unit fraction of a designated whole. I indicated in that paper how Joe used his multiplicative reasoning with whole numbers and his equi-partitioning scheme to establish fractions of composite units.

Subjects of this Report.

During the second half of Joe’s second year in the teaching experiment he was partnered with Patricia. We hypothesized that she would make a good partner for Joe based on our analysis of Patricia’s first year in the teaching experiment. We
hypothesized that she had constructed at least an Explicitly Nested Number Sequence (Steffe and Cobb, 1988) and possibly had constructed iterable composite units (Olive, 1999) prior to our work with her in the second year. Patricia was able to establish recursive partitioning operations that led to her construction of composite fractions not in simplest form. Patricia provided evidence of being able to project a partition into the elements of a partitioned stick (using our TIMA: Sticks software – see Figure 1 below) and maintain the relations between the different levels of partitioning. Joe evidenced a similar ability while working with Patricia during the episodes that took place in April and May of year 2. The teacher/researcher working with these two children during year 2 was a doctoral research assistant named Azita.

THE CONSTRUCTION OF COMMENSURATE FRACTIONS

We choose to use the term “commensurate fractions” rather than “equivalent fractions” so as not to imply that the children had constructed equivalence classes for rational numbers, a far more abstract mathematical construct than that with which the children and the researchers were grappling in this experiment. Commensurate fractions are fractional numbers that provide measures for the same quantity.

Provoking Recursive Partitioning by Taking a Fraction of a Fraction.

In a teaching episode that took place in April of the second year, we introduced composition of fractions as a problem situation that might bring forth recursive partitioning and an awareness of the inverse relation between the resulting fraction and the original whole. The context was established using our computer environment TIMA: Sticks to represent pizzas that could be cut into so many slices. In the course of the session, Joe explained how he worked out 1/2 of 1/3 of a pizza as 1/6 of the pizza: “It’ll be two, umm two of those (pointing to the half of one third) in each one (pointing to the 3 parts of the pizza stick), and just count them up and it’ll be six.” This explanation explicitly indicates recursive partitioning: mentally inserting a partition into the results of a prior partition in order to solve a non-partitioning problem. In this same episode Patricia spontaneously named twice 3/4 as 6/4. Joe renamed 9/4 as “2 whole pizzas and a fourth left over.” These responses indicated that both children were comfortable with fractions greater than one and could produce them through iteration of non-unit fractions.

Generating a Fractional Number Sequence for Twelfths.

The theme of baking pizzas continued in the next teaching episode that was conducted three days later. Our goal was to provoke the children into thinking about different fractional names for quantities of pizza, based on the number of slices in a pizza. The children chose to make pizza with 12 slices (sticks partitioned into 12 parts). Azita asked them to name all the different fractions of that pizza. Patricia began by naming 1/12, 2/12, etc. all the way to 12/12. Joe spontaneously went beyond the whole (13/12, 14/12 etc.). Patricia then realized that this naming process could go on indefinitely and chimed in with “infinity twelfths”! Twelfths had become units of a fractional number sequence for these two children that was on a par with
their whole number sequence. They reasoned with fractions now using their whole number operations. Joe found the stick that was 1/3 of the original stick by finding a 4-stick because “three times 4 is 12.” He was, however, able to rename the stick as a 4/12-stick when asked what he meant by “4”. Being able to switch back and forth between reasoning with whole numbers and naming the fractional number is further indication that the children’s fractional and whole number sequences had achieved similar levels of abstraction.

Later in this same episode Patricia offered the 3-stick as another possible fraction of the original 12-stick. Joe renamed this stick “one fourth” when asked by Azita because “Three four times...to make a 12-stick.” In demonstrating what he meant by this statement, Joe attempted to repeat the 3-stick four times to make a stick the same length as the original pizza stick. He inadvertently clicked one extra time when repeating the 3-stick, creating a stick that was five iterations of the 3-stick. Both children named this new stick as 5/4 of the pizza stick. Patricia explained that 3/12 was one fourth based on the classroom procedure she had been taught for reducing fractions:

We did this in math. What’s it called? You reduce. If you reduce 3/12. Like, how many... You divide by 3. Three will go into 3 and 3 will go into 12. So 3 divided by 3 is 1 and 3 divided by 12 is 4. So it’s reduced to 1/4. (Patricia drew the numerals on the table with her finger as she talked).

Joe’s way of demonstrating that the 3-stick was 1/4 of the 12-stick was to iterate the 3-stick four times to make a stick the same length as the 12-stick (an application of his iterative unit fractional scheme). Repeating the 3-stick one time too many was serendipitous for us as it gave evidence that both children could reason with their commensurate fractions beyond the original whole. Patricia counted in triplets to establish the 15-part stick as 5/4 of the original 12-stick. Later in this same episode, Joe indicated that he might be able to reason with commensurate fractions that were not unit fractions of the original whole. When they were asked to find a twelfths fraction that was the same as 3/4 of the pizza stick, Joe appeared to solve the problem by finding what 3/4 of 12 would be (9) and then looking for the stick that was composed of 9 parts (9 twelfths). It is unclear how Joe found 3/4 of 12. He may have remembered that 1/4 was 3 and then multiplied 3 by 3. If so, this would indicate a decomposition strategy that was lacking in previous episodes.

Finding Commensurate Fractions of a 24-Part Pizza Stick.

In the next teaching episode one week later, we decided to use a 24-part pizza stick with which the children could work. Both children quickly named fractions in terms of twenty-fourths. Joe spontaneously offered a half of the 24-part stick and correctly renamed it as 12/24. The encouraging surprise came when Joe established 1/4 of the 24-part stick by pulling 6 parts out of his 12/24-stick (see Figure 1). This indicates that he regarded each part of the 12-part stick as still being 1/24 of the original stick.
He maintained his 1/4-relation through the intervening half-stick. I hypothesize that he knew implicitly that 1/2 of 1/2 was 1/4 of the original whole.

---

Figure 1: Pulling out 6 parts from a 12/24-stick in TIMA: Sticks

Joe was also able to spontaneously rename the 1/4-stick as 6/24, again indicating that he was relating the 6 parts he pulled out of the 12-part stick back to the original 24-part stick. Patricia agreed with Joe that one fourth was 6/24 because “Six times four is 24.” Joe demonstrated the one-fourth relation by iterating the 6/24-stick four times to make a stick the same length as the original 24-part stick, an application of his iterative unit fractional scheme. In the continuation of this episode, however, Joe (J) appears to associate twelfths with his 12-part stick rather than with two parts out of the 24-part stick. The first protocol begins as Azita (A) asks Patricia (P) to think of a fraction.

Protocol I: Establishing 1/12 of a 24-part pizza

A: Now, Patricia, can you think of another you would like to do?

P: A twelfth.

A: You want to do a twelfth.

P: (to herself) A twelfth of 24, let’s see.

J: (Looks quizzically at P) I already did that one.

A: Which one?

J: Twelve. It’s right there (points to his 12-part stick).

A: (To Joe) What’s a twelfth of 24?

J: Twelve (he has his head on his arms). A half of 24.

P: I don’t know if it’s called that, but this is what I meant.

(Patricia pulls out a 2-part stick from the 24-part stick. Joe sees this and then won’t look at the screen. She repeats the 2-part stick 12 times making a stick the same as the 24-part stick and then lines them up one above the other.)

A: So what did you make?

P: I pulled 2 out like this (she pulls 2 parts out of the 24-part stick) and I repeated it 12 times and it made a 24-stick.

J: Yep, yep.
A: So what is that (pointing to the 2-part stick)? What fraction of the whole is that?
P: One twelfth of 24.
A: That's 1/12 of 24. That's really good.
(Azita asks Patricia to get rid of the two 24-part sticks and pull the 2-part stick underneath the 12-part and 6-part sticks.)
A: (Pointing to the 2-part stick) Is there another name for that guy, Joe?
J: (After 5 seconds) 2/24.
A: That's really good. Why is it 2/24?
J: There's only 2 of those twenty-fourths, umm stick.

Patricia apparently chose 1/12 as a fraction to make before she knew how much of the 24-part stick she would need. She may have chosen 12 as a possible divisor and then figured out that she would need 2 parts twelve times to make 24. Joe associated a twelfth with his 12-stick rather than as a fraction of the 24-stick. He seemed to be responding to his interpretation of Patricia's problem as to make a 12-stick from the 24-stick, and knew that this would be half of the 24-stick and that he had already done that one. When he saw Patricia pull out the 2-part stick, he realized his mistake and was able to accept the stick as not only 1/12 but also 2/24 of the original stick. In the second Protocol, both Joe and Patricia confirm their construction of a scheme for generating commensurate fractions for unit fractions of a 24-part whole.

Protocol II: Establishing a commensurate unit fractional scheme

(Next problem: Joe pulls an 8-part stick out of the 24-part whole.)
A: What are you trying to make?
J: A third... of 24.
A: Why is it a third?
J: Because, umm, it goes into 24 three times.
A: What fraction of the 24-part whole is that?
J: 8/24.
A: O.K.
J: Or a third.
A: Or a third. Excellent! You're next (to Patricia). Joe, how many 1/24 do we have in 12/24?
J: 12.
A: How many 2/24 do we have in 4/24?
J: Two.

In the first part of this protocol Joe used his equi-partitioning scheme for composite units to explain why an 8-stick would be 1/3 of a 24-stick: "Because, umm, it goes into 24 three times." He had partitioned his composite unit 24 into 3 equal parts, with 8 parts each. He also knew that this one third was also 8/24. He used the two names as referring to the same quantity. They were commensurate fractions for Joe.
In responding to Azita’s question that there would be two 2/24 in 4/24, Joe was reasoning with 24ths as composite units in much the same way as he reasoned multiplicatively with whole numbers. This is another indication that Joe had constructed a fractional number sequence (Olive, 2000b) at a level of abstraction similar to his explicitly nested whole number sequence.

While Joe was responding to Azita’s final question in the above protocol, Patricia pulled three parts out of the 24-part stick. Joe immediately named this 3-part stick “one eighth.” Patricia agreed with Joe and demonstrated the one-eighth relation by repeating the 3-part stick 8 times to make a stick commensurate with the original 24-part stick. Joe offered “3/24” as another name for the fraction “because it’s three of those 24ths.” Azita then asked Joe if he could make 1/6 of the original stick. Joe was about to pull out 4 parts when Azita asked him to stop. She covered the four parts he had selected and asked the children for another name for 1/6. Both responded with “4/24”. Joe commented “I already knew that. If I didn’t know that I wouldn’t know how many to pull parts.” This comment indicates that he was aware of his numerical operations and their results ahead of his actions in the microworld.

The above episode indicates that both children could now produce unit fractions commensurate with composite fractional parts of a partitioned whole, as long as the number of partitions was factorable. The episode continued with Azita asking the children to produce non-unit fractions of the 24/24. Protocol III begins with the problem of making 3/4 of the 24-part stick.

Protocol III: Establishing commensurate fractions for common (non-unit) fractions

A: Can you make me 3/4 of the whole?
J & P: Three... fourths.
P: Oh! I know.
J: I’ve got it! I’ve got it!

(Patricia is counting along the 8-part stick. She then moves the 6/24-stick to the middle of the screen.)

A: Patricia, do you know the answer?
J: Yes, I know. Tell me the answer first! Tell me the answer (to P).
P: Three of these, three of these (waiving the 6/24-stick around). Six, six, six.
J: Well, what is that? Tell us how long it will be.
P: Oh! Three times 6 -- 18. 18/24.
J: (Claps his hands) Yeah!

A: How did you know that? How did you know that was 18/24?
Both: Because 6 times 3 is 18.

In contrast to the preceding teaching episode just one week prior to this one, both children now had an immediate strategy for finding 3/4 of the 24-part stick. Patricia realized that it would be three of the 6/24-stick because that stick was 1/4 of the 24-
part stick. Her explanation that it will be “Six, six, six” and her response to Joe’s request for how long that would be: “Three times 6 -- 18, 18/24.” indicate that Patricia could use her iterative unit fractional scheme to generate composite units with commensurate fractions, thus extending her commensurate unit fractional scheme into a scheme for generating fractions commensurate with common fractions. Joe was asking for the length of Patricia’s iterated 6-part stick in terms of 24ths. Joe affirmed her result, indicating that he had already worked it out.

In the continuation of this episode, Azita asked Joe to find 5/8 of the whole pizza stick. Joe immediately responded with “15” and verified his response by iterating the 3/24-stick five times. This is further evidence that Joe had extended his commensurate fractional scheme to include common fractions by decomposing the quantity 5/8 into five of 1/8 of 24. It is also evident that he was working with the 3/24 as a composite unit of 3 units. In response to Azita’s request for another name for the 5/8, Joe exclaimed “Oh! It’s 15/24.”

This episode indicates that both children could iterate a composite-unit fraction (6/24) three times to construct a non-unit fraction (18/24) as the quantity 3/4. Further, they had constructed the operations necessary to transform a partitive fraction such as 3/24 (3 parts out of 24) into the quantitative relation 1/8 (of 24/24) and use the transformed fraction to create the quantity 5/8 of 24/24 by iterating the 3/24 five times. These are the constitutive operations of a commensurate fractional scheme. This episode also indicates that Joe was now able to decompose and recompose non-unit fractions. He saw 5/8 (of 24/24) as 5 of 1/8 of (24/24), and substituted the commensurate fraction 3/24 for the 1/8, thus obtaining 5 of 3/24 to give him 15/24.

DISCUSSION

Rather than interfering with their construction of commensurate fractions, the children’s whole number multiplicative schemes were instrumental in the construction of their fractional schemes. The decision (on our part) to use partitioned sticks as the referent unit for the children’s fractional reasoning created situations which were assimilated into both their multiplicative schemes and their iterative fractional schemes. This dual assimilation provided the children with powerful ways of operating whereby the same fractional quantities could be named in different ways. Their iterative unit fractional schemes enabled them to interpret 3/4 as three of 1/4; their multiplicative schemes enabled them to find 1/4 of the 24-part stick as 6/24 because “six times four is 24.” Combining these two constructions provided the children with the insight that 3/4 was three of 6/24, and that would be 18/24 “Because 6 times 3 is 18.” Using their multiplicative operations with whole numbers in this way is very different from Patricia’s learned classroom procedure: “Three divided by 3 is one and 3 divided by 12 is 4 – so it’s reduced to 1/4.”

Unit fractions were now unit items on a par with the children’s whole number units and the children could apply all the operations and complex unit structures (units of units of a unit) of their explicitly nested number sequence to these fractional units.
This transformation of their iterative unit fractional schemes is necessary for constructing commensurate fractions that generate quantitative equivalence.

NOTES

1 The teaching experiment was supported by grant number RED-8954678 from the National Science Foundation (NSF) in the United States. The retrospective analyses are being conducted under grant number REC-9814853, also from the NSF. Both grants are co-directed by Dr. Leslie P. Steffe and Dr. John Olive of the University of Georgia. All results and opinions in this paper are solely those of the author.

HOW MUCH DOES CABRI DO THE WORK FOR THE STUDENTS?

Federica Olivero, Graduate School of Education, University of Bristol
Ornella Robutti, Dipartimento di Matematica, Università di Torino

ABSTRACT
This report will discuss potentialities and pitfalls of a piece of technology (Cabri-Géomètre), as used by secondary school students in open geometry problems. A case study will illustrate in what way and how much the software can do the work for the students. The conflict between a perceptual-numerical way of using the software and a more theoretical-general one can be solved thanks to the intervention of the teacher, who leads the students to different schemes of use of the technology involved.

INTRODUCTION
"The computer by itself cannot fundamentally change either what is learned or how, and issues of learning and teaching are dependent on more than the simple presence of the computer in the learning situation" (Noss & Hoyles, 1996, p.52). This means that using new technologies in the classroom implies the redefinition of content, of methods and of the role of the teacher (Bottino & Chiappini, 1995).

Our research is focused on what the computer makes possible for mathematical meaning-making. This issue can be investigated from different perspectives, taking into account the interaction between the students and the technology, and the role of the teacher in this interaction. In relation to this, many recent works in the literature highlight a crucial question: what does it mean to say that a technology does the work for the students? (Hershkowitz & Kieran, 2001).

In this paper we will tackle this question as regards one particular piece of technology, that is Cabri-Géomètre. Cabri is a dynamic geometry microworld generally recognised as a powerful technological tool, which provides a useful mediation in many different directions (Arcavi & Hadas, 2000; Arzarello et al., 1998; Gardiner et al., 1999; Healy, 2000; Laborde, 1998; Mariotti, in press; Olivero & Robutti, 2001). This report, starting from the potentialities and pitfalls of using Cabri in open geometry problems (Arsac et al., 1988), first analyses in which way and how much this software can work for the students, and then points out the fundamental role of the teacher in the process of meaning construction.

In doing so, we take on board the perspective of the instrumental approach (Verillion & Rabardel, 1995), as elaborated by (Mariotti, in press). According to this, any technical device has a double interpretation: on the one hand it has been constructed according to a specific knowledge which assures the accomplishment of specific goals, and on the other hand, there is a user who makes his/her own use of the device.
In this perspective, it is important to highlight the distinction between artefact, which is "the particular object with its intrinsic characteristics, designed and realised for purpose of accomplishing a particular task" (Mariotti, in press), and instrument, that is "the artefact and the modalities of its use, as elaborated by a particular user" (Mariotti, in press). "For a given individual, the artefact at the outset, does not have an instrumental value. It becomes an instrument through a process, or genesis, by the construction of personal schemes" (Artigue, 2001, p.4, italics is ours), or schemes of use, which function as organisers of the activity of the user. As different and coordinated schemes of use are successively elaborated, the relationship between user and artefact evolves, in a process called instrumental genesis, which can be directed either towards the artefact or towards the subject. In the second case, the genesis "leads to the development or the appropriation of schemes of instrumented action which progressively constitute into techniques which permit an effective response to given tasks" (Artigue, 2001, p.4).

AIM

We consider Cabri as an artefact, which students use to solve a particular task. In using this artefact, an instrumental genesis takes place, and students construct meanings from the activity they carry out with the software. However the meanings constructed may not be the useful ones directed towards the solution of the given problem. "Meanings are rooted in the phenomenological experience (actions of the user and feedback of the environment, of which the artefact is a component) but their evolution is achieved by means of social construction in the classroom, under the guidance of the teacher." (Mariotti, in press).

This evolution may take different forms, according to the educational aims which are at stake. An evolution from a "mechanistic-algorithmic" way of using the technology, to one that is "led by students’ search for meaning" has been observed (Hershkowitz & Kieran, 2001) in another environment, i.e. the symbolic-graphic calculators. In our case, concerning geometry problem solving with Cabri, this evolution can be described in terms of a shift from a perceptual-numerical use to a theoretical-general one. A perceptual-numerical use of the software involves reading either qualitative or quantitative information about the figures on the screen, based on perception only, doing manipulations and taking measurements. A theoretical-general use implies a (re)-interpretation of what happens on the screen in terms of a theory. These two ways of approaching the software can be considered two different schemes of use.

In the next sections, we will present and discuss a situation of geometry problem solving in Cabri, in which the students use Cabri in the two ways mentioned above and are able to evolve from the one to the other thanks to the teacher’s intervention in the small group discussion.
METHODOLOGY

The example we discuss below is taken from a research project which aimed to develop and implement an integrated approach to new technologies in the classroom. Teachers and researchers developed and implemented classroom activities in an attempt to integrate geometry teaching and Cabri at secondary school level (15-18 year old students), with a particular focus on conjecturing and proving. All the classroom teachers involved in the project participate in a Mathematics Education Research Group [1] at the University of Turin asteachers-researchers (in the sense of Arzarello & Bartolini Bussi, 1998).

In the classroom sessions the students were presented with an open problem and were asked to work in pairs at the computer (with Cabri), trying to formulate conjectures and proofs, in a 2-hour session. Classroom observations were carried out. Two observers were usually present in the different classrooms and observed one pair of students. The data collected are field-notes and videotapes of the work of this pair, both in Cabri and with paper and pencil.

The observed students, in the protocol presented below, are 15 years old and attend 4 mathematics classes per week. They are medium achievers; they have used Cabri some times over the year before this activity [2].

“WHY AREN'T YOU PARALLEL?”

The problem given to the students is “The axis of a quadrilateral”:

You are given a quadrilateral ABCD. Construct the perpendicular bisectors of its sides: a of AB, b of BC, c of CD, d of DA. H is the intersection point of a and b, M of b and c, L of c and d, K of a and d. Investigate how HMLK changes in relation to ABCD. Prove your conjectures.

The students draw a quadrilateral and they drag it until they get a parallelogram.

[...]
542 Paola: (looking at Figure 1) so if ABCD is a parallelogram, HKLM is a parallelogram. Hypothesis: AB parallel and congruent to DC and AD parallel and congruent to BC. Thesis: KL parallel and congruent to HM, KH parallel and congruent to LM.
In the first phase, the students observe the Cabri figure while dragging it and formulate a conjecture. The use of Cabri, at this stage, is perceptual, because the students get the idea of the parallelism of some sides of the quadrilaterals only by observing the constructed figure.

543 Paola: but you can see that it's... wrong.
544 Giulia: no, it's right, try with measures!...you must define the segments.
545 Paola takes measurements of the sides of HKLM (Figure 2).
546 Paola: look at the measurements, it's right! End of the story! The proof is finished!

At this point the students search for a validation of their conjecture within Cabri, through the use of measures (544) [3]. According to Paola, once they have checked that the measures of the sides of HKLM correspond to (one of) the requirements of the thesis (which was previously formulated), the proof is finished (546). Cabri is now used in a numerical way, as the students focus on some quantities related to the figure. A first scheme of use appears: the perceptual-numerical one.

547 Giulia: well...in order to prove they are congruent we need to prove that the figures... [...]  
549 Giulia: are congruent!...of course...and then parallel, I have no idea how we can prove they are parallel! [...]  
551 Paola uses 'parallel line' and constructs the line parallel to d and going through M.  
552 Paola: they are not parallel...ok, they are not parallel.  
553 Paola deletes the line.  
554 Paola: why aren't you parallel?!...let's see if the sides of the initial figure (ABCD) are parallel...I'm worried about that!

Now the students want to prove the conjecture (547-549). The construction of the proof shows a strong link with the Cabri environment. Paola uses the construction of parallel lines in order to check whether HKLM is a parallelogram, that is in order to check if the thesis is correct (551). This test tells her that lines d and b are not parallel. In this case the checking does not support the conjecture previously formulated within Cabri. This provokes Paola to ask “Why aren’t you parallel?”[4] (554). She seems to rely on her conjecture and try to understand the answer given by the software, which contradicts what previously seen and formulated. This episode provokes a chain reaction: since the thesis appears to be wrong, the students go and check if the hypothesis is correct, i.e. if ABCD is a parallelogram (554). Their reasoning is mathematically correct, but it is not supported by a correct interpretation of the particular construction in Cabri. The way they use Cabri is perceptual-numerical, not connected with the theory: as a consequence, the conflict grows in the students’ minds.

555 Paola draws the line parallel to AD and going through B.  
556 Paola: actually...it's parallel...  
557 Giulia: well, but the other one as well...
Paola draws the line parallel to AB and going through C.
Paola: look. It's not...parallel
Giulia: then there's nothing to prove...it's all wrong!
Paola: I have no idea!
Giulia: neither do I!
Paola: those are not parallel, the sides are not parallel...there is still one thing missing: the angles! Let's measure the angles!
Paola measures the angles A, B, C and D.
Paola: They are not congruent...it's all wrong!
Paola deletes measures.

They check the parallelism of the opposite sides of ABCD (i.e. the hypothesis), and, by looking at the Cabri drawing, they realise the sides are not parallel, so they conclude that neither the hypothesis holds. For them the end of the story is that “it’s all wrong” (560). As a last resort, they check the congruence of the angles of ABCD, that is they check another property that should hold for ABCD to be a parallelogram. Using Cabri in a numerical way, they get the same result: “they are not congruent” (565), because their measures are different. The students trust constructions (parallel sides) and measures (equal angles), so they get to the conclusion that their conjecture must be wrong: “It’s all wrong!” (565). The Cabri figure does not correspond to the geometric properties a parallelogram should have from a theoretical point of view. In this case the use of measures and constructions in Cabri works against the validation of the conjecture. At this point the students are stuck, because they are presented with a conflict between a conjecture, discovered in Cabri, and a refutation of this conjecture, discovered in Cabri too. Will the software work for the students and help them to solve the conflict?

WHAT'S NEXT?

The answer to the previous question seems to be negative. The conflict can be solved only by a change in the way of looking at the situation. This change rarely happens if the students are not supported by the teacher, as happens in this case. In fact, the students call the teacher to understand how to deal with a figure that is supposed to be a parallelogram, but it is not a parallelogram in Cabri.

Giulia: miss! [...]  
Teacher: you had a conjecture, didn't you? Your conjecture was: if ABCD is a parallelogram, then HKLM...  
Giulia: but the problem is that ABCD is not a parallelogram!  
Teacher: but can you transform ABCD into a parallelogram?  
Giulia: I need to make the opposite sides parallel to each other!  
Teacher: can you do that?  
Paola: yes...but...it is no more the initial figure  
Giulia: you must construct another figure!
Paola: I mean, you need to move this line parallel to this (BC)
Teacher: (she takes the mouse) you get a figure which has got parallel sides...this is OK!
Paola: but they are not parallel...shall we do as if they were parallel?
Teacher: yes. You formulated a conjecture saying that if ABCD is a parallelogram then HKLM is a parallelogram. OK? Now, can you prove that? If you can construct a proof, then what you’re saying must be true.
Paola: eh...we can try... if we do as if that was a parallelogram, we'll make it!

The figure observed by the students is still the same, but it changes status and it is now seen as a generic object (in the sense of Balacheff, 1999), which has the mathematical properties of a parallelogram, even if on the screen it does not look like a parallelogram: “shall we do as if they were parallel?” (584). The students need to construct a proof, as the teacher says: “If you can construct a proof, then what you’re saying must be true” (585). A new scheme of use is developed through the intervention of the teacher: the use of Cabri in a theoretical-general way. While in the previous excerpts the words written in bold indicated facts (equal, parallel), in this last part of the protocol the words in bold indicate theoretical assumptions (do as if they were parallel; if ... then; as if that was a parallelogram). These words are indicators of a change in the scheme of use.

FINAL CONSIDERATIONS

How much did Cabri work for the students? In the first part of the protocol, the students stick to Cabri wanting to understand what is happening: why aren't you parallel? (554). They search for a ‘unity’: they want all the answers gathered in different ways (conjecturing, measuring the sides, constructing parallel lines) be the same and coherent. This solution path presents many similarities with others in the literature, for example with what is shown by (Hershkowitz & Kieran, 2001) in a problem situation involving the use of graphic calculators. The students want to make the technology work for them and do not abandon the technological device even if the figure produced cannot be justified mathematically. They develop a first scheme of use, which relies on a perceptual-numerical interpretation of the software's feedback. The artefact (Cabri) is transformed into an instrument, which however is not the one which serves to accomplish the goal of the problem situation.

The technology works for the students if there is an evolution from a perceptual-numerical use to a theoretical-general one, that is if there is a change in terms of schemes of use. A new instrument needs to be constructed by the students, based on a theoretical-general way of 'reading' the Cabri figures. The role of the teacher is crucial in developing this new scheme of use. On the one hand, the students use the artefact in order to accomplish a task and some meanings emerge; on the other hand the teacher uses the artefact to direct the students in the construction of meanings
which are mathematically consistent. Further research will analyse the role of the
teacher in the framework of *semiotic mediation* as presented by (Mariotti, in press).

From a didactical point of view, this classroom situation gives the opportunity to
introduce the concept of *generic object*, by reproducing in a concrete case what
happened in history. In fact, the dialectic between perceptual-numerical and
theoretical-general approaches has a long history. For example, Locke considered the
generic triangle as the one which is not oblique, nor rectangle, nor equilateral, nor
isosceles, nor scalene. Berkeley defined the generic triangle as the one which has no
particular properties and he does not assume any particular hypothesis about it. And
he specifies that even if the drawing of a particular triangle is used when constructing
a proof, its particular properties should not be used in the construction of the proof.
Kant solved the debate assuming that the generic triangle is a triangle which is
constructed by imagination in the pure intuition, whom a drawing is a representation.
From the didactical point of view, it is crucial that the teacher shows how to “see that
it is not” (Lolli, p. 139), that is to see that a proof does not depend on the particular
 graphical representations being used. In this respect, Cabri may support students
because of the multitude of representations it produces. However, students need to be
able to give those representations the correct theoretical status (as either hypothesis or
thesis) in order to fulfil the aim of proving. The software does not work for the
students if a particular *scheme of use* is not developed by students, through the
interaction with the teacher.

---

1 In this group teachers and researchers collaborate in the development, implementation and
evaluation of new materials for the classroom.
2 They use Cabri I-7, because this was the version available in the school at the moment of the
experiment (2000).
3 The numbers refer to the lines in the transcript.
4 This situation is very similar to other situations reported in the literature, as for example “*So why
aren’t they meeting?*”, reported by (Hershkowitz & Kieran, 2001), and commented with: “They
now pay attention to the hard numerical evidence that there was a single point of intersection. Their
inability to match this evidence and the graphical representatives they had obtained became very
clear and waited to be resolved and explained” (p.103).

about instrumentation and the dialectics between technical and conceptual work*. Paper
presented at the 2° CAME Symposium, Utrecht, The Netherlands.

A program to teach measurement of length, area, volume and mass in grades kindergarten to three is described. This program, "Count Me Into Measurement", was introduced into 38 elementary schools across New South Wales in 2000. The implementation was evaluated and in this paper the teachers' reactions to the program and their assessments of student learning are analysed. Overall, the teachers' reactions were positive; they found the Program easy to use, they particularly liked the expanded lesson notes and they felt the Program improved their teaching of measurement. Teachers' assessments of student learning showed increased knowledge of specific outcomes as a result of using the Program.

INTRODUCTION

Although measurement is a fundamental aspect of everyday mathematics, there is some evidence that measurement concepts are not well understood by students (Bragg & Outhred, 2001; Hart, 1989; Lokan, Ford & Greenwood, 1996; Outhred, 1993). For example, an analysis of elementary school students' knowledge of length measurement found that many students measured from 1 on a ruler or counted marks or spaces; few appeared to perceive the units as linear (Bragg & Outhred, 2001).

Students may not realise that there are major differences between measurement and number concepts, in particular, that measurement involves subdivision of a continuous quantity and is inexact, and that the same quantity can be measured using different units, both informal and formal. For the quantities, length, area and volume, spatial organization of these units is crucial, while for quantities, such as mass, time and temperature, spatial organization is not important.

However, students may consider that measurement is essentially a process of counting or calculating units, and may not realise how the actions, of exhaustively aligning, covering or packing lengths, areas and volumes respectively, are related to subdivision of quantity. The spatial structure of the iteration of identical units for these quantities does not seem to be emphasised in textbooks and curriculum documents, yet it would seem to be central to understanding and linking these two processes of unit enumeration and subdivision of quantity.

Emphasising the spatial structure of the unit iteration may assist students to link concrete, pictorial and symbolic representations of measurement concepts. For example, moving one length unit and marking the end of each move (without gaps or overlap) creates a linear scale analogous to that of a ruler. Although many students can use rulers, few of them understand how the scale is constructed (Bragg & Outhred, 2000) and many of them do not seem to understand linear measurement in such a way that they could generalize the procedures to practical problems. One possible explanation for students' reliance on procedures might be that teachers rely largely on
worksheets and textbook exercises that focus on techniques of measuring. Thus, abstract concepts, such as knowledge of linear scales and the relationships between quantities and also measurement units are not developed.

Studies by Outhred and Mitchelmore (2000) and Battista, Clements Arnoff, Battista, and Borrow (1998) have found that the structure of a unit covering of squares is not well understood by students. Their findings suggest that students will not be able to subdivide a region into equal parts if they cannot visualize the unit structure for area—a rectangular array (tessellation) of squares, partitioned into rows and columns with equal numbers of units in each row and in each column. However, teachers may not emphasise the tessellation structure because they conceive area measurement to be a process of covering and counting, rather than of subdividing of a region (Outhred & McPhail, 2000). In their descriptions of teaching area measurement, the teachers did not mention any structural features of a covering (e.g., no gaps or overlaps, congruent units, rows and columns). An emphasis on counting suggests that area is a set of discrete points rather than a region and may hinder students’ development of abstract representations of area units, in particular, rows and columns as composite units.

Structural knowledge of unit packings of rectangular containers has also found to be difficult for students, especially linking the structure of packed cubic units to the dimensions of the container (Battista, 1999; Hart, 1989). Early experiences of volume are often limited to filling containers with water (capacity). Such an approach avoids completely the structural problems of packing. The two situations appear to be very different, and students may not see that both involve measurement of volume. As with area, volume measurement seems to involve the construction of composite units (in this case, layers or sections), but the process is more complex because students have to coordinate three dimensions and diagrams cannot show the layer structure clearly. Campbell, Watson, and Collis (1990) found that elementary students counted the number of individual cubes in pictured regular rectangular prisms and that many students counted only the visible cubes.

The Count Me Into Measurement Program

Many teachers may not be familiar with or confident of fundamental measurement processes and how these can be designed as sequences of instructional activities. To assist them, the New South Wales Department of Education and Training (NSW DET) has commissioned the “Count Me Into Measurement” (CMIM) project (Outhred and McPhail, 2000) to develop materials to support the teaching of measurement concepts in the elementary school. The CMIM materials are based on the assumption that students’ understanding of the spatial organization of the units develop from practical activities involving estimation and measurement, followed by discussion or recording of the measurement process. The materials provide a conceptual framework to elaborate significant measurement concepts and processes and to provide a sequence of similar conceptual levels for length, area, and volume. The first three levels are:
Level 1: Identification of the attribute includes directly comparing and ordering quantities.

Level 2: Informal measurement includes finding the number of units to cover, pack, or fill a given quantity without overlapping or leaving gaps; knowing that the number of units used gives a measurement of quantity; using these measurements to compare quantities and realizing that a quantity is unchanged if it is rearranged (the principle of conservation).

Level 3: Unit structure includes replicating a single unit to cover, pack, or fill a given quantity, either by drawing or visualizing the unit structure; and realizing that the larger the unit, the fewer units will be needed.

While the first two levels are common to other suggested measurement teaching sequences, the third level does not seem to have been included previously. These levels provide a conceptual sequence for teaching the topics, length, area and volume—students are expected to progress through these levels for each topic but they are not expected to be at the same level in each topic. A sequence for mass that partially fits the framework has also been devised. Formal units are introduced in Level 3 and the Program is currently being extended to include additional levels for Grades 4 to 6. Accompanying the framework are suggested activities that are sufficiently open-ended to promote different approaches to measuring. Teachers can exploit this diversity of approaches to focus student attention on fundamental measurement principles and processes. Example lesson plans for some activities are also provided to scaffold teachers’ knowledge of key questions they might ask to develop students’ knowledge of measurement processes.

This paper presents the results of an evaluation of the introduction of the first three levels of the CMIM Program in the second half of the year 2000.

**METHODOLOGY**

Each of the 40 districts in NSW was invited to participate in the initial trial of CMIM and 38 agreed to take part. In each district, the mathematics consultant nominated one teacher who would act as a facilitator for their school to implement the CMIM Program in Kindergarten to Grade 3. These facilitators all attended one training day in Sydney. Facilitators were provided with eleven release days to train and assist a minimum of three teachers from their schools to trial the Program with their students. In addition to teaching ten lessons across two of the four topics (length, area, volume and mass), each teacher was asked to complete an open-ended questionnaire about their responses to the CMIM materials and to assess five students before and after teaching each topic. Facilitators also completed the questionnaire, which sought feedback about:

- The CMIM document itself.
- The facilitators' and teachers' approach to teaching measurement.
The final sample comprised 36 facilitators and 118 teachers, 154 in all. The teachers who returned completed questionnaires included 33 Kindergarten or Year K/1, 44 Year 1 or Year 1/2, 30 Year 2 or Year 2/3, 11 Year 3 or Year 3/4.

The questionnaire responses were scanned for commonly occurring themes, issues and concerns. These responses were formulated into categories and a coding system was devised for each question; these categories were then coded. A response to a question might encompass one or more categories. The written responses were also analysed to identify any insights, issues or suggestions.

The student assessments were complex to analyse and only assessments for which common outcomes had been assessed at both the beginning and end of the implementation were included. Thus, the numbers of students varied for each topic and level. Although, the data for all the classes were combined for a topic, the results for Level 1 mainly included Kindergarten and Grade 1 students while Level 3 mainly comprised students from Grades 2 and 3. Fewer students were assessed on Level 3 than on the earlier levels.

RESULTS AND DISCUSSION

The responses of both facilitators and teachers have been combined in reporting the results in this paper and for simplicity both are referred to as teachers. In general, the facilitators' responses were more positive and detailed than those of the teachers, perhaps because the facilitators were more familiar with the document and had a broader perspective as a result of their professional development role.

The CMIM program

The responses clearly indicated that both facilitators and teachers were satisfied with the CMIM document. The majority of the respondents (57%) commented positively on the organisation (clearly set out, well-organised, sequential) of the document and many (42%) on its ease of use (easy to follow, user friendly). However, simply providing the lesson ideas and the knowledge and strategies that teachers should look for did not seem to be sufficient. Teachers valued the expanded lesson notes that gave examples of questions that teachers might ask—about a quarter of both facilitators and teachers commented on the helpfulness of these: "Within the expanded lesson notes, the section entitled "Questioning, Comments and Discussion" is important as it is through this and teacher knowledge that the children can potentially think on a deeper level and in addition become more aware of, and able to use and understand specific mathematical terminology" (School 17).

The expanded lesson notes also emphasised the mathematical language associated with measurement and some teachers had not realised that their students did not know this, "The language or lack of it was an eye opener and emphasised the necessity of doing these lessons" (School 10). Since many measurement terms (e.g., length, area, row, column) are commonly used in everyday life, teachers may assume that students
understand the mathematical meaning of the words. Often misunderstandings of the
terms only become apparent when teachers ask students to explain their reasoning.

Requests for more expanded lesson notes and lesson ideas were common responses
from teachers, presumably because of time constraints—teachers expressed a need for
a "pick-up and teach" document (School 5)—but also because the expanded lesson
notes were seen to be a "good model" (School 38) and provided guidance about the
mathematical concepts underpinning the activities. About a fifth of the teachers
mentioned that using the document had encouraged them to reflect on how to teach
measurement or had clarified their own concepts of measurement: "Yes, it gave
measurement a sequence. Something that I didn't understand." (School 38); "Yes,
taught concepts I'm not confident in teaching. Made me use the correct vocabulary"
(School 20).

Even teachers who are confident about teaching measurement may have limited
knowledge of basic measurement processes. In the small-scale study mentioned earlier
(Outhred & McPhail, 2000) in which teachers described their teaching of area
measurement, even when teachers were specifically asked about skills and
understandings, they did not mention important area concepts. Most teachers
construed area to be a covering. Few used the term “surface” and only one
mentioned that the same units should be used for comparison and that an appropriate
sized unit should be considered.

The main change that teachers recommended to improve the CMIM document was to
clarify the student assessment. Teachers suggested the inclusion of either proformas or
work samples to provide explicit assessment guidelines. They thought that annotated
work samples would help to clarify differences between the levels, as well emphasising
what they should focus on in their assessments.

Approaches to teaching measurement

Almost all respondents (96%) agreed that the document had helped them to teach
measurement. The majority of responses reinforced comments that had been made
about the strengths of the document—the teachers approved of structured, sequenced
material that provided information about what they were expected to teach and that
students were expected to learn. For example, “The clear progression of activities, the
activities themselves, the framework seems so logical although I'd never really thought
out those divisions of learning.” (School 34); “Yes, it made me realise that I take some
things for granted. For example, I may have assumed that a particular child knew
something that they didn't yet, or I may have underestimated some children's abilities
and been surprised with their response or interpretation” (School 23).

Student engagement would seem to be fundamental to learning and many teachers
(21%) mentioned student interest in the activities, often associated with the use of
concrete materials. About a third of all respondents referred positively to the "hands-on"
activities—although some teachers said they taught measurement using such an
approach, others did not. The responses of students to the CMIM activities appeared to
prompt several teachers to reconsider their methods of teaching while others mentioned that it increased their confidence in teaching measurement: “It made the class teacher reflect on the present style of teaching concepts and gave them practical examples of how to achieve new concepts in a motivational way.” (School 27); “Yes, it gave us a different view of teaching measurement, more learning by doing with concrete materials and students were accountable for learning records.” (School 21)

A number of teachers (14%) commented that they liked the Program’s emphasis on students discussing, drawing and writing explanations of their mathematical thinking. Such recording appeared new to many teachers and they seemed to find this feature of the document informative: "I especially liked the idea of students recording what they had learnt so (1) they thought about it and (2) I was aware of their strengths and needs" (School 21). One teacher’s assessment of student writing made her aware that "the lower ability children were always focussing on irrelevant factors when writing about their experience. Eg It was fun, I used pink counters, Pink is my favourite colour" (School 15). Teachers who are aware of the problems of such students would seem to be in a good position to offer assistance.

The main concerns raised by teachers involved resource and time issues because the activities were designed as small group ones in which the students undertook practical tasks using a variety of equipment. As one teacher commented "practical groupings could be difficult without assistance if I had to teach a larger group as there is a lot of equipment involved and many children need guidance" (School 3). Others were concerned about the preparation of resources; “My only concern would be the time factor. Whilst these lessons were great, in reality if a teacher had to prepare all the resources before teaching especially volume/mass strands I don’t think many would or could afford the time” (School 1).

The time and resource issues are important ones to address because many teachers will not continue to incorporate practical measurement activities into their classrooms if they find the management and organization of groups and materials too demanding.

**Student learning**

The results indicated a large change in student achievement over the period of the project. The only length outcome that more than 50% of students had mastered at the beginning of the study was to directly compare and order lengths (Level 1); only about 10% could replicate a given unit to measure a line (Level 3). By the end of the project more than 80% of students appeared to have mastered the first two levels, that is, they could measure, compare and order lengths using informal units, as well as by direct comparison. The results for Level 3 had also increased dramatically—about 50% of the students assessed at Level 3 were considered to have mastered the outcomes for this level.

The results for area indicated that area concepts were much less well known than those for length. Only about 20% of the students assessed could directly compare and order areas, as well as systematically cover areas with identical units and compare them. The
results for Level 3 were similar to those for length; few students appeared to have any knowledge of the structure of a rectangular tessellation at the beginning of the project. After the CMIM lessons the assessments show increased performance on all levels with teachers reporting that about half the students perceived the structure of a unit tessellation in terms of rows and columns. The results for volume were consistent with length and area—teacher reports of students' learning increased markedly.

However, these results would have to interpreted with caution, as the teachers were likely to be biased towards finding an improvement in student learning because they had spent much time and effort in implementing the program. Nevertheless, the data on student learning provided some evidence that the sequencing of the levels and activities was sound.

CONCLUSION

Overall, the first implementation of the CMIM Program appeared to have been successful. Teachers approved of the Program and felt that it assisted their teaching of measurement. They liked the open-ended, practical nature of the activities although there was evidence that they may not continue such teaching without support because of the time and effort that was required in terms of resources, time and organization.

A number of teachers reported that they did not feel confident about the measurement concepts they were expected to teach, nor the sequence in which these concepts should be taught. Many teachers appeared to rely on commonly published textbooks for teaching measurement. In effect, publishers are interpreting the mathematics curriculum for teachers. In textbooks, concepts are often fragmented, for example, a worksheet on length may be followed by ones on area, mass, and volume, interspersed with pages presenting number and space concepts. Several teachers commented that they found that teaching a sequence of five lessons on one topic as part the CMIM Program consolidated students' learning.

Teachers may not realise the extent to which the complexity of measurement increases with the dimensionality of the units. Anecdotal comments on the training day indicated that some teachers considered volume concepts to be easier than length or area ones, suggesting that these teachers may have focussed on filling containers with liquid (capacity) rather than volume as the packing of an interior space, or as displacement. There was also some evidence from work samples that were sent back with the questionnaires that a few teachers may not have realised the importance of constructing the unit iteration to reinforce the structural properties of measurement to students.

Building connections between a linear scale, two-dimensional array structure, and three-dimensional packing are important if students are to understand relationships among measurement concepts. These concepts are also closely linked to repeated addition and array multiplication. The difficulty of applying multiplication skills in a meaningful way has been documented for concepts of area and volume (Hart, 1989).
She found that many students continue until well into secondary school to determine both area and volume measures by counting, rather than by multiplying. Counting does not generalise to fractional dimensions or to formulae. Students require instructional tasks that assist them to construct links between the measurement unit and the spatial structure of the unit iteration, as well as to repeated addition and multiplication. Teachers’ knowledge of measurement processes may also need to be developed so that they realise the fundamental differences between the enumeration of discrete and continuous quantities.

AN ACTIVITY FOR CONSTRUCTING A DEFINITION

Cécile Ouvrier-Buffet
Laboratoire Leibniz – IMAG – Grenoble (France)

The notion of definition is central in mathematics. We notice differences and analogies between axiomatic definitions in education (which often come at the beginning of a lesson) and definitions in mathematical research (which come generally at the end of a research process). The core of this paper concerns the activity for constructing a definition (called definition-construction). We aim to study a situation of definition-construction and to bring up conclusions about the nature and functions of definitions (constructed by students).

THEORETICAL FRAMEWORK AND EXISTING RESEARCH

In the usual mathematical activity of a researcher, a dialectic exists between the concept in construction as well as its definition which is constructed, too. According to Kahane (1999, p11):

la transposition didactique est de règle en sciences: (...) l’exposé d’un sujet prend pour point de départ un aboutissement historique et réécrit l’histoire à l’envers. En mathématique, ce point de départ est une définition. [1]

Besides, Lakatos recommends a heuristic approach, in opposition to the usual deductivist one and underlines the dialectic between the construction of definition and the construction of concept within the framework of problems resolution. He develops two concepts in his thesis (1961): zero-definitions and proof-generated definitions. Thereby two functions of definition appear in a problem-situation: on one hand, zero-definitions, so called alluding to their place at the start of the investigation, are initial and tentative definitions and “the different choices of zero-definitions do not affect the domain of the proof” (p.71,ibid). They must be a little vague, and their heuristic rules correspond to Popper’s remark [2]. This notion of zero-definition does not thwart Vygotsky’s idea about language and verbal definitions; indeed Vygotsky (1962) studies the capacity to use language as a problem-solving tool and accounts for the importance of the naming process: the word guides and determines the course of action. Furthermore, Vergnaud (1991) describes three functions of language: communication, representation and contribution to the conceptualisation. On the other hand, Lakatos underlines the importance of the relation between proof and definition, and presents a new concept: the proof-generated concepts (i.e. generated by proof: it consists in establishing the domain of validity of a primitive conjecture) and their definitions, the proof-generated definitions. According to Pimm (1993), this notion

... seems particularly problematic in terms of teaching mathematics, because of needing to perceive the definition as a tool custom-made to do a particular job that cannot be known by those trying to learn it, certainly not with an order of presentation that seems to require definitions to come first (p.272).
We keep this idea of concept generated by proof as a possible situation for constructing a definition. We know that a lot of difficulties exist in teaching about understanding a concept with a formal definition. Annie and John Selden [3] focus their attention on the role of examining examples and non-examples in order to help students to understand definitions and ask how to help them to understand newly-defined concepts. Furthermore, we retain Vinner's hypothesis (1991,p79), who notes that "the ability to construct a formal definition is for us a possible indication of deep understanding" and explains the "scaffolding metaphor" which presents the role of a definition as a moment of concept formation. Vinner assumes that "to acquire a concept means to form a concept image for it (...) but the moment the image is formed, the definition becomes dispensable" (p.69,ibid) and proposes some interplay between definition and image. We suppose that concept image and concept definition are necessary to analyze an activity of definition-construction. Moreover, we share Vergnaud's idea (1991,p.135): "un concept ne peut être réduit à sa définition; c'est à travers des situations et des problèmes à résoudre qu'un concept acquiert du sens" [4]

An activity for constructing a definition

For the purpose of this article, to construct a definition is an activity which could concern three types of problems. P1 = the request of a definition (starting from given examples and counterexamples); P2 = a problem-situation whose resolution passes by the construction of an object (or a concept) and its definition (alluded to by Lakatos); P3= a situation of modelling. We will retain several aspects concerning the definition of a mathematical object: characterization of this object, naming process, relations between definition and proof.

About the naming process, two aspects emerge: the importance of the denomination (when the mathematical concept is of interest in that it can be used usefully) and, on the other hand, a denomination allows two mathematicians to speak about the same thing. And the expression "good definition" is frequently used, it means "precise definition" according to the mathematical accuracy and the arbitrary character of definitions, as they are presented in axiomatic form.

To consider an activity of definition-construction requires a change of point of view (relatively to handbooks) which consists in accepting the provisional status of a definition, the multiplicity of the definitions of the same object (thus equivalent definitions), the dialectic between definition and properties and the operational aspect of a definition in a proof. We will explain our point of view about definition-construction and possible analysis with the presentation of an activity (type P1).

PRESENTATION OF THE ACTIVITY

For the activity of definition-construction the mathematical object that was selected was the tree, for several reasons: in France, it is a familiar object in teaching, used in the handbooks as a tool of representation (it is recommended by the official secondary syllabus), however it is absent as a mathematical object, hence there is no
institutionalised definition (before University). An experimentation by Balmand (2001) proved that definitions and properties of this mathematical object are unknown to French teachers (discrete mathematics are not learnt in France before University). However, the tree is a “natural tool” of representation and resolution, which can be used in restricted fields (combinatory, probabilities).

From a mathematical point of view, it is an accessible object (by its representations) but hard to theorize and to define owing to the difficult concept of connectivity. Let us notice that the students did know neither the word ‘connected’ nor the concept ‘connectivity’ before our activity. Moreover, the tree has equivalent definitions which are different in nature. We don’t claim to construct all the aspects of the mathematical concept ‘tree’ but some of them, and we assume that the construction of a mathematical concept is required for knowing and mastering this concept.

We chose to call it “thingummy” (a neutral name, whose semantic meaning is attached to nothing) to avoid students connecting too quickly with the meaning of tree as it is used in probability (otherwise we assume that it would stall the situation). Etymologically, to define means to delimit (one defines an object compared to another in order to find out a criteria of recognition) and we believe the construction of a definition is possible starting from examples and counterexamples.

Presentation
First, 4 examples and 2 counterexamples were proposed to students, with the question

![Figure 1: examples and counterexamples of “thingummy” (first question)](image)

1- How could you define the mathematical object ‘thingummy’, knowing that: T1, T2, T3 and T4 are representations of ‘thingummy’ and T5, T6 are not representations of it?

We think that a definition is not a finished product in itself, so we proposed a second question (when the students think they have done with the definition): “2- Exercise: Let G be a graph (i.e. a collection of dots and lines between two dots) connected (i.e. in only one piece). Prove that G admits a spanning tree (i.e. a tree with same vertex set than G)” [5]
Analysis

There are a lot of mathematical definitions of "tree": let $G$ be a graph on $n$ vertices. Then $G$ is a tree if and only if one of the following equivalent assertion holds:

<table>
<thead>
<tr>
<th>Definitions</th>
<th>Nature of the definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Def1- $G$ is connected without cycle.</td>
<td>Perceptive</td>
</tr>
<tr>
<td>Def2- Between any two vertices of $G$, there exists a unique path.</td>
<td>Perceptive</td>
</tr>
<tr>
<td>Def3- $G$ has no cycle and $n-1$ edges</td>
<td>combinative (counting)</td>
</tr>
<tr>
<td>Def4- $G$ is a connected graph with $n-1$ edges</td>
<td>combinative (counting)</td>
</tr>
<tr>
<td>Def5- $G$ has no cycle and if we add a new edge then we create a unique cycle (which means that $G$ is a maximal acyclic graph).</td>
<td>Dynamical definition: requires action on the object</td>
</tr>
<tr>
<td>Def6- $G$ is connected and if we remove any vertex $v$ then $G-v$ is disconnected (which means that $G$ is a minimal connected graph).</td>
<td>Dynamical definition</td>
</tr>
<tr>
<td>Def7- A tree is a vertex (basis) or a tree $T$ for which we add a new vertex adjacent to only one vertex of $T$ (induction step).</td>
<td>Constructive, inductive and dynamical definition</td>
</tr>
</tbody>
</table>

Table 1: mathematical definitions of ‘tree’

The exercise has two aims. First, it allows students to return to the definition, and second, to use (and perhaps reconstruct) the definition. To achieve the proof means to use a definition to plan an overall structure of the proof [6]. Two definitions of a tree are particularly “effective” to write the proof. We propose the main ideas of these proofs:

Resolution with inductive definition: we search the tree directly and we avoid cycles; we choose a vertex and we connect it (by edges) to its neighbours which are not yet connected (it is possible because the graph is connected) and so one.

Resolution with connected minimal definition: the idea is to remove some edges of the given graph in order to obtain a tree. We search if an edge exists of which suppression does not disconnected the graph: if such an edge does not exist, we have a tree (with def6). If such an edge exists, we remove it and we search a new one to remove. When we can not remove any edge, we have a tree whose same set of vertices than $G$.

RESULTS

Devolution of the problem

The students were not reluctant to do the first question. We note that to define is not an activity strictly reserved for mathematics and this can support the devolution of the problem. Moreover the examples and counterexamples allow a process of comparison. Lastly, the students feel they have enough elements. In order to explain the main results, we will study three representative groups (called group 1, 2 and 3).
Defining-methods: defining by genus and differentia

Aristotle's defining method by genus and differentia [7] is to indicate what specific object a word means ('thingummy' here), to take a bigger class (graph) within which that object falls, and then to try and see what distinguishes it from the rest of that class. For Aristotle, a definition is a discourse according to specific rules (about language, syntactic and semantic rules). The chosen activity of definition-construction is by genus and differentia, so called because the students try to distinguish the examples from the counterexamples. But their regulations are not specifically like Aristotle's rules. Let us describe some of the main students' regulations and conceptions.

The two expressions "sufficient definition" and "minimal definition" were often used. These search for a sufficient definition proves that they seek a sufficient condition allowing the recognition and/or the construction of the mathematical object i.e. they evaluate up to what point their definition does not relate to too large a class of objects. When the students talked about 'minimal definition', it was not a matter of minimal sufficient condition, but short sentence. Moreover, the two properties 'connected' and 'acyclic' were mixed-up (conceptually and at the linguistic level) as testified by this extract (the student does not distinguish 'connected' and 'acyclic'):

Yohan: a unique path: that leads to only one condition. Instead of having two conditions to check on each figure each time.

The wish to define the "vague" terms of their definition was expressed by the students rather quickly when they defined 'thingummy' as a "set of dots and lines without cycle and in only one piece". This last property was "fuzzy" for them and some of them worked on the definition of connectivity to redefine "in only one piece" by "a path exists between two unspecified dots of the figure". We assume that when the students have given a name to a property ("in only one piece" for connectivity and "closed polygon" or "circuit" for cyclic), that allows them to work on this property (cf. Vygotsky) and to overstep simply verbalising the representation.

Produced definitions

Vygotsky notes the deep discrepancy between the formation of a concept and its verbal definition. With the examples and counterexamples, the students described the representation of 'thingummy': "in only one piece, without cycle". We notice that this zero-definition was as narrow as to coincide with def1 (table1). But the students did not agree to accept this assertion as a mathematical definition (although it could be a "good" one for a researcher because it gives the structure of the mathematical object) in accordance with one of their conceptions: a mathematical definition should be specified. So they questioned the mathematical object, its properties and its representation. In the table 2, unfinished proof-generated definition concerns the proof-generated definition and means that it was unfinished in terms of its form and its use. We notice that def5 (table1) was not constructed by the students: this is an inappropriate exercise to make it worthwhile.
### Functions of produced definitions

The research of a definition was guided here by functions of definition: to communicate, to recognize, to build and to prove.

*Definition in order to communicate* means to explain to another person what a tree is, i.e., the properties and the construction of the mathematical object.

*Definition in order to build* is alluded to by these students (group 3):

- **Arnaud:** here is the definition to create a thingummy, and there the definition to know if we have a thingummy or not.

- **Yohan:** but to check, I prefer the idea of the path. If one wants to check whether the figure is a thingummy or not, one takes the first definition (a unique path), and if one wants to build a thingummy, one takes the inductive definition.

Group 3 spoke about “good definition”. For us it means algorithmic definition,

- **Yohan:** It is a good mathematical definition when one can make a program [...] One can make a data-processing program which checks the thingummy, if it gives the good result each time, that means that the definition is good, inevitably since the computer does not think.

and/or it allows the recognition of the object:
Fabien: let's consider one must give a definition. If I, who don't know the thingummy, I have it explain to me by somebody, I inevitably see what it is.

The last function of a definition was to prove: the interest of equivalent definitions (multiplicity of the possibilities in a demonstration) is alluded to by group1 and we find the connection between a definition and the function which it will be able to have, in particular in a proof (operational definition):

Arnaud: And then finally, especially the inductive definition, that facilitated the second exercise to us.

Yohan: Yes, one can choose a definition to prove. In fact a few moments ago, it was not useful. If you want to draw a tree, you don't need to know that.

DISCUSSION AND CONCLUSION
We raised some properties in the protocols, for example: “when one adds a dot to a tree, one always has a tree”. Another property emerges at the time of the proof: “when a line is removed, that disconnects”. Why did these “potential” definitions not emerge under the status of definition? Which leads us back to the question: which criteria allow a definition to be recognized (perceived) as such? Let us notice perhaps that these two characterization properties of the tree alluded to above contain a dynamic aspect in opposition to the static representation of the tree available to the students’ experience. Moreover, we already mentioned the gap between definition and characterization properties which can be one of the causes of the non-emergence of these definitions as such. This gap means that a definition is enough, what can appear later only represents properties, as testified by this extract (group2):

Vincent: That will be included in the first definition (...) I have the impression that we have finished our work.

Angelique: It will be the same thing. Actually it all boils to giving properties. Finally they are not definitions, but properties for me.

We would like to stress the following: group1 has not reconstructed an appropriate definition in order to solve the exercise because the constructed definition (first question) has a form and a content that institutionalised it. Moreover, the definition represents a common knowledge for the resolution of a problem (Balacheff,1987).

It’s possible to make students construct a definition of an object which is accessible by its representations. It was through examples, counterexamples and the produced definition that the students were able to build their concept images. We assume that a definition is not a finished product, so the necessity of the exercise. It appears that this activity of definition-construction could be a part of a process of concept acquisition.

We would like to study the dialectic between the formation of a mathematical concept and its definition (with definition-constructions’ activities) or more precisely the role of a definition-construction in learning. And also, the students’ conceptions on mathematical definitions could be an obstacle to the concept formation. These
conceptions concern the dynamic and static points of view, the functions of a definition and the gap (and the relations) between a definition and characterization properties.

NOTES

1. “the didactical transposition is the rule in sciences : (...) the presentation of a subject takes as a starting point a historical result and rewrites the history in reverse. In mathematics, this starting point is a definition”.

2. “we are always conscious that our terms are a little vague... and we reach precision not by reducing their penumbra of vagueness, but rather by keeping well within it, by carefully phasing our sentences in such a way that the possible shades of meaning of our terms do not matter. That is how to avoid quarrelling about words.” (p19. Popper (1945) The Open Society, Vol.II – London ; Henley : Routledge & Kegan Paul)

3. See columns of research sampler (www.maa.org).

4. “a concept cannot be restricted to its definition (...) it is through situations and problems to be solved that a concept acquires meaning”.

5. A graph is made up of dots (vertex/vertices) connected by lines (edges).

6. For the possible ways of operating with definitions in doing proofs, see Moore.

REFERENCES

This paper focuses on how children express their ideas for randomness in two-dimensional continuous space, through tools for directing and redirecting the simulated movement of balls. It reports the findings of a study in which children aged between 6 and 8 years old engaged with a game-like environment to construct for themselves random behaviour by making spatial representations of sample space. In response to a range of tasks, the children manipulated the sample space in ways that generated corresponding outcomes in the game. We present some case studies of children's activities, which illustrate how the medium mediates the children's understanding of chance events.

INTRODUCTION

The literature on randomness overflows with references to children's and adults' incompetence in dealing with judgements of chance (for just one of many references, see Kahneman et al., 1982, who set out a series of heuristics that, because of their inherent bias, have been termed by other authors as "misconceptions"). Piaget and Inhelder's (1951, translated 1975) work represents a seminal effort to investigate the origin of chance. They devised a number of experiments, which yielded 'chance' outcomes and they used these for probing the conceptual development of children from pre-school ages to adolescence. One of their experiments concerned a tilt box, where the child was given a rectangular box, resting on a transversal pivot, allowing seesawing. They concluded that young children fail to understand the random nature of mixture. Their main argument is that a fundamental property of operations is that they are reversible, so that even when a child is a concrete operational thinker, randomness is still a strange idea that does not fit into the way they normally see the world. Further, they maintained that the idea of chance is not acquired before the stage of concrete operations.

However, Fischbein (1975) has reported how children have intuitions for relative frequency from a very young age, and this leads us to search for other evidence that even very young children have emergent cognitive resources for making sense of randomness. In research on intuitions and fairness, Pratt & Noss (1998) found out how their subjects make sense of dice situations and they show how existing intuitions about fairness, often based on actual outcomes, are co-ordinated with new meanings, derive from interacting with the microworld. Papert (1996) has argued that educators should look in pragmatic ways for connections between pieces of knowledge and that, on a theoretical level, the metaphor of learning by
construction leads to a range of interesting questions about the connectivity of knowledge.

In terms of knowledge about stochastic phenomena, Pratt (2000) has also reported on how children (aged 10/11) were observed to use four separable resources for articulating randomness namely: unsteerability, irregularity, unpredictability and fairness. Children constructed meanings for randomness in the context of a computational microworld, visualising how the random behaviour of objects actually worked. In this paper we describe the activities of even younger children (aged between 6 and 8) who were expressing their ideas for randomness in two-dimensional continuous space, through tools for directing and redirecting the simulated movement of bouncing balls.

THE SOFTWARE

The game was written in a rule-based system, called ‘Pathways’ and was designed to afford children the opportunity to talk and think about probability in the context of quasi-concrete manipulations. The game is shown in Figure 1.

![Figure 1: The game](image)

In the right-hand corner is a square. A small ball bounces around the walls of the square and occasionally collides with and bounces off other balls. In Figure 1, one red and one blue ball is depicted (they are the other two larger balls inside the rectangle), but the child can control the number, size and position of the balls. Each time there is a collision with a red ball, one point is added to the red score (just above the rectangle), and the "space kid" (the triangular creature) moves one step up the screen. Similarly, collisions with the blue balls add one point to the blue score and move the space kid one step down the screen. Whilst individual collisions can be seen as single trials in a stochastic experiment the totality of these movements gives an aggregated view of the long-term probability. The game itself is defined in terms of simple iconically represented rules, which are designed so that the children can easily change the nature of the game itself (see Goldstein and Pratt, 2001, for a fuller description of the Pathways environment).

The task was given to the children to construct for themselves representations of the sample space. They constructed for themselves random behaviour by making spatial representations of sample space in a game-like environment. In order to

---

1 This research was funded by the European Union as part of the Playground Project, Grant No. 29329. See http://www.ioe.ac.uk/playground/
explore children’s connections between fairness and randomness, we began with a situation in which the children had to try to make the space kid move around a centre line in order to construct a ‘fair sample space’. Later, we asked children to make changes to the two-dimensional continuum space to make the space kid move upwards or downwards from the centre line in ways that represented other global outcomes (such as being likely to go off the top of the screen).

**METHODOLOGY**

The findings reported here are part of a broader study that adopted a strategy of iterative design, in which the computer-based tool was developed alongside the gathering of evidence for children’s use of the tool. The children were interviewed before and during their interaction with the computer: all interviews of each iteration were videotaped and transcribed. The role of the researcher was that of participant observer, interacting with the children in order to probe the reasons behind their answers and their actions. In the final iteration, 22 children, aged between 6.5 and 8 years, were involved. The children worked with the software individually for between 2 and 3 hours. The semi-structured interview began with children expressing their ideas about Piaget & Inhelder’s tilt task. The children were then asked to inspect the rules of the game through the Pathways tools, and finally worked with a range of game-oriented problematic situations.

**EXPRESSIONS OF RANDOM MIXTURE**

The results from the interviews on the tilting task were consistent with those of Piaget and Inhelder. Most of the children responded to the task by expressing what the order of the colours should be when the balls move to the other side of the tilt box. For example, Jane said, ‘The reds will move here, then the yellows, the greens here and the oranges here’. The children envisaged that the balls would finish up in an organised manner, rather than being mixed up in the tilting process.

In this context, the children were generally unable to express notions of random mixture. In contrast, they seemed able to express the notion of random mixture in two-dimensional space continuum environment. The computer environment supported several ways in which the idea of mixture could be expressed. The children changed the position, size or number of the red and blue stable balls in the sample space, or they described in words the ‘uncontrolled’ continual movement of the white ball. We describe four categories of children’s strategies below: haphazard movement, complex movement, symmetry of placement and equal size of balls.

**Haphazard movement**

The children’s awareness of a lack of pattern and lack of controls over the movement within the two-dimensional space is evocative of the local resources for making sense of randomness as reported by Pratt (2000). Lucy (age 7 years and 8 months) characterised the white ball’s movement and mixture as follows: ‘It goes
right-left, up, down and on the balls. We don’t know where it goes. It moves in the yellow square, where it wants to go. Mixture for Lucy meant to move where the ball wants to go, without any obvious pattern or pre-ordained positions. Children were using similar internal resources or intuitions as one might expect in a more conventional study of randomness, and so lends credence to the idea that these very young children were indeed constructing meaning for a random mixture, in a way that was not evident in Piaget & Inhelder’s experiment.

**Complex movement**

Paul (age 6 years and 10 months) expressed his idea of random mixture in a different way. He was influenced by the manipulations of the task, and he attempted to make all the balls bounce around, collecting points.

Paul: Ok now! Ah! I know what to do!

He changes the balls and the speed again.

Researcher: The blues have more points than the reds.

Paul: Do you know what to do? We can take out all the white balls and give a speed to the red and blue balls and when the blue touches to a blue or a red touches to a red ball to get two points otherwise to get one point.

Paul gave movement to the red and blue balls and decided to change the rules under which points were scored and the mixture of the balls was made more complex.

**Symmetry of placement**

**Symmetrical teams**

Most of the children tried to achieve a fair game by placing the balls symmetrically. They didn’t care so much where each ball was placed, but were concerned about the positioning of a team of the balls. This is very obvious to Brian (age 6 years and 6 months), who not only separated the two colours, but also put lines between the two teams and constructed new rules.

Researcher: Can you do changes in the lottery machine?

Brian: I want to make a line... I will blow this ball... I know, I will do something (Figure 2).

He separates the two colours and he constructs a new object.

Researcher: What do you want to do?

Brian: I need a rule ‘When the ball touches me, I take all the
messages from all the red balls and I give them to the red scorer.‘ I need the same to happen to the blue balls.

The children saw each colour as one team. For example, Jane (6 years and 7 months) expressed randomness by first separating the two colours to create two different teams of equal numbers.

Jane: Because I will put them near to each other in the middle. So, when the ball goes to touch the one, it will touch also the other that’s near it. So, it will touch both of them and we will have equal points. We do not know where it (the white ball) will go, but if it touches one ball it will touch the other as well.

Researcher: That sounds a nice idea...

Jane: ...I will put the two lines in the middle. Now, I need another two balls. I’ll get the magic wand to get more balls. It’s the good fairy that gave it to us...

Researcher: Do you know how many balls do we have?

Jane: Yes...they are equal. I know they are equal, but I don’t know how many balls I have (Figure 3).

Researcher: How do you know that they are equal?

Jane: I copied one red and one blue each time. It doesn’t matter actually how many they are. They are equal.

This excerpt emphasizes that what mattered to Jane was the equality of the teams, rather than precisely how many there were. She seemed to equate equality with fairness, and presumably fairness in some way with randomness.

Making a pattern

The pattern was very useful for Lucy to create a random environment.

Researcher: Can you arrange the balls in a way in order the space kid to move near the yellow line?

Lucy: I will then leave only two balls...or...I will make a pattern in order not to move so up or so much
down... I will copy some more balls (Figure 4).

*She destroys balls and keeps only one red and one blue. Then she copies some to make a pattern.*

**Researcher:** How does the pattern work?

**Lucy:** They are going to have equal numbers. It (the white ball) will move up, on the edges... the ball will get the same points. I will also copy another white ball to move quickly... They became rows.

*She starts the game.*

**Researcher:** What happens? Where does the white balls go?

**Lucy:** It goes everywhere... around the balls. They have equal numbers now! I got one ball and another. I made a row and then another row and I made the white ball to move in a way and now they are going to have the same numbers.

The logic behind it was for one colour to be near the other, so that when the white ball was going to touch one colour it would touch the other as well. The pattern was also used as a way, as she described, to have equal number of balls, without counting.

**Making circles**

The circle was made to trap the white ball in order to touch the balls in the circle the same number of times, and sometimes it turned out to be a start for a symmetrical development, as well. Anne (age 6 years and 6 months) here started by having the white ball in a circle and then constructed another random situation by copying more balls.

**Anne:** ... I'm going to make all the balls have the same size. I'll do another arrangement.

**Researcher:** So, what are you doing now? (Figure 5)

**Anne:** I'll make more copies of them.

*She switches the game on.*
Researcher: Oh...does it work?
Anne: Yeah...It keeps going up, down, up, down....
Researcher: Great!
Anne: I’ll make more copies...
Researcher: What’s the arrangement now?
Anne: That one (the blue ball) is facing that one (the red ball) and that one is facing that one and so on...
I’ve got also a better idea! They (the red balls) will face a blue one. There! (Figure 6)

Researcher: What did you do?
Anne: The blue ones are facing the red ones and the red ones the blue ones.
Researcher: Ok! What number will you have here (on the scorers)?
Anne: I don’t know, I’ll try it out!

She starts the game.

Anne started here by constructing a circle and developed that into a symmetrical picture.

Equal size of balls

The spatial environment played a major role in helping Jane to look at whether two balls were equal in size or not. As she said, one of the balls ‘is bigger and it (the white ball) will touch the most of the time, because the ball takes up more space in the yellow square’. She looked at the effects of the game and she used the global event, the movement of the space kid, to see whether her environment was fair.

Jane: I think the red will win.
Researcher: Why is that?
Jane: I think I made it a little bigger than the other... We can open the game and if the scorers are the same that means that they have the same size, otherwise the one is bigger than the other (Figure 7).

Researcher: What about the space kid?
Jane: If it is as now that means our balls have the same
Jane was making a connection between the spatial appearance of the sample space and the possible outcome from the game in the longer term.

CONCLUSIONS

The study seems to indicate interesting differences between the way that children responded to Piaget & Inhelder’s experiment and how children in this non-conventional context were able to express ideas for random mixture. A main difference from the Piagetian study was perhaps that, in this study, the children constructed randomness, not just as a cognitive act or thought experiment, but in a quasi-concrete way. Children’s thinking moved from finding outcomes and describing the random behaviour to constructing a random behaviour. The study indicates that children have various cognitive resources for constructing randomness, beyond those that might be expected from classical experiments. We believe that a possible reason for this is that the tool offers them the opportunity to use these resources for random mixture in a two-dimensional continuum. Moreover, children’s culture involves many experiences of random movement, and the context for such experiences is changing from playing board games towards playing video games. We conjecture that cognitive resources for making sense of random mixture may be more likely to find a means of expression in continuous two-dimensional movement than in more conventional contexts that involve discrete number.

Fischbein, E. (1975). The Intuitive Sources of Probabilistic Thinking in Children
London: Reidel

Over recent years, various theories have arisen to explain and predict cognitive development in mathematics education. We focus on an underlying theme that recurs throughout such theories: a fundamental cycle of growth in the learning of specific concepts, which we frame within broader global theories of individual cognitive growth. Our purpose is to use our experience in such areas as the SOLO Model, van Hiele levels, process-object encapsulation and symbols as process/concept, to raise the debate beyond a simple comparison of detail in different theories to move to address fundamental questions in learning. In particular, a focus of research on fundamental learning cycles provides an empirical basis from which important questions concerning the learning of mathematics can and should be addressed.

The named author is the presenter of this paper. This paper was written as a joint paper by John Pegg and David Tall. It is presented here as a single authored paper to comply with a newly-implemented rule restricting the number of papers that can be accepted by a given co-author.

INTRODUCTION

We here focus on two kinds of theory of cognitive growth:

- **global theories of long-term growth** of the individual, such as the stage-theory of Piaget (e.g., Piaget and Garcia, 1983).

- **local theories of conceptual growth** such as the action-process-object-schema theory of Dubinsky (Czarnocha et al, 1999) or the unistructural-multistructural-relational-extended abstract sequence of SOLO Model (Biggs & Collis, 1982, 1991; Pegg, 1992).

Some theories (such as that of Piaget, the SOLO Model, or more broadly, the enactive-iconic-symbolic theory of Bruner, 1966) incorporate both aspects. Others such as the embodied theory of Lakoff and Nunez (2000) or the situated learning of Lave and Wenger (1990) paint in broader brush-strokes, featuring the underlying biological or social structures involved.

Our focus is on local theories, formulated within a global framework whereby the cycle of learning in a specific conceptual area is related to the overall cognitive structures available to the individual.

A range of global longitudinal theories each begin with physical interaction with the world and, through the use of language and symbols, become increasingly abstract.
Table 1 shows four of these theoretical developments. It is not our purpose to make a detailed stage-by-stage comparison of these theories here. Although reports on comparisons between SOLO and van Hiele can be found in Pegg and Davey (1998), and between SOLO and Piaget and SOLO and Bruner in Biggs and Collis (1982).

Table 1: Global stages of cognitive development

What stands out from such theories is the gradual biological development of the individual, growing from dependence on sensory perception through physical interaction and on, through the use of language and symbols, to increasingly sophisticated modes of thought. SOLO offers a valuable viewpoint as it explicitly nests each mode within the next, so that an increasing repertoire of more sophisticated modes of operation become available to the learner. At the same time, all modes attained remain available to be used as appropriate. As we go on to discuss fundamental cycles in conceptual learning, we therefore need to take account of the development of modes of thinking available to the individual.

LOCAL CYCLES OF DEVELOPMENT

We now turn to the core of our study: the cycles of development that occur within a range of different theories. These have been developed for differing purposes. The SOLO Model, for instance, is concerned with assessment of performance through observed learning outcomes. Other theories, such as those of Davis (1984), Dubinsky (Czarnocha et al., 1999), Sfard (1991), and Gray and Tall (1994, 2001) are concerned with the sequence in which the concepts are constructed by the individual (see Tall et al., 2000, for a further analysis of these theories).

Table 2: Local cycles of cognitive development

¹ Davis used the term ‘visually moderated sequence’ for a step-by-step procedure.
As can be seen from table 2, there are strong family resemblances between these cycles of development. Although a deeper analysis of the work of individual authors will reveal discrepancies in detail, there are also insights that arise as a result of comparing one theory with another as assembled in table 3.

First, Gray and Tall (2001) note the role that objects operated upon play in concept formation which focus on actions of those objects. These base objects may be perceptual or conceptual, provided that the individual conceptualises them as entities. Gray and Tall see the configuration of the base objects (such as a set divided into three equal pieces and two of these being selected) as an embodied representation of the encapsulated abstract concept 2/3.

Second, Dubinsky’s notion of action begins at a more primitive level than the notion of procedure, formulated in the following terms:

**Action.** A transformation is considered to be an action when it is a reaction to stimuli which the subject perceives as external. This means that the individual requires complete and understandable instructions giving precise details on steps to take in connection with the concept. (Czarnocha et al, 1999)

The SOLO Model is in the Piagetian tradition. Here humans are seen as actively constructing their world as a result of processes of interaction between a person and his or her social and physical environment. The resulting development can be identified through ‘logically’ sequential, qualitatively different, levels each representing a coherent viewpoint of the world. This pattern of thought is revealed through the underlying cognitive structure of what the person says, writes or does. Growth in understanding is seen as an active change in patterns of thinking. Hence, cognitions are seen to be structures that are rules for processing information.

The central task associated with SOLO codings, and one that can be very demanding, is to analyse the pattern of responses provided by individuals and groups. In doing this, it is important to distinguish between the content and the cognitive structure. There is a tension here. The pattern of responses has to be sensitive to (i) those aspects that are cultural or individual and primarily associated with the subject content, and (ii) the reasoning structures of a student’s thoughts that are part of our human heritage and true for all individuals.

The unistructural level of SOLO focuses on the appropriate domain but uses relevant data seen by the students as a single entity. This notion seems to encompass the levels of base object, action and procedure. On the other hand, the distinct SOLO level of ‘multistructural’ is not explicitly mentioned in any of the other theories. Analysing the Gray and Tall distinction between procedure and process, we find that it is possible for students to have more than one procedure to carry out a process, but yet may not have a flexible conception of process itself. For instance, in the analysis of Ali and Tall (1996) considering Malaysian students’ flexibility in having different procedures to differentiate a given formula in calculus, there are examples of students having different procedures available for a given derivative, and yet their
thinking remains procedural, rather than conceptual. Thus the procedure-process-procept spectrum naturally expands to procedure-multiprocedure-process-procept.

The relational level of SOLO readily equates to the process level of the process-object encapsulation theories. Here the learner has an overview of the elements or procedures. The data known to the student are able to be woven into an overall mosaic of relationships. The whole has become a coherent structure with no inconsistency within the system known by the student.

The fourth level titled unistructural relates to a combined object-schema level. This level highlights the two possibilities of cognitive growth that exist within SOLO when development occurs past the relational level. This is summarised diagrammatically in figure 1. If the nature or abstractness of the thinking is the same as that identified in the previous three levels, i.e., U₁ M₁ R₁, then the next level is a new unistructural level, U₂. It is distinguished by the person seeing as a single concise entity what was previously an integration of several aspects.

Figure 1: At least two cycles within concrete symbolic mode.

If, on the other hand, the new response represents a qualitatively different, more abstract way of thinking, then the response can be coded outside of the current mode and within the next acquired mode. This new level can be described as a new unistructural level, a U₁, in the next acquired mode. In the case of moving from the concrete symbolic mode into the formal mode, this new unistructural level can be written as U₁F and represents the start of a new Fundamental cycle. It is this cycle that has most to offer students in their late secondary and early tertiary education.

There is support from a range of papers in the literature to see the object-schema level as a coherent whole (which may be subdivided as appropriate). The first is Skemp’s varifocal theory, which sees the duality of concepts and certain types of schema, depending on whether it is seen as a whole (concept) or in detail as a structure of relationships (schema). The second, in part, is Dubinsky’s own perception that objects can be formed not only in terms of encapsulation of processes, but also of encapsulation of schemas (Czarnocha et al, 1999).

An in-depth discussion of the relationships between process, object and schema is given in Tall & Barnard (2001). This discussion shows a correspondence between these local theories and a fundamental cycle of conceptual development, see table 3.
The first stage involves some kind of action on one or more base objects with the focus of attention of the individual either on the objects, or on the actions. These can lead to different kinds of learning, one which focuses on the nature and properties of objects, the other on the nature and properties of the actions, involving symbols being introduced to represent the actions. Isolated actions are consolidated into (step-by-step) procedures, possibly with several procedures available to carry out essentially the same activity. The activity may then be seen as a single process that may be carried out by different procedures. At this stage, with the support of some kind of symbolism, the individual may construct a mental object that is both a schema within itself and becomes manipulable within a wider schema of activities.

Table 3: The fundamental cycle of conceptual construction

Example: Fractions

In the case of the fraction concept, the base objects may be a single object (a cake) or a collection of objects (the children in the class). The action is to divide the object (or separate the objects) into equal parts, by some kind of division or sharing process, then selecting a given number of the parts. Different actions (e.g., divide into 3 parts and take 2 or divide into 6 parts and take 4) lead to the same output. Different techniques for carrying out the activity may lead to procedures, then multi-procedures to carry out the action.

When the child realises that different procedures have the same output and focus on the effect of the procedures, then this moves to the process level where different procedures have the same effect (Watson & Tall, 2002). The introduction of the symbols 2/3 or 4/6 for the two distinct actions leads to the notion of equivalence of fractions that have the same effect. The notion of equivalent fraction is a schema in itself (as in Skemp's varifocal theory) which, conceived as a single entity, may become an element within the wider schema of arithmetic of fractions.

To expand on the above let us consider a particular problem asked of some several hundred students in the age range ten-to-fifteen years. This question was asked in mathematics lessons along with several other fraction-related questions. Students were asked how much would each person receive if nine apple pies were divide between sixteen people so that each person receives the same amount. In analysing
the student responses we can identify an initial fundamental cycle followed by several components of a second fundamental cycle. In terms of SOLO modes all responses were within the concrete symbolic mode. Early cycle responses, which attempt to deal with the problem, focus on the need (the action) to cut the pies equitably, usually in halves. However, a problem emerged for some students when their action of cutting did not result in each person gaining an equal amount: “cut the pies into halves and you have two pieces left over” (for these students there was one pie too many). These students did not resolve this issue.

The next category of response also has the cutting of the pies fairly as its focus, but the problem is seen in two parts with a new procedure employed to deal with the left over pie. “Cut one pie into 16 pieces and the rest into halves.” The third category of response considers the effect of the cutting. The response moves on past the focus on equitable cutting to provide a summative view on how much each person would receive. “Cut each apple pie into sixteen pieces and each person gets 9 pieces each.” Missing from this response is any use of standard fraction notation.

The next level of response, a new unistructural level occurs as the response provided is more succinct and fraction notation is employed to express the different parts of the problem. “I would cut 8 pies in half and then cut the last pie into 16 pieces. So everyone gets 1/2 and 1/16 of a pie each.” In this response students use fraction notation freely in their written language. This is the culmination of the first fundamental cycle and also represents the first element in a new cycle. This new Fundamental cycle represents a development of fractions as numbers.

The second level in this new cycle is on combining the fractions identified previously. The method employed is equivalent fractions whereby all fractions are rewritten with the same denominators before combining. “Cut 8 pies in half and give one half to each person. Then cut the last pie into 16 pieces and give one piece to each person. 1/2 + 1/16 = 8/16 + 1/16 = 9/16 each person ends up with 9/16 of a pie.” Here, work with fractions takes on a more systematic process.

This was the highest level of response identified from the responses received. One could predict that the next level is when students can approach the task with considerable versatility. They can use a number of written approaches and are usually able to provide the answer efficiently in verbal form. These options of response were not available to the students in this study.

THE BIOLOGICAL BASIS OF THE FUNDAMENTAL CYCLE

The biological basis of this phenomenon was discussed in Tall (1999), in which the stimulation of neurons places them on alert so that they will fire more easily for a while. They then react to a lower level of stimulation and, if this occurs, the link becomes even easier to make, until the neurons concerned fire together as a unit in a more subtle pattern. This long-term potentiation of neuronal links builds
sophisticated structures that act in consort, which are both complex (because they have many connections) but also simple (because many neurons fire as one unit).

However, this highly subtle mental development has a consequence. If the individual becomes aware that certain sequences of activity tend to occur, the individual can operate with them at a higher level. Thus, whilst individuals may need initially to be externally guided at the action level before contemplating procedures, then processes and then symbolise the activities to build a sophisticated mental schema, others are aware of the overall scheme of things. Thus a natural attribute of the fundamental cycle is the possibility of seeing the kind of outcome that might be possible and have a ‘top-down’ view of the need to build actions into processes into schemas to construct the wider vision in greater detail.

Here the different modes of operation may be of great advantage. For instance, an embodied combination of SOLO’s sensori motor and ikonic modes may enable the individual to gain an insight into the overall plan before building the more powerful symbolic and deductive modes of thought. On the other hand, an embodied approach which may work for some (natural) thinkers (using the language of Pinto, 1998) may be less effective with (formal) thinkers who have highly developed symbolic and deductive cognitive structures.

CONCLUSION

A primary goal of teaching should be to stimulate cognitive development in students. Such development as described by these fundamental learning cycles is not inevitable. Ways to stimulate growth, to assist with the reorganisation of earlier levels need to be explored. Important questions about strategies appropriate for different levels or even if it is true that all students pass through all levels in sequence. Research into such questions is sparse. Nevertheless, the notion of fundamental cycles of learning does provide intriguing potential for research.

REFERENCES

Abstract. This is the report for the study of a teaching program consisting on activities related to the use of fractions. The study was conducted on a small group of second grade primary education students at a state school. Students had received no previous teaching of fractions. In this investigation, we will show the feasibility of manipulative material and of the collective game as a type of tool to assist the student in building an initial understanding of sharing out (although it can not be take as the only tool). A questionnaire was given to the students as well, both before and after the teaching program. In order to prove that the results reported in the final questionnaire were accurate, various individual interviews were carried out on three children that participated in the teaching program.

Introduction

In Mexico, like in other countries, fractions make up one of the most difficult areas in the teaching of math at the basic educational levels (particularly regarding primary and secondary school). Therefore, many students who complete their secondary education and go on to a higher level find themselves with limited knowledge of fractions, even though they have studied fractions since primary school. This problem has become evident from the results obtained from some recent studies (Fredenthal, 1983; Pitkethly and Hunting, 1996; Kieren, 1980, 1998; Valdemoros, 1993; Figueras, 1998; among others), and from the teaching experience of those that participated in this study. It is possible that one of the many factors that fall into this process is the teaching method, which is considered not only determinant but also a process through which the child acquires knowledge.

As we face this problem of complexity when students acquire fraction knowledge, we must ask: What teaching activities can a teacher design in order to promote or facilitate a rich understanding of fractions among students? This question has served to delimit and concentrate on the problems presented in this study, which focus on how the systematic school teaching influences a child’s previous knowledge regarding the sharing out and elementary notions of fractions.

---

1 Mexico: Fractions are first taught in the third grade of primary school and the didactic strategies are taught between the third and sixth grades. During this time, a broad semantic overhaul of the relationship between equivalences and order is developed along with an elementary introduction of addition and subtraction.

2 Previous knowledge is made up of an organized set of notions, social representations, and hypotheses and/or theories that put into play the understanding of scholastic components and that function as true, assimilated instruments of such components.
Our hypothesis is set out as follows: The manipulative material will provide the third grade primary school student with assistance in order to build a formal understanding of the sharing out upon his previous knowledge.

Therefore, the objective of the present investigation is to identify and analyze the effects on students in the third year of primary school when solving sharing out problems in continuous\(^3\) and discrete\(^4\) models with the help of manipulative materials.

**Theoretical Framework**

Freudenthal (1983) states that the dividing into equal parts is a link to the mental construction of all types of magnitudes. While observing children from seven to eight years old, he realized that they are capable of estimating the half or one third of an irregular shaped area. Freudenthal considers this ability to divide as an important component in the mental area object.

On the other hand, Kieren (1983, 1984, 1988) recognizes that the division, the equivalence, and the formation of a divisible unit (constructive mechanisms) constitutes the cognitive basis for fraction language of the part-whole relationship. In their studies, researchers like Kieren, Nelson and Smith (1985), Figueras (1996), Piaget and Inhelder (1966), Hunting and Korbosky (1990), Pitkethy and Hunting (1996), and Pothier and Sawada (1989) have separated the strategies children use to solve partition and sharing out problems.

Freudenthal (1983) states that the formation of mental objects should come prior to the acquisition of concepts because the mental objects lay the foundations for the acquisition of concepts. The phenomenon are first seen as mental objects and then are transformed into concepts. Using specific material, the mental objects are formed of phenomena and not of concepts. Comparing mental objects will lead to the concept. The specific material holds a temporary significance because, once a student has formed long-lasting and permanent mental objects, the specific material is no longer necessary.

Researchers like Behr and Post (1988), Behr, Wachsmuth and Post (1998), Kaplan, Yamamoto and Ginsburg (1989), Bezuk and Cramer (1989), and other researchers, have used manipulative material when teaching fractions. They have suggested as well that it be used with primary school children and have given teachers both orientations and suggestions for correct usage.

Likewise, Kamii (1985) introduces three teaching principles: autonomy, daily situations, and collective games. She points out that if the teacher considers autonomy as the main purpose of teaching, he must foster the exchange and coordination of the students' points of view, allow them to express their thoughts freely, to make their own decisions, encourage them to think on their own instead of

---

\(^{3}\) Continuous models: Fractions are a way to relate one part to the whole and are put into context with geometric figures in that the fraction symbolizes a part of the unit (Hart, K. 1981).

\(^{4}\) Discrete models: Fractions are a way to relate a subset of a set in which it is included and it is put into context in sharing out situations.
reciting correct answers, let them debate his answers. Moreover, he suggests that
everyday situations happening in the classroom should be taken advantage of by the
teacher, since they are great opportunities for arithmetic. In the same manner, Kamii
says (1985, 1994) that collective games are an essential part of constructive teaching.
Games provide a way of organized playing through which, children are encouraged to
think in numerical combinations and remember them. They also allow children to
develop their ability to govern themselves, foster social interaction, and provide
feedback among participants.

Methodological Aspects

In the Mexican school, as mentioned in the beginning of this text, the teaching of
fractions starts officially in the third grade of primary education; however, at the time
of this study, we became aware of the fact that this subject had already been taught to
third graders. Consequently, this study is carried out on a second grade class during
the last period of the school year (May – June). This period was chosen because it
would be certain that there be no previous teaching of fractions. This study is of a
qualitative kind, due to the fact that an analysis of the progress of a small group of
children in their natural environment (the classroom) is enclosed in this study, in
order to recognize the effects produced in their thinking during the process and
termination of the application of a brief teaching program focused on sharing out.

The study began with an exploratory exam given to 28 students, with the purpose of
getting information about the previous knowledge on fractions the children had.
Moreover, the questionnaire allowed the selection of 10 children who participated in
the study and whose spontaneous and intuitive knowledge on the subject was
recognized before the start of the teaching program.

The questionnaire included 13 tasks organized in five blocks, with sharing out
situations represented by pictograms. In the first block, all are distributed
continuously among several objects or several people. In the three following blocks,
all are distributed discretely among several people, the result of the sharing out may
be less than one or more than one. The last block focuses on the comparison of
different sharing outs and on the reconnaissance of equivalence. The following is a
task from the last block: From this cookie drawing, Julie will eat one fourth, and
Michael will eat two eighths. Who will eat more, Rosa or Luis?

The study’s second instrument was the teaching program, with a constructivist focus,
which basically considers that children learn and develop as they build accurate
concepts of their study subjects. This building includes the child’s active attitude, his
availability, his previous knowledge in an interactive situation where the teacher’s
role is that of a guide and mediator between the child and the culture (Solé and Coll,
1999).

5 Pictograms: drawing representations of qualitative and quantitative aspects of a certain
problematic situation involving the use of fractions. Operations can also be made with the use of
pictograms (Valdemoros, 1993).
The didactics considered for the teaching program is Kamii’s proposal (1985), presents three teaching principles: autonomy, everyday situations, and collective games. From this point of view, the purpose of the teaching program was to create a proper environment where the child could adequately develop the activities proposed in the work sessions and that would allow him to acquire experiences in which he could establish different types of relations that would help him building basic knowledge on the subject of fractions.

The tasks that make up the teaching program were designed taking into account the results obtained from the initial questionnaire (the child’s previous knowledge on the learning content) and the purposes of our research. The activities included are related to the context of everyday situations and collective games.

It was carried out in twelve 45 minute sessions every three days. The activities developed in the work sessions were: covering a figure’s surface with other equal figures, building a figure with other equal figures, figure-folding to obtain two, four, and eight equal parts, partition of figures in two, four, and eight equal parts, comparison of a figure’s fractional parts, identification of a figure’s fractional parts, writing the fraction that represents each part of the fractioned unit in halves, thirds, quarters, and eighths, the game used for the exchange of ideas and coordination of points of view for the debating of answers as a feedback process of acquired knowledge, and the solving of verbal sharing out problems.

In said activities several manipulative materials were used, some were acquired, others adapted and others were designed. The manipulative materials were used in the first ten work sessions but not in the last two. Below, we enumerate some of them.

Pattern Blocks is made of prisms in different colors, shapes, and sizes that can fit together to build other figures. It was used in activities to cover and build figures. Geometric figures made from sheets of paper in different colors and sizes (squares, rectangles, and circles), they were used to carry out activities of partition in half, quarters, and eighths. They were also used to represent objects such as: chocolates, cakes, cookies, jellies, etc., in sharing out situations.

The “figure resaque” was taken from the Montessori didactic material called “metallic resaque”, with several modifications. It was used for comparisons of fractional parts, which fraction is larger than or equal to another.

A domino set was designed in plastic, with the characteristics of a common domino. The difference lies on the fact that it is related to the fractions: \( \frac{1}{2}, \frac{1}{3}, \frac{1}{4}, \frac{1}{5}, \frac{1}{6}, \) and \( \frac{1}{8} \), and it was used to bring about the exchange of ideas and coordination of points of view among the children, in order for them to debate their answers as a feedback process of acquired knowledge from previous activities.

---

6 Sessions: the number of sessions developed in teaching is equal to the amount of time which is officially dedicated to these topics.
After applying the teaching program, the initial questionnaire was applied again to
the ten children who participated in the working sessions. The period of time which
went by between the first and second application was of five weeks, which makes
the solution of the second one based on the first one impossible. The purpose was the
assessment of the advances achieved during the teaching program. Based on the
results obtained in the last questionnaire and the participation of the teaching
program, three students were chosen to carry out an interview with each one of them.

The purpose was to verify if the given results were solid in the last evaluation, as well
as to search for an answer to some situations manifested in said evaluation, which
weren’t fully appreciated. Likewise, the interviews allowed the strengthening if the
manipulative material is required by the student when developing his/her resolution
strategies of the given tasks. The interviews were semi structured (according Cohen
and Manion, 1990), due to the fact that there was a previous protocol and the needed
material for each case. The general nature of the interviews may be considered as an
evaluation instrument, which means that it was carried out a priori of the last
questionnaire application so as to verify that the answers to the tasks presented by the
students in said evaluation were sound. The purpose of this interview evaluation is
different from Piaget’s exploratory one (1978).

The interview’s design consisted of the presentation of five semi structured tasks.
Pictograms were not shown on them so that the children could solve the problems
using different strategies. The three first tasks are presented in sharing out situations,
the result of the first and the third ones are less than one and the result of the second
one is greater than one. The fourth task presents sharing out situations in which
relations of order and equivalence between ½ and ¼ of a whole are established. The
last task establishes the equivalence between ½ and 2/4 of a whole. Next, we present
the fourth task: from a whole pie, Mrs. Linda bought a half and Mrs. Rosa bought a
fourth. ¿Who bought more pie?

In order to validate this study, the results obtained in the questionnaire were
considered. Such questionnaire included the one of the interviews and the
observations of the research responsible and the one of another observant. The
compiled data in the questionnaire, the observations in the teaching sessions, and the
observations and data obtained in the interviews were compared in the previous
analysis.

Results

In the analysis of the initial questionnaire, the children resorted to their previous
knowledge (acquired from experiences of their family and the society) in order to
solve the tasks. They did not come across with any obstacles to carry out equitable
partitions in two and four parts of a continuous quantity. Nevertheless, most of them
presented problems when fractioning in three equal parts a continuous whole,
manifesting non-equitable partitions; despite the fact that the task’s sentence specifies
that “all the persons must get the same”. They also had problems when solving
sharing out activities of a discreet whole among x number of persons.
The children who participated in this evaluation showed greater difficulty in the activities when establishing the relation of order and equivalence between the obtained parts in two different situations of sharing out. It is safe to state that the few experiences which with the second grade students count, in regards of the equal division of continuous wholes limit their skills to develop appropriate sharing out strategies. These students also showed lack of vocabulary in order to name the fractional part in the distributed whole, which reveals that the cultural contents of their previous knowledge was really low.

While developing the teaching program, teamwork qualified children to exchange their ideas, carry out decision-making, discuss their answers, as well as accept their own mistakes and their knowledge feedback. The manipulative material was required by the children so they can solve problems; sometimes it was used as a feedback support when they had doubts of what they were doing or when they wanted to prove their answers.

The individual work brought about development in discovery and creativity skills when the children solved the tasks by themselves.

The result analysis given by the second application of the questionnaire, confirms the advances achieved by the children within the teaching program. The difference between both evaluations is self-explanatory, not only due to the number of right answers per student, but also because of the processes of significance, representation, and partition which they develop in order to solve the tasks.

Regarding partitions, the children carried out equitable partitions in two, three, four, and eight parts of continuous and discrete. Wholes in matters of sharing out, they made exhaustive equitable situations of sharing out in two, three and four equal parts. They established the order and equivalence relations between two different situations of sharing out. The students used symbolic fraction expressions to name the fractional part which came as a result of distributing the whole.

The capacity shown by the children when trying to solve these tasks by means of the appropriate procedure in the second application of the questionnaire, may be considered as a background for a development in their mental structures. To seek and find the answer to a problematic situation by themselves is a sign of improvement. With the aforementioned information, we may state that the teaching program fostered the usage of more appropriate partition and sharing out strategies.

After assessing the results obtained in the last questionnaire, we carried out the interview of three children: Manuel, Ana y Lizeth in order to enquire about the answers to some situations which manifested themselves in the evaluation and which were not possible to analyze in depth.

Manuel solved the tasks mentally, providing the correct answer for each and everyone of the tasks given to him. We believe that the child effortlessly constructed the mental objects related to the fraction, which allowed him to do without the manipulative material. He also learned the meaning of fraction as related to with
sharing out. This was evident when he mentally manipulated the fractional parts of a unit obtained by using a partition. He also established the order and equivalence relations between two different situations of sharing out made in one same unit.

Ana had to use the manipulative material to represent each problematic situation in order to visualize it first and then continue to construct the mental strategy. The educational assistant helped her in developing the correct process for each activity in order to get the correct answer. She was able to identify the existing relation between the numerator and the parts given to a person. She also found the correspondence between the denominator and the parts into which the unit was divided. The generalization of the concept was made in an intuitive fashion. But she was not able to recognize the equivalence relations between two different situations of sharing out done for one same unit, despite using the manipulative material to develop strategies. There’s no doubt she will require more teaching time to attain a solid learning of the relations of equivalence between fractions.

Lizeth used pictograms to develop her strategies and to solve the tasks. The representations of the problematic situations by means of pictograms, made getting the right answers easier. She also managed to mentally establish the relations of equivalence of two different situations of sharing out made for a single unit. Such pictographic representations proved to be a good aid when explaining her thought.

Conclusions

This teaching program fostered and developed the basic semantic contents related with fractions, helping the children to construct their own knowledge based on daily life experiences. During the development of the teaching program, the students successfully handled diverse geometric shapes with the aid of manipulative material, involving several modes of sharing out in: halves, fourths and eighths. In the final stage of the teaching program when solving sharing out problems, the students were able to use the technical-symbolic language with clear support in diverse significance processes.

By using the manipulative material, the children managed to establish the relations of order and equivalence between fraction couples. The manipulative material, geometric shapes, divided into halves, thirds and eighths were useful when the child wanted to identify and write the fraction represented by each fractional part of the unit. The educational assistant, "domino", fostered debate and exchange of ideas between the students for them to have a feedback in their acquired knowledge.

After building some basic fraction notions, the students broadened their knowledge when solving sharing out problems using different strategies without the aid of manipulative material. This research shows that the study of fractions in primary schools may be taught in a very propitious fashion through partition, sharing out and equivalence activities for which the manipulative material have proven to be extremely useful.

THE ROLE OF MATHEMATICS EXPERIENCES IN FORMING PRE-SERVICE ELEMENTARY TEACHERS' VIEWS OF MATHEMATICS

Anu Pietilä
University of Helsinki, Finland

Abstract. The purpose of the study was to examine pre-service elementary teachers' views of mathematics and the experiences that influence their development. A model was created in order to be able to investigate students' experiences and views in a fruitful way. The study was carried out in a mathematics methods course during the academic year 1999-2000 in a Finnish university. The study shows the importance of finding out and taking into account students' views of mathematics during their mathematics studies. In addition, the data lead to the conclusion that it is possible to influence students' views of mathematics during their studies.

Introduction

Over a period of several years pre-service elementary teachers have many experiences that are linked to mathematics and its teaching and learning. The experiences shape their views of mathematics and thus influence their ability to receive new knowledge during their studies. In addition, their views of mathematics influence their teaching at school in the future and therefore also their pupils' views of mathematics. (e.g. Ernest 1989) The results of prior research show that pre-service elementary teachers’ views of mathematics are not the best possible at the beginning of their studies from the point of view of their future career. Their beliefs and knowledge about school mathematics seem to be restricted. In addition, many of the students have a poor attitude toward mathematics and some of them are even afraid of it. (e.g. Ball 1990)

This paper addresses a major problem that has been noticed in mathematics education in many countries: that mathematics education programmes appear to have only a limited affect on pre-service elementary teachers’ capacity and willingness to change their teaching (e.g. Hill 2000). There have been many attempts to develop mathematics studies in order to bring about permanent changes in students’ views of mathematics and their teaching practice. Some studies have paid attention to students’ school memories (e.g. Trujillo & Hadfield 1999), others to increasing students’ knowledge (e.g. Graeber 1999), to improving their attitudes (e.g. Ellsworth & Buss 2000) and to diversifying their beliefs (e.g. Vacc & Bright 1999). Despite all of these studies, the problem of effectiveness still remains unsolved. The study reported in this paper was designed to contribute to the solution of this problem (Pietilä 2002).

The view of mathematics

The purpose of this study was to examine pre-service elementary teachers’ experiences in mathematics and their influence on students’ views of mathematics. The view of mathematics develops with exposure to different experiences with mathe-
matics in interaction with affective, cognitive and conative factors (e.g. Op 't Eynde, De Corte & Verschaffel 1999). Emotions, beliefs, conceptions and attitudes work as a kind of regulating mechanism in the formation of one's view of mathematics. In addition, learning demands cognitive aptitudes, like understanding, identification, thinking, evaluation and reasoning as well as conscious goal-oriented aspiration and activities. On the other hand a student’s view of mathematics also influences his or her understanding, decisions, affective reactions and actions, for example in different mathematics-related learning situations (Schoenfeld 1985). In addition, self-concept is of great significance in the formation of the view of mathematics (cf. McLeod 1992).

The view of mathematics is therefore defined here to be a combination of knowledge (e.g. Shulman 1986), beliefs and conceptions (e.g. Thompson 1992) as well as attitudes and emotions (e.g. McLeod 1992) that develop with exposure to different experiences with mathematics. The view of mathematics consists of two parts: knowledge, beliefs, conceptions, attitudes and emotions about

1) oneself as a learner and teacher of mathematics, and
2) mathematics and its teaching and learning.

Both parts can be divided into smaller parts. The second part includes, among other things, views about how teaching should be organized and what the roles of teacher and students are.

Mathematics experiences are of central importance in the formation and development of the view of mathematics. A model for personal experiential knowing made by Malinen (2000) was modified to model the formation of the view of mathematics. The view of mathematics consists of a hard core, which contains the persons‘ most fundamental views, and a protective belt, which contains more flexible views (cf. Green 1971: the psychological centrality of beliefs; Kaplan 1991: deep and surface beliefs). Mathematics experiences need to be penetrated to the hard core in order to change the view of mathematics in an essential way.

Former experiences (or rather the situations that are linked with them) are marked in the model so that their arrows reach the hard core of the view of mathematics (at the bottom of figure 1). This is based on the reasoning that home, school, friends, myths about mathematics, and temporary posts as teachers have influenced a student’s view of mathematics before his or her studies. One example of the mechanisms of this influence is the fact that students’ study of mathematics at school is usually textbook-centred. It is then natural that mathematics is merely considered to be computation. Likewise for example the myth that boys are better in mathematics may have influenced one’s view of mathematics.

Experiences during studies (or rather the situations that are linked with them) are marked in the model (at the top of figure 1) so, that their arrows reach only the border of the protective belt. Student can have meaningful experiences in mathematics methods course, other studies and practice teaching. In addition, temporary posts as a
teacher can be significant even at this stage. For example, a student can receive guidance in the mathematics methods course on how to use manipulatives in his or her teaching. Students also have an opportunity to use temporary posts as a means of applying what they have learned and can reflect on its usefulness.

Figure 1. A model for the formation of the view of mathematics

The study reported in this paper was designed to determine 1) how pre-service elementary students viewed mathematics at the beginning of the mathematics methods course and what experiences had shaped their views, 2) what kinds of experiences students find meaningful in shaping their views of mathematics during their first year of university study, and 3) the main changes in the students’ views of mathematics during their first year of study.

Attempts were made to influence students’ views of mathematics using a variety of research-based methods during the mathematics methods course (4 credits). It was considered important to focus on the students’ views at the beginning of their studies in order to be able to arrange the most beneficial learning environment (cf. Malinen 2000). In addition, it was thought significant that students pondered their views of mathematics, which demanded a safe atmosphere (e.g. Stuart & Thurlow 2000). The studies were designed so that students could try out as much as possible of what they had learned. It was assumed that exploring and learning the use of manipulatives would help students to understand elementary school mathematics more deeply (cf.
Quinn 1998). At the same time it was assumed that students would learn to teach for understanding (cf. Graeber 1999). In addition, combining theory and practice was thought to be able to help students to consider the learned topics useful (cf. Hill 2000).

Methodology

A research method based on phenomenological starting points was used in methodological solutions, but problems related to interpretation and understanding were also examined from the viewpoint of hermeneutics (cf. Giorgi 1997). The research material was gathered from the students (N=80) in the form of written homework as a normal part of their study. The questions were made as broad as possible and they were designed to obtain information about certain themes. Students wrote five different letters during their mathematics studies that dealt for example with their experiences of mathematics at school and at the mathematics methods course. In addition, eight students were interviewed approximately one year after the end of the mathematics methods course in order to increase the trustworthiness of the study.

The research material was analysed using following steps: 1) The material was read through twice in order to get a sense of the whole. In addition, it was important to ‘bracket’, which means to put aside things that we know in order to experience students’ experiences freshly. 2) The texts were divided into meaning units (themes of the study). 3) The students were grouped based on their situation in the beginning of their studies. 4) The research material was analysed one research question at a time. 5) The contents of the meaning units were identified and recorded. 6) The common features and structures for different groups were recorded. (cf. Giorgi 1997)

Interviewed students read analyses of their views of mathematics at the beginning of their studies and checked their correctness (member check). An effort was made to increase the validity of the study by means of triangulation, prolonged engagement, peer debriefing and referential adequacy. (Lincoln & Guba 1985)

Results

The students were divided into four groups based on the answers given at the beginning of their studies. Students’ views of themselves as learners of mathematics were considered as criteria for this grouping because they influenced very holistically both their descriptions of their experiences and their views of mathematics. The groups were categorized according to their views of mathematics as follows: 1) Mathematics is challenging problem solving (13%), 2) Mathematics is important and usually pleasant (36%), 3) Mathematics is one subject among others (20%) and 4) Mathematics is difficult and unpleasant (31%). This data led to the conclusion that only approximately half of the students are interested in and/or enthusiastic about mathematics and about studying it at beginning of their studies. Some students were even afraid of mathematics (c.f. Trujillo & Hadfield 2000).

Mathematics is a bugbear. Mathematics is just the thing that I have always felt difficult. When I was small others were afraid of bugbears while I was afraid of mathematics. That bugbear...
has kept me in his possession until these days. (a letter written at the beginning of the studies, group 4)

In addition, all students but the students in group 1 had a very narrow view of mathematics and its teaching. Most of them thought that mathematics is merely computation and that it is based on rules and procedures that should be memorized (cf. Ball 1990).

I think that mathematics is a tool that gives means, formulas and instructions for solving computational problems. (a letter written at the beginning of the studies, group 2)

In addition students’ knowledge of mathematics was compartmentalized, usually very superficial and not based on understanding (cf. Hill 2000). Thus it became important to find out students’ views of mathematics at the beginning of their studies and to pay attention to them during the studies.

Mathematics studies helped students to question and redefine their views of mathematics and its teaching and learning. Students felt that their view of mathematics became better organized and they knew more about what they think about mathematics (cf. Llinares & al. 2000). They noticed that mathematics could be taught using many different methods that had not been used when they were in school. They realized that it is important to understand what they learn and not just to memorize. In addition, they understood that it is important to actively involve pupils in the learning process.

A new insight to teaching and learning mathematics was that one should try to figure things out by oneself instead of trying to memorize rules. (a letter written at the end of the studies, group 2)

The studies also challenged students to re-evaluate their relation to mathematics. Their views of mathematics became more positive and they became enthusiastic about teaching it (cf. Raymond & Santos 1995).

Mathematics has actually surprised me. As a subject it is really many-sided, at its best an impossibly inspiring and attractive subject. (a letter written at the end of the studies, group 3)

In addition, as they learned more about the subject and its methodology their views of mathematics became broader and more accurate. The studies gave the students an opportunity to understand elementary school mathematics more deeply, for example by using manipulatives (cf. Quinn 1998).

The belief that not everybody can understand mathematics has vanished and I noticed during the mathematics methods course that I realized many things that I had not understood at school. (a letter written at the end of the studies, group 4)

Students reported many factors that were important from the point of view of the change in their views of mathematics. The mathematics methods course, practice teaching, holding temporary teaching positions and other studies combined to make it possible for the students to consider their studies to be meaningful. Students thought that it was important that the mathematics studies gave them the opportunity to try to
explore different things by themselves. The close relationship between theory and practice helped students to see that the studies were useful (cf. Ellsworth & Buss 2000).

*It is important that we did things instead of just talking about them. We handled the materials and tried them out. If you can’t use them in the course why should you try them later? (a letter written at the end of the studies, group 3)*

Pondering and talking about own experiences and views, finding models for their own teaching and understanding the learned topics were also experienced to be important. In addition, a positive learning atmosphere was considered to be very essential (cf. Stuart & Thurlow 2000). Conversations helped students to understand their past and improve their attitude.

*The fact that I have been obliged to ponder on my past experiences as a learner of mathematics has helped me to disprove the myth: “I don’t understand anything about mathematics.”... We have discussed fears and attitudes toward mathematics. It has been rich and has changed my attitudes. (a letter written at the end of the studies, group 4)*

The students had an opportunity to use practice teaching and temporary posts as a means of applying what they had learned. Students’ experiences were mainly positive and they recognized the usefulness of what they had learned (cf. Stuart & Thurlow 2000). Students noticed that they could explain so that pupils understood. In addition, the pupils were enthusiastic about the new teaching methods.

*I could test my own ability to demonstrate and concretize when I helped students. It was enlightening to realize how much concretization helped students to understand. Some of them seemed to understand some basic things for the first time. (a letter written after practice teaching, group 4)*

Other studies helped students to see mathematics studies in a larger context, although their significance for enhancing their views of mathematics seemed to be small. Students noticed during their studies that they needed many skills in order to develop into good mathematics teachers. They realized they needed knowledge about both the subject and pedagogy. On the other hand the learning of new skills and knowledge increased their self-confidence as teachers (cf. Raymond & Santos 1995).

*I noticed during the mathematics methods course how many facilities and skills I actually needed in order to develop into a good mathematics teacher. We treated mathematics broadly during the lectures and especially during group meetings, and I became aware of many new facets. (a letter written at the end of the studies, group 3)*

**Conclusion**

Many positive changes took place in students’ views of mathematics during their first study year. The depth and the durability of the change can still only be guessed. Some idea of this was gained through the interviews that were carried out one year after the mathematics studies had ended. Four students had participated in practice teaching during their second study year, and their views of mathematics had became
even more positive because they had become more confident as mathematics teachers. Four students had not studied anything that could be linked to mathematics. Their views had remained almost unchanged, becoming perhaps a bit more realistic.

It was important on the point of view of the stability of the change that students developed the ability to recognize and reflect on their views of mathematics (cf. Raymond & Santos 1995). In addition, the awakening of students’ responsibility gave the researcher faith in their willingness to change their teaching. The students realized that most of the pupils’ understanding and enthusiasm depend on teacher’s teaching methods. The stability of the change could probably be increased by combining theory and practice even more (cf. Hill 2000). It would be important for the students to try out what they learn as much as possible in practice (with students) during the mathematics methods course. By doing so, they would have the opportunity to become more convinced of what they learn. In addition, the material would be easier to internalize and remember.

The model developed for researching the students’ views of mathematics seemed to be functional. Based on the changes in the students’ views of mathematics, it was possible to conclude that knowledge, beliefs, conceptions, attitudes and emotions affect the formation of their views of mathematics. In addition, the division of the view of mathematics into two parts was justified because students’ views of themselves as teachers had such a strong influence on their views of mathematics as a whole. In addition, the graphic model of the view of mathematics seemed to be functional and useful. It provided an opportunity to portray their experiences and their views of mathematics in a compact picture.

It would be interesting to follow the students’ views of mathematics when they obtain posts as teachers. In addition, it would be interesting to study what experiences have the most influence on their views of mathematics, for example, the school’s curriculum, colleagues, size of the class, textbook, teaching materials, in-service training and so on.

MENTAL REPRESENTATIONS IN ELEMENTARY ARITHMETIC
Demetra Pitta-Pantazi*, Eddie Gray** and Constantinos Christou*
*University of Cyprus **Warwick University

This paper discusses emerging themes about the nature of embodied objects and symbolic procepts in the context of elementary arithmetic. Drawing upon the mental representations and strategies children use whilst executing mental addition and subtraction the paper also aims to illustrate how the nature of base objects may be determined and used within elementary arithmetic. The paper indicates how the nature of base object may change in the development of arithmetical concepts and illustrates how for some it may be a stepping stone to more sophisticated thinking whilst for others it acts as epistemological obstacle preventing the attainment of such thinking.

INTRODUCTION
The notion of numerical concepts being formed from actions with physical objects forms the background for the conceived cognitive development of simple arithmetic (see for example Piaget, 1985; Gray & Tall, 1994). Encapsulation (or reification) theories suggest that a cognitive shift takes place between carrying out actions and the formation of numerical concept. How this process takes place, however, remains the subject of theory and open to debate. More recently, Gray and Tall (2001) suggested that a simple switch of viewpoint where theorised encapsulation (or reification) of a process as a mental object may be linked to a corresponding embodied configuration of the objects acted upon (the base objects) may reveal some powerful insight into the different ways which individuals construct mathematical concepts. Our effort to gain an insight into how this is happening has taken a route to consider mental representations.

This study considers the association between different kinds of mental representations projected by 8-11 year olds and the construction of arithmetical concepts. Different kinds of mental representations are identified based on what objects and actions are mentally represented when children are presented with an addition or subtraction. Our purpose is to compare the meaning embodied in the objects and their configurations as denoted by the children's mental representations with process-object abstraction.

Earlier research by Gray, Pitta, Pinto and Tall (1999) indicated that students who consider the descriptive qualities of the embodied object remain at a more primitive level whereas, those that rely on the more intrinsic qualities of the object such as the mathematical symbolism and its relationship to other objects move to a more sophisticated level.
Encapsulation (or Reification) of a procedure

Piaget believed that learning as well as performing mathematics was a matter of active thinking and operating on the environment. This activity was strongly linked to ‘physical experience’ which “consists of acting on objects to discover the properties of the objects themselves... not from the physical properties of particular objects, but from the actual actions (or more precisely their co-ordinations) carried out by the child on the objects” (Piaget, 1973, p.80). His focus was on the way in which actions and operations became thematized objects of thought or assimilation (Piaget, 1985, p.49). Interiorising processes into mental objects is seen as a fundamental way of constructing mathematical objects; dynamic actions conceived of as conceptualised entities is now frequently associated with notions such as encapsulation (Dubinsky, 1991) and reification (Sfard, 1991). In the context of number what is clear is that there is a growing sophistication in the nature of the entities operated on, from physical objects to mental operations with the number symbols themselves. This development is manifest in an increasing detachment from immediate experience, the evolution of different aspects of counting and a change in the form of unit counted (Steffe, Richards, von Glasersfeld & Cobb, 1983).

In the context of elementary arithmetic the nature of the unit counted may be seen to be analogous with the nature of the object operated on. Tall, Thomas, Davis, Gray and Simpson (2000) draw the distinction between “perceived objects” and “conceived objects”. The first is based upon perceptual information where the focus is upon specific physical manifestations of the object. The second occurs when the focus shifts from the physical manifestations to the actions/process performed on them. Such a distinction has been used by Gray and Tall (2001) to distinguish between the notions of embodied object and symbolic procept. The former “begins with the mental conception of a physical object in the world as perceived through the senses” (p.66) and can “only be constructed mentally by building on the human acts of perception and reflection (p.67)”. Though they see an increasing sophistication in the notion of embodied objects, Gray and Tall see a significant distinction between embodied objects such as a triangle and a graph on the one hand and the symbols of arithmetic on the other. The latter

“act as pivots between processes and concepts in the notion of procepts and provide a conscious link between the conscious focus on imagery (including symbols) for thinking and unconscious interiorised operations for carrying out mathematical processes”

(Gray & Tall, 2001, p.67)

Within the field of elementary arithmetic the theorised encapsulation or reification of a process as a mental object is often linked to a corresponding embodied configuration of the objects acted upon which we have indicated to be the base object. Counting processes operate on physical objects. Thus the seemingly abstract
concept of number already has a primitive existence in the physical configurations of base objects. In the context of addition, for example, the base objects are initially physical objects, then they become figural objects but later these become redundant as they are subsumed within a counting process which itself can be compressed into the concept of sum.

This emphasises a proceptual structure that consists of a theory of related procepts, including the base objects on which the processes act, the symbols as process and concept, and the concept image on which the processes act. (Gray & Tall, 2001, p.68)

This paper attempts to consider the way in which children’s explanation of the way in which they solve elementary number tasks may give us insight into the nature of the object that is being used. We feel that the distinction is essentially one that is to be made in terms of the use of external or internal representations. The latter suggests the notion of mental representation and in the sense that is discussed within this paper these mental representations may be embodied objects or symbolic procepts. Clearly a mental conception of a finger is an embodied object and of course the actual physical object ‘finger’ is not. Both may be referred to as base objects. However, we suggest that the ‘threeness’ associated with the display of three fingers is embodied. Clearly then, the mental representations of numerical objects reported by Seron, Pesenti, Noel, Deloch, and Cornet (1992) may also be seen as embodied objects. Their subjects reported seeing simple digits or numbers, numbers transformed into patterns as found on a dice, numbers with colour and numbers as on a number line. They suggest that quantity directly represented by “patterns of dots, or other things such as the alignment of apples or a bar of chocolate (p.168) may be deemed to be analogical. In our sense these objects are embodied — they arise initially in perception but they can carry mental ideas. Thus the dots on the dice may carry the idea of five.

In this study one portion of the complex structure of mathematics is isolated, that of mental additions and subtractions to 20. By considering children’s mental representations and more specifically the object of the representation whether embodied object or symbolic procept, it tries to make sense of the influence that they have on children’s successful understanding.

METHOD

The research was conducted in a “typical” primary school in the English Midlands. Sixteen children aged 8-11 years old, representing the extremes of numerical achievement in each of the four years - thus two at each extreme of each year - were presented verbally with mental additions and subtractions to 20. The children’s numerical achievement was measured by criterion based test results available in the school and a numerical component which formed part of a larger study of which this paper is part.
For these combinations children were reminded that the object of the interview was for the interviewer to get a sense of the approach the child used to solve particular items and to gain some indication of what was happening in the child's head while doing these mental additions and subtractions.

**Classification of the Results**

To classify children's representations we have adopted some of Steffe's *et al* (1983) classifications for two reasons, since it is a finely-grained analysis of counting units and provides valuable insight into numerical development.

*Automatic Responses*: These were identified whenever a child indicated that "I just knew it" and no overt or covert actions appeared to be associated with the response. Here the base objects will be the inputs, for example 3 and 5, although it is difficult to discern whether an individual who knows facts projects the use of a mentally embodied object or the use of a symbolic procept (see abstract representations below).

*Perceptual Representation*: Strategies are applied with the support of physical items, for example fingers. Physical items are the base objects. The embodiment is the mental association made between the configuration of the fingers, as sets to count, and the quantity counted.

*Verbal Representations*: Here the number word is taken as a substitute for countable items. Typical examples include:

- Five, counted in my head three, four, five. (Y3-, 3+2)
- 9, 8, 7,... just said that to myself. (Y6-, 9-7)

Here the base objects are mental embodied objects. The number words, are embodied as mental conceptions of the number counted.

*Figural Representations*: Here the counting process is taking place in the absence of actual items but is associated with visual or verbal analogues of the items:

- I saw a line of numbers. It was one, two, three, ...13, 14, 15. After 10 the numbers got bigger. I counted from 1 until I got to 8. (Y3-, 3+5)

The mental conceptions of fingers are embodied objects.

*Abstract Representations*: The use of the term is based on the notion of Steffe *et al.* (1983) but in the current context not only did a child not require to construct countable units but the symbol was identified as the object of thought. The classification was most frequently associated with derived facts. A typical response could be:

- [Said to myself] the difference between six and seven is one, so two sixes are 12 and 12 plus 1 is 13. (Y4+, 7+6)

This category suggests the use of symbolic procepts.
All responses were videotaped and supported by field notes. The results are established from analysis of the video transcriptions.

RESULTS

Analysis of Results

Children's combinations to twenty

As illustrated in Table 1 (which illustrates the percentage use of each representation) perceptual and verbal counting responses were given more often by low achievers whereas automatic and abstract responses were given more often by high achievers. Very few figural responses featured in either of the two groups.

Table 1: Representations of Mental Arithmetic: Number combinations to twenty

Low achievers' combinations to twenty

Perceptual representations featured strongly amongst 'low achievers' and this may have been associated with vocal or sub-vocal counting. Most frequently fingers, these perceptual units, became objects of thought which were sequentially tagged in the counting procedure. Tagging was mostly overt in that children looked directly at their fingers, tagging those on one hand with those on the other, or, if the number was relatively large, tagging through touching the desk or even the nose. On some occasion motor acts were used as substitute for tagging. At times the counting was not associated with any obvious tagging. Children would “feel” movements in their fingers without any obvious sign that they were doing so. When this happened, it seemed that the younger the child or the more difficult the sum the more exaggerated this movement was. Therefore, while a Year 4 ‘low achiever’ said:

7, 8, 9, 10, 11 and I was counting on my fingers. (Y4-, 4+7)

a Y6 child said

I was counting in my head 6, 7, 8, 9 but had it as a finger feeling. (Y6-, 6+3)

We conjecture that the need to use perceptual items amongst the ‘low achievers’ reinforces the evidence that symbols need to be concretised.

There were few instances where low achievers made reference to figural representations. These may be seen in the context of analogical representations. In the instances associate with number combinations to 20 these figural representations resembled the number forms of Seron et al (1992) in that they were based on the number line:
I saw the number line in my head and saw a lot of numbers in my head on a number line. There are lots of numbers but it depends on how high the numbers are. High means how big the numbers are. This time it was three plus four.  

The smaller combinations were often associated with verbal counting and the numbers themselves served as countable objects.  

I was thinking of it. Add. It is 11. I said 10, 11 to myself.  

5. I counted in my head 3, 4, 5.  

Often the verbal tone or double counting accompanied the counting act, although this sometimes led to errors:  

Got to 13 to add up to 17...13, 14, 15, 16, 17. 13. One 14, two 15, three 16, four 17, five ...said all in the mind.  

In all the above examples there is an intrinsic similarity, ‘low achievers’ use a lengthy counting procedure as if it is a generalisable process. Irrespective of whether the object is a concrete finger or a mental number line or a number word they are essentially doing the same thing. Low achievers seem to be trapped in the only process that one is able to do with base units that are physical — counting. The overemphasis on embodied objects and on surface characteristic of objects and processes does not allow children to see the power of symbolic procepts. Therefore, things are becoming increasingly difficult as numbers are getting bigger.  

**High achievers’ combinations to twenty**  

High achievers’ responses were mainly ‘automatic’ and ‘abstract’, the first category indicating an almost immediate response whereas in the second the symbols dominated the children’s thinking.  

The symbols were frequently associated with the input combination or with the final solution.  

I saw the eight then the two and then I see them altogether.  

The tendency to see the input symbols and/or the final output was relatively common amongst those ‘high achievers’ who reported seeing symbols though other characteristics were also apparent.  

I saw a picture of 9-2, black.  

I saw 9 and 7 flash, not as a sum but just 9 and 7. I then saw 2 much stronger.  

‘High achievers’ also reported symbolism associated with the formation of derived facts:  

I said [to myself] seven and seven and take away one. Told you thirteen.  

I saw 13-2 and thought I would split it up into different parts to make it easier. This stood out. Saw 13-3 then 10. Then I saw 10-2 this stood out. Then I saw 8. 13-3 and 10-2 stayed at the same time. I saw 8 on its own.
In the second example the child seems to be oscillating between visual representations “saw” and verbal representations “thought”. This relationship between visual and verbal mental representations was one that clearly gave the child the power to complete the combinations. The visual image of the high achiever generates the idea and then it is put aside so that she can focus on the relational characteristics. The symbols are thought generators and not the mental embodied objects used to carry out an action. Of course the fact that their mental representations are dominated by symbols, which can either be seen or talked about, gives them this flexibility.

‘High achievers’ are not only able to filter out the surface characteristics of embodied objects and the lengthy procedures but they are also able to avoid “difficult” numerical combinations by transforming the question to a more manageable one, or one that is derived from an easier known fact:

I said to myself the difference between 6 and 7 is 1 so 2X6=12, 12+1=13. (Y4+, 7+6)

‘High achievers’ seem to be able to filter out surface characteristics from the embodied objects, condense the counting procedure or most often omit it altogether and carry out their mental processes in a truly abstract fashion. Their emphasis lies on the more intrinsic qualities of the mathematical symbolism, process to do and concepts to know. Another strength of the mathematical symbolism is that it can be seen and also talked about. It is very rare that an embodied object can be interpreted as a process and a concept or carried in the mind as a visual sign or a verbal word.

DISCUSSION

Hearing the combinations triggered the ‘low achievers’ to carry out a procedure; in this instance an overwhelming desire to count. It could be hypothesised that in their failure to recall combinations the representation that the ‘low achievers’ used, evoked either physical objects or mental conceptions of these objects. In the first instance, their mental representations were embodied as general representations of the number sequence. This general mental representation was retrieved either as physical objects or as an embodied object, such as the number line. Qualitative differences in the nature of the base objects were determined through this real or imaginary difference. Thus the ‘specificity’ of the number sequence is not only identified through the inclusion of the numbers that need to be counted but also through the different objects used. Therefore, it seems that the choices the children make (consciously or subconsciously) focus on the nature of the counting procedure and representation (mental or physical) they need to support this procedure. Increasing procedural efficiency may determine both the counting strategy, for example, count up as opposed to count back, and the nature of the base unit to be used. However, within the three categories of representations identified, physical, figural and verbal we may see the gradual shift in the nature of the base unit from perceptual to a mentally embodied object.
In contrast categories identified for ‘high achievers’ illustrated extensive use of the retrieval of known facts, either to give an automatic response or in order to proceed to a derived fact. Clearly the nature of the entities operated upon have changed. Now they signify conceptual entities that appear to exist “independently of the child’s actual or represented motor activity” (Cobb, p.168). The ‘high achievers’ are performing the operations of addition and subtraction on symbolic procepts. It is conjectured that underpinning this approach is the power that emerges from their representational flexibility. They seem to be carrying out a ‘search’ for the most appropriate number fact that can be used. They retrieve it and either present it as the answer or manipulate it in order to reach an answer. The former is not easy to qualify, the latter is the essence of proceptual thinking. The symbolic procept acts seamlessly to switch between a mental concept to manipulate to a process to carry out.

Essentially the role of base objects may be seen as a stepping stone to higher order concepts. However, they may have specific meanings for some individuals that act as epistemological obstacles that prevent a hierarchical development that is essential to progress. These differences would seem to become apparent very early within the child’s mathematical development.

REFERENCES

This report centers on the diversity of interpretations of the norms of mathematical practice. In particular, it focuses on one such norm and in how a group of students changes its interpretation after a whole class discussion in which issues of social positioning and power are clearly in play. We argue that an understanding of these social issues is necessary in order to develop learning environments that are more sensitive and hence equitable to all learners.

INTRODUCTION
The frequent lack of cultural and social affinity in the mathematics classroom requires an understanding of what factors lead the learner to re-construct his/her first interpretations of certain norms. The presence of different meanings for the classroom norms and the obstacles to negotiate these meanings are to be taken into account when analysing shifts in students' participation trajectories. An understanding of these shifts in participation seems necessary towards the development of equitable learning environments. In this report we center on one episode from a recent research (Planas, 2001) that illustrates the diversity of interpretations for the norm of the "context of a problem" in a problem-solving situation. Relevant excerpts from classroom transcripts will be used to uncover the construction of social meanings behind the multiple ways of interpreting this norm.

THEORETICAL FRAMEWORK
The idea of a system of meanings has been broadly used to characterize the so-called 'culture of the mathematics classroom' (Voigt, 1998). In particular, the normative meanings, that is the obligations and rules of how to act, conform an important part of this culture. The research of Yackel and Cobb (1996) has pointed to the diversity of interpretations of classroom norms and its impact on the teaching and learning of mathematics. However, recently some researchers have
questioned an approach essentially based on the cultural issues of the classroom. There has been a call to emphasize the ‘social’ in the socio-cultural paradigm of research in mathematics education (see, e.g., Lerman, 2000). As it is argued by Morgan (1998), the study of the norms from a socio-critical perspective is still in its beginning stages. There is a need to look at how norms can be interpreted differently as well as how different interpretations may be related to different values given to participants (Abreu, 2000). Abreu states that the tasks which need to be solved in the classroom can be made difficult or easy depending on how participants interpret the legitimate norms.

RESEARCH QUESTIONS AND METHOD

In this report we address the following questions:

a) Given a norm, can it be interpreted differently by the various participants?

b) How do different interpretations of a norm influence each other?

The research was conducted in three classes located in three urban high schools in Barcelona, Spain. In these schools there is an increasing number of students socially at risk. They are students belonging to ethnic minorities, first or second generation immigrants. Many local families do not want their children to attend such schools due to the high percentage of immigrant population from Magreb, Pakistan, India, South America as well as the local gypsy students. The enrollment in these schools is therefore lower than usual.

A total of 36 lessons were videotaped, tape-recorded and transcribed. Non-participant observer methods, field notes and individual interviews of students were also used. There was a triangulation of methods for obtaining the data and a triangulation of perspectives in analyzing them. The video-recordings and the interviews’ transcripts were discussed by the teacher, the observer and an external researcher in regular meetings. The lesson we document here is embedded in a problem-solving unit. The nine students were asked to work in small groups. This
was followed by a whole class discussion in which the three groups shared their approaches. They were given the following problem:

*Here you have the population and area of two neighbourhoods in your town. Discuss in which of these places people live more spaciously*:

<table>
<thead>
<tr>
<th>Neighbourhood 1 (N1)</th>
<th>Neighbourhood 2 (N2)</th>
</tr>
</thead>
<tbody>
<tr>
<td>135,570 inhabitants</td>
<td>297,930 inhabitants</td>
</tr>
<tr>
<td>14 km²</td>
<td>3 km²</td>
</tr>
</tbody>
</table>

(*Neighbourhoods 1 and 2 were given their real names and were known to the students*)

**RE-CONSTRUCTIONS OF ONE MATHEMATICAL NORM**

The question ‘where do they live more spaciously’ created important differences in the interpretation of what was required to solve the problem. Some students decided that there were data missing while some others were comfortable with solving the problem as it was. This led to different interpretations of the norm “context of the problem”. One group (GA) took the problem as a typical school task and solved it in an algorithmic way. They divided the population by the area and reached the conclusion that “they live 10.25 times better at N1 than at N2.” Clara, this group’s leader said, “we’ve solved similar problems before; you have to make some divisions, that’s all. The more neighbourhoods, the more divisions.”

Another group (GB) also used the concept of density. They divided the population by the area but then expressed some concern as to whether the answers were reasonable. For example for Neighbourhood 1, the division led to 9,683.57 persons per square kilometer. They agreed that it should be 9,684 p/km² because “you cannot have 0.57 people.” This group also concluded that people would “live much better in N1” but most of their time on the problem was spent on their concern on what to do with these decimal answers for people.

The third group (GC) engaged in an animated discussion about the wording of the problem. Their concern centered on a need to know more about the living
conditions in the two neighbourhoods. Albert, one of the group members, said, "well, it doesn’t say anything about the people. We need to know if they live in flats or houses. Some of them live very spaciously and some of them live very badly, right?" And Lordwin, another student in this group said "it depends on how many children there are in each family, then we write the number of children there, we’d better write it again." Group C took their task as that of rewriting the problem to fit more closely their own lived experience.

All the groups offered reasonable explanations without making incorrect uses of mathematical operations or procedures. The difference was in their understanding of the norm of the context suggested by the problem. Groups A and B followed academic procedures and used the concept of density. Neither of these groups questioned the wording of the problem. Group A took it as typical school problem, while Group B showed concern for the real-world context and was aware that one cannot have decimal numbers as answers about people. Group C took the problem as a real situation for which more information was needed. These neighbourhoods were real to them. Their approach to the task reminds us of critical pedagogy contexts in which students would be encouraged to use mathematics to make sense of their world (Skovsmose, 1994). The teacher in this case, however, did not seem interested in pursuing such an approach. The other two groups were surprised at Group C’s questioning of the problem statement. The whole class discussion that followed the group work shows how the social positioning of the students may have influenced their subsequent approach to the problem.

As each group faced comments from the class and was confronted with alternative norms, first approaches were reaffirmed or changed. This allows us to study not only the various interpretations of the same norm but also how dynamic these interpretations are. We only look at the changes that occurred during the whole class discussion, though other possible meanings for the appropriate context of the problem may have emerged in the small groups. Groups A and B insisted on their
first approach. The notion of density was still considered the key factor. Group C’s change was highly significant. The change was apparently radical but we wonder whether this change was more the result of pressure from members of the other groups than from having reached internal conviction that the other approaches were more valid. Group C ended up rewriting the problem as follows:

In N1, houses have gardens and swimming pools. Families have one children. In N2, there are small houses and skyscrapers. Families have many children. But the important thing is that there are 135,570 people and 14 km² in N1, and 297,930 people and 3 km² in N2. Where do people live more spaciously?

The first part of the problem (until the sentence starting with “But”) is what they had at the end of their initial group work. The second part is what they added to conform to the whole-class discussion. The critical context was somehow combined with the school context. All throughout the discussion, however, comments from this group indicate that they were not really satisfied with their revised approach. For example, Lordwin kept on mumbling that they needed to know how many children there were, and said, “now you have a number but you don’t know anything about the kind of houses they live.” An indication of the pressure they felt is given by Albert’s comment “if we don’t do as we are told, the teacher is going to get angry.” The group was reluctant to give in, “we don’t need to cross out our problem, do we? Just say ours is the same as Clara’s (Group A leader).” In the next section we focus on the case of Albert, the leader of group C, to explore the possible role of social positioning in classroom dynamics.

EXPLORING ISSUES OF SOCIAL POSITIONING

Why did group C change their initial approach to the problem and ended up with one that somehow conformed to the expected school context? We argue that an understanding of the social positioning of students in the class may shed some light on this question. The other two groups’ reluctance to accept Group C’s strategy, and this group’s decision to change their approach must be analysed taking into account the valorizations that were made explicit between the first attempts and the
re-constructed contexts that appeared some minutes later. This expresses not only a normative difference between the three groups, but also interpersonal relations of power between individuals. For example, if we focus on Albert, we see a student who seems concerned about the teacher’s reaction (“if we don’t do as we are told, the teacher is going to get angry”). While the teacher showed concern about Albert’s involvement, he was also somewhat sarcastic in his reaction to that group’s attempt to rewrite the problem (“how cute of you…”). We also see how other students reacted rather negatively to Albert’s suggestions. For example, Clara (GA) got very upset at him, “if you don’t know what to answer, just shut up!”, and Bernat (GB) was extremely concerned about Albert making them waste time. At a certain point, many participants were frowning at Albert. Table 1 summarizes some of the negative valorizations given to this student as well as his reaction.

Teacher: “How cute of you! If someday I put you in charge of writing a problem, please, remind me of your sense of humour... You are confused about what it means to think about a problem, but don’t worry, don’t be discouraged about the problem, it’s very normal that you find it difficult”

Clara: “You must be joking as usual! Ask for help if you have no idea of how to solve the problem... if you don’t know what to answer, just shut up!”

Bernat: “Don’t make us waste our time! Stop clowning around! You are always trying to get the teacher’s attention by saying silly things! This problem has nothing to do with swimming pools and gardens!”

Albert’s responses: (utterances and speech defects such as stuttering)

(to Teacher) (stumbling) “We didn’t know it was forbidden to improve the problem, we thought we had to understand the situation, if...if we had known it was forbidden, we would have never tried to change it, teacher, we promise”

(to Clara) (without looking at her eyes) “I’m not joking, I’m saying the same as you are but in a diff... different way”

(to Bernat) (puzzled) “I’m not a clown, you are always putting... putting me down! We didn’t mean to make you waste your time, don’t be so hard on me!”

Table 1: Some negative valorizations given to Albert

Albert is a 16 years old student who usually interprets the problems by himself without having to wait for the teacher to interpret them. His responses during an interview that same day seem to indicate that he was not really willing to change
his group’s approach but felt like he had no choice. The following excerpt from the interview shows to what extent he is aware of issues of power and status that took place in the class:

Interviewer: What do you think about the other groups’ strategies?
Albert: What Clara and Bemat said is okay, but what I said is also okay.

Interviewer: Why do you think they didn’t like your ideas?
Albert: I don’t like looking for the most difficult way to solve a problem and they do.

Interviewer: What about the teacher? He didn’t seem to like your ideas either...
Albert: I don’t care if they [Clara and Bemat] know a lot of math because I also know a lot of things. But they don’t want to know what I know... and neither does the teacher.

(...) Interviewer: Did you like what they told you?
Albert: I’m sure they wouldn’t talk to me like this if I was not repeating this grade for the second time.

Different people in front of similar circumstances may feel in very different ways. Individual differences are then an important issue in the understanding of certain re-construction processes of the mathematical norms. The same circumstances can encourage some students and discourage others. In other words, the processes of re-constructing normative meanings refer to both the characteristics of the context and those of the individual. Students like Albert easily feel upset and do not seem to struggle with such difficulties. During the interview, he reflects on how his role in the classroom would be different if he was not repeating the year. The data obtained reveals that we need a better understanding of the interaction of cultural, social and emotional factors.

When students participate in the mathematics classroom and get involved in certain practices, they do so in ways that other participants may perceive as appropriate or unappropriate. To what extent these perceptions of correctness influence the ongoing patterns of participation? Do some students have less opportunities to
negotiate their meanings and patterns of participation? Do unequal opportunities have to do with status as well as with the distance to the legitimate norms? Although the results of the study do not provide complete answers to these questions, they suggest the kind of research that is needed. Cases like that of Albert illustrate the need to go deeper into the ‘social’. We strongly believe that if we want any educational act to be positive both for the individuals and their communities, it will be necessary to consider the impact of the classroom social context on the learning processes.

ON HEROES AND THE COLLAPSE OF NARRATIVES: A CONTRIBUTION TO THE STUDY OF SYMBOLIC THINKING*

Luis Radford
Université Laurentienne, Ontario, Canada

This paper is dedicated to Raymond Duval on the occasion of his retirement

KEY WORDS: Husserl's philosophy of language, signs and meaning, semiotics.

INTRODUCTION AND THEORETICAL FRAMEWORK

The use of symbols in mathematics raises two different problems. The first one is linked to the mode of designation of the objects of discourse. The second one corresponds to the operations that are carried out on the symbols designating the objects. Although these problems are related, they are underpinned by different semiotic and cognitive demands. As far as algebra is concerned, the designation of objects of discourse requires a substantial reduction of vocabulary (Duval, in press). Indeed, while natural language accounts for a large set of words allowing one to describe objects (e.g. the next figure, the small rectangle), algebraic symbolism requires that these objects be designated using combinations of a few characters (viz. 0, 1, 2, ..., x, y, √ and the like). In previous papers (Radford 2001a, in press-a), I reported the tremendous difficulties that Grade 8 students had in finding a symbolic expression for the rank of the figure that follows the figure of rank ‘n’ in a pattern. Although the students could refer to the objects of discourse using more or less accurate descriptions in natural language, it took a long time before they could, with the teacher’s help, figure out the expression ‘n+1’. Algebraic language does not include adjectives, adverbs and other linguistic terms that prove to be crucial in natural language-based communication.

In addition to this, even if the students reported in my previous research could start designating simple objects with a few characters, they were not able to operate with symbols. They could not recognize that (n+1) +n, (n+n)+1 and 2n+1 referred to a same state of affairs. The problem is not merely the students’ impossibility to operate with the unknown. As a matter of fact, at the same time that they were struggling with the generalization of patterns they were able to easily solve equations like 14+2e = 2+4e (see Radford, in press-b). The problem is related to the students’ mode of designation of objects through algebraic symbolism.

*This article is part of a research program funded by the Social Sciences and Humanities Research Council of Canada.
Indeed, in the designation of objects, the way signs stand for something else is related to the individuals’ intentions as they hermeneutically unfold against the background of the contextual activity. In the designative act, intentions come to occupy the space between the intended object and the signs ‘representing’ it. In doing so, intentions lend life to the marks constituting the corporeal dimension of the signs (e.g. alphanumeric marks) and the marks then become signs that express something, and what they express is their meaning. The possibility to operate with the unknown thereby appears linked to the type of meaning that symbols carry.

Intentions occur in contextual experiences that Husserl called noesis. The conceptual content of such experiences he termed noema. Thus, noema corresponds to the way objects are grasped and become known by the individuals while noesis relates to the modes of cultural categorial experiences accounting for the way objects become attended and disclosed (Husserl, 1931).

Pursuing my investigation on students’ semiotic processes of meaning construction and symbol use, in this paper I want to address the question of how the students’ symbolic expressions are intended to convey meaning when the students proceed with the designation of objects and operate with the designating signs in a typical short story-problem. Within the sketched theoretical framework, the research question will be addressed in terms of the manner (the noesis) in which students use signs to express particular features (the noema) of the objects of discourse. After briefly commenting on the methodology, I will suggest a distinction between story-problems and symbolic narratives. This distinction will allow us to provide an interpretation of some ‘nonsensical’ symbolic expressions elaborated by novice students. I will then discuss the concept of nominalization whose theoretical interest is not simply to account for the introduction of unknowns in a problem. I intend it as a theoretical tool to examine how symbolic expressions become endowed with meaning in this limbo where we have neither fully left the original story (told in natural language), nor have fully entered into the symbolic narrative (told in symbols). The last section presents a short discussion concerning the problem of abstract or formal use of signs in obtaining the equation associated with the story-problem.

METHODOLOGY

The data presented in this paper comes from my longitudinal classroom-based research program involving 4 classes of Grade 9 students. The classroom activities were designed to be carried out co-operatively by the students according to a small-group (2 or 3 students) working format and were usually followed by general discussions conducted by the teacher. Due to space constraints, I shall mention excerpts of the video-taped word-problem solving activity of 3 small groups of only one of the 4 classes. Transcriptions from the video-tapes were analyzed using the qsr N5 software for interpretative, qualitative research (details in Radford 2000).
The mathematical activity was based on the following short story: “Kelly has 2 more candies than Manuel. Josée has 5 more candies than Manuel. All together they have 37 candies.” The same story was used to generate three problems involving transformations in the algebraic expression of the data. In problem 1, the students were asked to designate Manuel’s number of candies by $x$, to elaborate a symbolic expression for Kelly and Josée, and, then, to write and solve an equation corresponding to the short story. Problems 2 and 3 included similar questions. The difference was that, in Problem 2, the students were asked to designate Kelly’s number of candies by $x$ while in Problem 3 the students were asked to designate Josée’s number of candies by $x$.

RESULTS AND DISCUSSION

From Heroes to Objectivities

One of the difficulties in dealing with problems involving comparative phrases like “Kelly has 2 more candies than Manuel” is being able to derive non-comparative, assertive phrases of the type: “A (or B) has C”. If, say, Manuel has 4 candies, the assertive phrase would take the form «Kelly (Subject) has (Verb) 6 (Adjective) candies (Noun)». In the case of algebra, the adjective is not known (one does not know how many candies A has). As a result, the adjective has to be referred to in some way. In using a letter like ‘$x$’ (or another device) a new semiotic space is opened. In this space, the story problem has to be re-told, leading to what has been usually termed (although in a rather simplistic way) the ‘translation’ of the problem into an equation. I prefer here to use the term symbolic narrative since what is translated still tells us a story but in mathematical symbols. Although there are similarities in the story problem and the symbolic narrative, the personages change. This change is best characterized as a noematic shift that brings forward certain parts of the story while putting others in the background. The ‘heroes’—so to speak—of the re-told story are no longer Kelly, Manuel or Josée, but numerical relationships between the amount of candies that constitute the objectivities expressed in the new semiotic space (i.e. the symbolic-algebraic one).

Difficulties in accomplishing this noematic change or shift of attention may become an obstacle in the learning of algebra. Let us show an example in which we can see the students of Group 1 trying to produce symbolic expressions without achieving the aforementioned noematic change.

Signs as marks in narrative acts

In this group, a (wrong) calculation with comparative phrases led the students to conclude as follows:

Stacey: Kelly has 2 more candies than Manuel. Josée has 5 more candies than Manuel. Together, they [Kelly and Josée] have 7 more candies than Manuel.

Instead of transforming comparative phrases into assertive ones, the students changed the comparative phrase into an adverbial form (‘more’), something that allowed them...
to rank the heroes in the story problem according to the number of candies that each one had:

Stacey: Josée has 5 [more]. Josée has more, Kelly is second, Manuel third. Okay, so you put x that represents... no x that represents 7, okay? 12 [as the result of 7+5], 9 [seen as the result of 7+2] but I don’t know how to find... [...] He [Manuel] has 7 less than these two put together (she writes) x−7 [...] This [37] has to equal x−7 (suggesting 37=x−7 or x−7=37).

The transformation of comparative phrases into assertive ones is related to the possibility of explicitly taking into account the unknown amount of candies. However, the clear introduction of a letter for the designation of such an unknown amount of candies does not fix the problem. This is shown in the excerpt below (Line 2). When the teacher came to see the students’ work, he realized that the students had not taken into account x as the amount of Manuel’s candies. Trying to help, he said:

1. Teacher: Manuel is x.
2. Stacey: Yeah. Josée has 5 more candies than Manuel and the 3 together have 37 candies.
3. Teacher: Here, they are asking you to write the algebraic expression for the number of candies represented by Kelly. So, if he is x, she is what? That’s what you have to figure out.
4. Stacey: (while looking at the teacher, she says) x-2.

Although the teacher’s utterance took an elliptical form (Manuel is x), it was an attempt to cause the students to focus on Manuel’s amount of candies. His attempt to shift the noematic content, nonetheless, was countered by a phrase (Line 2) that amounts to a monotone answer “Yeah, yeah, we know that”.

Constructing a symbolic narrative for the story-problem requires a new approach: while the story-problem unfolds according to a left-to-right lineal reading (with eventual flashbacks) the starting point in the symbolic narrative does not have a permanent location. In the symbolic narrative, the order of discourse (to borrow Foucault’s term) is different and the thematic character is about other things.

What, then, is the role of symbols in the students’ previous symbolic expressions? We shall now see that the students’ signs constitute short scripts recounting salient parts of the original story. Let us take a closer look at Stacey’s algebraic expressions (“x-7”, “x-2”). Each one of them is made up of three signs: the signs in the second one are: ‘x’, ‘-’ and ‘2’. Their meaning, of course, is not the one required in the practice of algebra. We cannot say, however, that the expression is meaningless. The expression “x-2”, which is polyphonic in tone in that it merges the teacher’s voice (Line 1) and Stacey’s understanding of it (Line 4), might be read as telling us that Manuel has a certain amount of candies (‘x’) and that he has two (‘2’) less (‘-’) candies than Kelly. Thus the sign ‘-’ is not performing a subtraction on the unknown x but is an orienting mark of a short script about the story-problem. In a similar vein, the sign ‘7’ in the expression “x-7” does not translate merely as “x minus 7”. As indicated by Stacey’s utterances, the number 7 comes to form part of the symbolic expression with an imported meaning so that each symbol in the equation tells us a part of the original story.
Later, the teacher came to inspect the group’s work. He said:

Teacher: x is Manuel, right?
Caroline: Yes.
Stacey: (interrupting) So, x minus…

Teacher: (continuing his utterance) Kelly has 2 more candies than Manuel. Let’s suppose that Manuel has 20 candies, how many candies would Kelly have?
Stacey: 22?
Teacher: 22. (He looks at Caroline). If Manuel had 30 candies, how many …
Stacey: (interrupting) 32.
Teacher: (He looks at Jessica). Therefore, um, what did they do to find Kelly?
Stacey: You put the 2.
Teacher: (correcting) You add 2.

Stacey: (having understood how to algebraically express the relationships, says, referring to Josée) There you add 5. […] So, it’s x+5. (The students write ‘x+2’ and ‘x+5’.)

Teacher: Then, this (indicating the question about the equation for the problem on the page) would be equal to what? This is an equation so it has to equal something. (The teacher is called by another group and feeling that the students are on the right track he leaves.)

Caroline: (adding the 3 algebraic expressions) So, if I have 3x+7, (she looks at Stacey) 3x+7? […] That means 3, no, 3x+7. This equals 37?

Stacey: (recognizing the number 7, says) I don’t believe that! 3x+7 is equal to 37! … oh!

We see how using the elliptic formula ‘x is Manuel’ and through a calculation on numbers (which functions here as the ground of noesis, i.e. the meaning-conferring act), the teacher shifts the students’ attention to the relationships between amounts of candies. What is important, though, is not that the students could write the sought symbolic expressions. The important point is the emergence of a kind of awareness that, in the symbolic expressions, the heroes, without being thrown away, are put in the background and predications in the symbolic narrative are done about other things, about objectivities. Perhaps elliptical formulas based on the verb ‘to be’ of the kind “x is Manuel” are not the best way to forge the distance between the story-problem and the symbolic narrative. And, perhaps, the use of the verb ‘to have’ would have been more suitable in terms of the goal of the activity (of course, we became aware of this only after the activity was analyzed). Nevertheless, in the classroom context, the choice of the elliptical formulas allowed the students to start moving into the realm of algebraic symbols and to begin learning the incredible amount of meaning that these phrases encompass despite the dramatically limited number of signs they use.

Nominalization

Groups 2 and 3 did not face the same difficulties as Group 1. For instance in Group 2, we find Anik saying:

Anik : Okay. … Manuel is going to be the variable x. (she points to the paper) like… like if they want… find the equation there… the equation for Kelly is… because … uh, she has 2
more than Manuel. Manuel has... has the amount x. So x+2 because we don't know, x is how many Manuel has. Right? So, she [Kelly] has ... (she points to the paper) has like whatever Manuel has +2.

We see how the comparative phrase was transformed into an assertive one ("she has like whatever Manuel has +2"). By introducing the letter x (in "Manuel is going to be the variable x" and "Manuel has ... has the amount x"), Anik (first using the verb 'to be' and then the verb 'to have') opens the door that leads to the symbolic narrative. We can see, despite the final reformulation at the end of her utterance, how the heroes start fading away. The insertion of x as a designation of Manuel's number of candies, allows room for a nominalization, that is, a process in which something becomes enabled to function as the subject or the object of a verb. In saying "whatever Manuel has", the expression can now become the noun in the assertive phrase "Kelly has (noun) +2". It is indeed interesting to notice that, without help, Group 1 could not offer nominalizations. Groups 2 and 3, in contrast, did offer clear instances of nominalizations. Here is an example, taken from Group 3, concerning Problem 3 (where x designated Kelly's number of candies).

1. Michelle: Kelly... (inaudible) ... There the x is all moved around. They're trying to trick us. So if Kelly has 2 more candies than Manuel, then Manuel has 2 candies less than Kelly, right? [...] But now that Kelly is x, minus 2 ...

2. Jessy: (interrupting) Yeah, yeah.

3. Michelle: I'm thinking... Josée has 5 more candies than Manuel. So Manuel has x-2. Then Josée has 5 more than that, right? So x-2 in brackets ... +5.

Line 1 indicates a change of meaning. Although the sentences "Kelly has 2 more candies than Manuel" and "Manuel has 2 candies less than Kelly" refer to the same state of affairs, the meaning is not the same (as in Frege's famous example also discussed by Husserl: the victor at Jena versus the vanquished at Waterloo). The meaning changes because of differences in the way of attending the object -the noematic content is not the same. In the last part of Line 1 and the first part of Line 3, Michelle establishes Manuel's amount of candies. The insertion of the sign 'x' allows for a first nominalization which makes possible the phrase 'Manuel has x-2' (an important hybrid phrase where meaning is lent from the story problem to the symbolic narrative). In the second part of Line 3, the attention is focused on 'x-2' only. Instead of seeing this expression as expressing any of its various possible meanings (e.g. 'the amount of Kelly's candies minus two' or 'Manuel's amount of candies'), Michelle proceeds to a subtle and fundamental suspension of these by using the deictic 'that'. In doing so, a second nominalization is produced: the referent is formally nominalized and can thereby become the noun of the verb 'to have' in "Josée has 5 more than that". As mentioned in the Introduction, the theoretical interest of nominalizations is to inform us how symbolic expressions become endowed with meaning in this limbo where we have neither fully left the original story, nor have fully entered into the symbolic narrative. In particular, nominalizations make it possible to see how high-order meanings are made available
for further predication. Let us now discuss the didactic problem of the operations with signs necessary to obtain the equation.

The collapse of narratives

This is an excerpt from Group 2 during their discussion about Problem 1:

1. Anik: Yeah ... Well guys ... *(She takes the papers)* what we’re trying to do is to put *[the symbolic expressions]* with the people, okay? Kelly has 2 more than Manuel. Manuel has x. Plus 2 is what Kelly has. *(She)* has whatever he has +2. Okay. That’s going to be x+2, that’s in brackets, plus x+5. That’ll be what Josée has, plus x, that’ll be what Manuel has *[she intends the expression ‘(x+2)+(x+5)+x’]*.

2. Luc: Equal to what? 30? 37? *(Chantal writes 2x+5x+x.)*

3. Anik: *(looking at Chantal’s symbolic expression)* 2x, I don’t think so.

4. Chantal: Why not?

5. Anik: *(She points to the paper)* because there you are about to do 2 times x.

7. Anik: Here we’re doing 2+x. *(Anik writes (x+2)+(x+5)+x.)*

8. Luc: *(looking at Anik’s expression)* You group them together, you group all the x’s *(Chantal erases what she had written.)*

9. Anik: *(Talking to Luc)* No, no!

10. Luc: Yeah! You group all the x’s.

11. Anik: No! Wait guys! Wait! *(She points to the paper.)*

12. Luc: Oh my God!

13. Anik: I just want to explain it to you. Guys, here! He has ... she has x+2, right?

In line 2, Chantal uses a syntax based on the criterion of juxtaposition of signs. The sentence is structured in the manner of a narrative where signs become encoded as key terms – much as pictographic signs used by Mesopotamian scribes did in the proto-literate periods ca. 3300-2900 BC where, e.g., a set of pictograms representing “sheep” “two” and “temple” may mean “two sheep delivered to (or received from) the temple” (see Radford 2001b, 28-33). The expression 2x does not mean twice x or two times x. For Chantal, 2x does convey the idea that Kelly has 2 more candies than Manuel, and this is why she is surprised (line 6) that Anik could have interpreted it in a different way. But the previous dialogue shows another feature of the students’ struggle with algebraic symbolic language. In line 8, Luc proceeds to collect similar terms. This action is radically opposed by Anik. Why? The reason is that the collection of similar terms means a rupture with their original meaning. All the efforts that were made at the level of the designation of objects to build the symbolic narrative have to be put into brackets. The whole symbolic narrative now has to collapse. There is no corresponding segment in the story-problem that could be correlated with the result of the collection of similar terms, i.e. with 3x+7. Anik’s desperate effort not to lose track of the narrative meaning is clear in line 13.
CONCLUDING REMARKS
Focusing on a story problem, in this article, I dealt with two main points: (1) the designation of the objects of discourse in the construction of symbolic narratives and the meaning of symbolic sentences, and (2) some of the problems arising in the operations that are carried out with signs that recount the symbolic narrative. As for the first point, the analysis of some key lines in the students’ dialogue suggests that the students’ success in constructing the symbolic narrative depends on their ability to move across different layers of noematic content. We have indeed seen the interplay between the various meanings and the dynamics required to enrich, shift, and abandon these meanings as well as the role played therein by nominalizations. As for the second point, the classroom observations intimate how difficult it may be to tackle what I termed the collapse of narratives. The constitution of meaning after such a collapse deserves more research. While Russell (1976, p. 218) considered the formal manipulations of signs as empty descriptions of reality, Husserl stressed the fact that such a manipulation of signs requires a shift of intention, a noematic change: the focus becomes the signs themselves, but not as signs per se. And he insisted that the abstract manipulation of signs is supported by new meanings arising from rules resembling the rules of a game (Husserl 1961, p. 79), which led him to talk about signs having a game signification. I think that the richness of Husserl’s metaphor resides in its stressing the cultural, conventional role of rules. Since convention and arbitrariness are two different things, the weakness of the metaphor is that it does not help us to see the rationale behind its conventional nature.

Notes
1. Story-problems of this kind have been investigated in depth by Bednarz and Janvier (1994) in terms of the effect that different kinds of comparative relationships (e.g. additive vs multiplicative comparisons) have on the students’ strategies.
2. Husserl (1961, 44) coined the term objectivity (Gegenständlichkeit, objectité, objectidad) to refer not necessarily to an individual thing but also to complex things, categories and states of affairs as they become the referent in sentences.

References
Definitions and images of the definite integral concept were examined in 41 English high school students. A questionnaire was designed to explore the cognitive schemes for the definite integral concept that are evoked by the students. One question aimed to check whether the students knew to define the concept of definite integral. Five others were designed to categorize how students worked with the concept of definite integral and how this related to the definition. The results show that only 7 students out of 41 of our sample knew the definition.

All mathematical concepts except the primitive ones have definitions. Many of them are introduced to high school or college students. However, the students do not necessarily use the definition to decide whether a given idea is or is not an example of the concept. In most cases, they decide on the basis of their concept image, that is, all the mental pictures, properties and processes associated with the concept in their mind. (Tall & Vinner, 1981; Rasslan & Vinner, 1997).

The concept of the definite integral is a central in the calculus. In many countries, including the UK, it is taught in the last two years of school to students aged approximately 16–18. The students in this study followed a curriculum based on the School Mathematics Project A-level. In the current version of the textbook (SMP, 1997), integration is introduced through activities to estimate the area between a graph and the x-axis using pictures and numerical methods. After this experience the notion of integral is defined as follows (in the form of a description rather than a formal Riemann sum):

The symbol \( \int_a^b f(x) \, dx \) denotes the \textit{precise} value of the area under the graph of \( f \) between \( x = a \) and \( x = b \).

It is known as the integral of \( y \) with respect to \( x \) over the interval from \( a \) to \( b \).

The integral can be found \textit{approximately} by various numerical methods.

**Figure 1**: The definition of the integral concept (SMP, 1997, p.143).

This is followed by ten pages of experience with numerical approximations including functions with positive and negative values before algebraic integration is introduced in the next chapter. Here the student is encouraged to build up the relationship between polynomials and their (definite) integrals, before the fundamental theorem is introduced using local straightness as a visual form of derivative in the following terms:

For any differentiable function \( f \), \( \int_a^b f'(x) \, dx = f(b) - f(a) \).

**Figure 2**: The fundamental theorem of calculus (SMP, 1997, p. 169).

---

PME26 2002
Several studies have highlighted difficulties with the integral concept. Tall (1993) remarked on conflicts and contradictions that arise as students study the calculus. For instance, in the ‘function of a function rule’ \( \frac{dy}{dt} = \frac{dy}{dx} \frac{dx}{dt} \), the student is told not to cancel the \( dx \) — it has no separate meaning. Later in \( \int f(x) \, dx \), its meaning changes to ‘with respect to \( x \)’. Orton (1980) observed student difficulty with the integral \( \int_{a}^{b} f(x) \, dx \) when \( f(x) \) is negative or \( b \) is less than \( a \). Mundy (1984) reported student problems with integrals slightly beyond their experience, such as \( \int_{a}^{b} |x + 2| \, dx \).

Students also experience difficulties with communication. Rather than responding conceptually, they may exhibit ‘pseudo-conceptual behaviour’ by using minimal effort to respond in a way they hope will satisfy the teacher (Vinner, 1997; Rasslan & Vinner, 1997). Examples of such responses will arise in this study.

The empirical data collection is based on a questionnaire designed to seek the students’ definition of the definite integral and to categorise their responses to selected problems for their use of the definition or image. The research questions are as follows:

- What definitions of the definite integral are given by high school students?
- What images of the definite integral do students use in various problems?
- What misconceptions do they exhibit relating to the definite integral?

**METHOD**

**Sample**

Our sample comprised 41 students in four classes of final year (‘upper sixth form’) English high school students. All these students had access to graphical calculators and had encountered all the concepts on the test. The average A-level score of the school is 20.2, which is above the national average of 18.5.

**The Questionnaire**

The Questionnaire in figure 3 was administered to all subjects in the sample. Questions 1 to 5 were designed to examine aspects of the respondents’ concept images revealed through doing integration, whereas Question 6 was designed to examine their definitions. Question 1 was designed to examine how students apply the definite integral to integrals when the integrand becomes infinite. Question 3 examines whether the students understand an integral when the function changes its sign.

Questions 2, 4, and 5 test the student using functions that are not simple formulae. They are more easily answered by drawing the graph and calculating the area directly from the picture. Are the students able to see the integral as ‘the precise value of the area under the graph’ as given in the definition in the text, or do they feel a need to carry out symbolic integration attempting to extend the techniques at their disposal?
1. Find, if you can: (a) \( \int_0^1 \frac{1}{(x - 4)^{2/3}} \, dx \)  \( \int_1^2 \frac{1}{x^4} \, dx \).

If you can, please explain the sign of the answer.

2. The function \( f(x) = x - [x] \) is given. Find the area directly below the graph and above the x-axis between \( x = 0 \) and \( x = 3 \).

3. Find the area bounded between the function \( y = \sin x \) and x-axis over \([0, 2\pi]\).

4. The following function is given: \( f(x) = \begin{cases} 2x, & x \leq \frac{\pi}{2} \\ 2x - 2, & x \geq \frac{\pi}{2} \end{cases} \). Find: \( \int_0^\pi f(x) \, dx \).

5. The following function is given: \( f(x) = 1 - |x - 1| \). Find \( \int_0^1 f(x) \, dx \).

6. In your opinion what is \( \int_a^b f(x) \, dx \) (the definite integral of the function \( f \) in the interval \([a, b]\)).

Figure 3. The Questionnaire

Procedure

The questionnaire was administered to the students in their classes. They were not asked to fill in their names, only their background information. It took them 40-50 minutes at most to complete the questionnaire. All the questions in the questionnaire were analysed in detail by the two authors in order to determine the answer categories.

RESULTS

The Definition Categories

We categorized the student's answers according to methods described elsewhere (Vinner & Dreyfus, 1989; Rasslan & Vinner, 1997). We illustrate each category with a number of sample responses.

**Question 6: The definition of \( \int_a^b f(x) \, dx \)**

**Category I:** The area between the graph and the x-axis between \( x = a \) and \( x = b \). (4/41).
Example: The area between the x-axis and the graph \( f(x) \) between the limits \( x = a \) and \( x = b \).

**Category II:** A procedure of calculation; \( \int_a^b f(x) \, dx = F(b) - F(a) \). (3/41).
Example: \( \left( \int f(x) \, dx \right) \big|_a^b \).

**Category III:** Students substitute specific formula in the definite integral. (3/41).
Example: \( \int x^2 / 2 + c \, dx = (b^2 / 2 + c) - (a^2 / 2 + c) \).

**Category IV:** Answers based on pseudo-conceptual mode of thinking or wrong answers. (5/41).
Examples: 1. \( f(x) \). 2. \( f(x) \) increases.

**Category V:** No answer or missing answers. (26/41).
In the above categorization only seven students out of 41 (categories I, II) gave a definition of the definite integral concept. The three category III students show that they can use the concept of integration in specific cases. The majority are in category IV and V, with five erroneous responses and twenty six not responding. The students were not directed to memorise definitions and the majority do not appear to be able (or willing) to explain the definition of the definite integral.

The Concept Images. Questions 1-5

Various aspects of the definite integral concept, as conceived by the students, were expressed in their answers to questions 1 to 5. Some of these aspects are given below:

**Question 1.a**

**Category "Zero":** Students with correct theory. (0/41).

**Category I:** The definite integral is the area between the function and x-axis in \([a, b]\). (7/41)

- **Category Ia:** As above with the correct calculation of the definite integral. (3/41)
  
  Example: 
  \[
  \int_{0}^{6} \frac{1}{(x - 4)^{2/3}} \, dx = \left[3(x - 4)^{1/3}\right]_{0}^{6} = 3.78 - (-4.76) = 8.54.\]
  
  The graph is all above the x-axis from 0 to 6, and so the sign will be positive.

- **Category Ib:** As above, but only giving the final answer without showing any working. (3/41)
  
  Example: 
  \[
  \int_{0}^{6} \frac{1}{(x - 4)^{2/3}} \, dx = 8.542.\]

  The area indicated by the integral is above the x-axis.

- **Category Ic:** As above, with wrong calculation of the definite integral. (1/41)
  
  Example: 
  \[
  \int_{0}^{6} \frac{1}{(x - 4)^{2/3}} \, dx = \left[3(x - 4)^{1/3}\right]_{0}^{6} = 3.78 - (-4.76) = 8.54.\]

  If the sign is positive, the area calculated from the x-axis and above (i.e. for positive values of \(y\)).

**Category II:** Answers without explanation: the definite integral is a procedure of calculation. (27/41)

- **Category IIa:** As above, but with right calculation of the definite integral. (8/41)
  
  Example: 
  \[
  \int_{0}^{6} \frac{1}{(x - 4)^{2/3}} \, dx = \left[3(x - 4)^{1/3}\right]_{0}^{6} = 3.78 - (-4.76) = 8.54.\]

- **Category IIb:** As above, but with wrong calculation. Incorrect use of algorithms. (19/41)
  
  Example: 
  \[
  \int_{0}^{6} \frac{1}{(x - 4)^{2/3}} \, dx = \left[3(x - 4)^{1/3}\right]_{0}^{6} = (\ln(x - 4)^{2/3}) - (\ln(0 - 4)^{2/3}) = 0.46.\]

**Category III:** Wrong explanations, which based on pseudo-conceptual mode of thinking. (2/41)

Example: 
\[
\int_{0}^{6} \frac{1}{(x - 4)^{2/3}} \, dx = 4000.\]

The graph has their area above x-axis, so the sign is true.

**Category IV:** No answer. (5/41)

From the above categorisation only 3 students out of 41 (category Ia) give evidence that they understand the definite integral concept. For eleven students of our sample (categories Ib, IIa) we cannot claim it but we cannot claim the opposite. The remaining 27 students (categories Ic, IIb, III, IV), do not seem to be able to handle the concept of definite integral with an infinite discontinuity.
Question 1. b

The categories of this question were intended to be the same as in question 1. a. This was true in the majority of the cases (see Table 1). However, the three students adjudged correct in Question 1.a gave a faulty answer to question 1.b which diverges, indicating that they may have simply ignored the question of convergence in both cases.

<table>

<td>5</td>
<td>0</td>
<td>26</td>
<td>4</td>
<td>6</td>
</tr>
</tbody>
</table>

Table 1: Distribution (Number of respondents) of the Categories to Question 1.b (N=41)

When we analyzed Question 1.a we added category "zero" which refers to the correct theory. It turns out that no one of our sample knew the correct theory according to the improper integrals. This fact is true also for Question 1.b.

Question 2

Category I: Numerical answer. (14/41)

Category Ia: As above with indication of knowledge how to calculate the area correctly (the student draw a graph of the function and calculate the area). (9/41)

Example: 0.5 + 0.5 + 0.5 = 1.5 (with right graph).

Category Ib: Right answer without explanation. (5/41)

Example: 1.5.

Category II: Wrong answers based on overgeneralization of symbolic method. (13/41)

Example: \[ \int (x - [x]) \, dx = \left[ \frac{1}{2} x^2 - \frac{1}{2} (x) \right]_0^3 = 1.5. \]

Category III: Incorrect use of algorithms. (4/41)

Examples: 1. Area = \([1 - [x]]_0^3 = 2 \times 0.5. \]

In the first example the students uses differentiation and not integration. On the other hand the student does not know what to do with [x], so leaves it as it is.

Category IV: No answer. (10/41)

From the above it turns out that for only 9 students out of 41 (category Ia) give evidence that they know how to find the area between the graph of the function and the x-axis. As for other 5 students (category II), we cannot claim that, but we cannot claim the opposite. The remaining 27 students of our sample (categories Ib, III, IV), either make errors or do not respond.

Question 3

Category I: The area is the definite integral. (5/41)

Example: area = \[ \int \sin x \, dx + \int^\pi_0 \sin x \, dx = [-\cos x]_0^\pi + [-\cos x]_0^\pi = 2 + 2 = 4. \]

Category III: Positive/negative area means positive/negative \( y \) respectively. The area is 0 because the positive area and the negative area cancel each other. (11/41)

Examples: 1. 0. (See figure). 2. Area = 0 units\(^2\).

Category IV: The area is the definite integral \( \int_a^b f(x) \, dx \). The student does not refer to the sign of the function in \([a, b]\). (15/41)

Example: \( \int_0^\pi \sin x \, dx = [-\cos 2\pi] - [\cos 0] = 2 \).

Category V: Pseudo-conceptual or seemingly nonsensical answers. (3/41)

Example: \( \int_0^{180} \sin x \, dx = \left[ \frac{\cos x^2}{2} \right]_0^{180} = 114.54 \).

Category VI: No answer. (6/41)

From the above categorization, 5 students out of 41 (category I) may be claimed to understand the definite integral concept. For one student we cannot claim that, but we cannot claim the opposite. The remaining 35 students of our sample (categories III, IV, V, VI), either make errors or do not respond.

In our analysis of the results in Question 6, we hypothesised that the students not necessarily know how to calculate the area when the function change its sign. From the above categorization, it follows also that 15 students out of 41 (category IV) do not explicitly evoke a change in sign when it occurs in a given interval \([a, b]\).

**Question 4**

Category I: Numerical answer. (24/41)

Category Ia: As above with right integration and calculation. (17/41)

Example: \( \int_{1/2}^1 2x \, dx + \int_{1/2}^1 (2 - 2x) \, dx = [x^2]_0^{1/2} + [2x - x^2]_1^{1/2} = 0.25 + 0.25 = 0.5 \).

Category Ib: As above with wrong integration / calculation. (7/41)

Example: \( \int_0^{1/2} 2x \, dx = [x^2]_0^{1/2} = 0.25 \).

Category II: Visual answers: the student draws a correct graph of the function and calculates the triangle area. (4/41)

Example: 0.5\( \cdot \)1/2 + 0.5\( \cdot \)1/2 =0.5.

Category III: Answers without explanations. (2/41).

Examples: 1. 0.25 + 0.25 = 0.5. 2. 0.5.

Category IV: No answers. (11/41)

For 21 students out of 41 (categories Ia, II) we can claim that they are able to apply the definite integral to a split domain function. For 2 other students (category III) we cannot claim that, but we cannot claim the opposite. The remaining 18 students (categories Ib, IV), either make errors or do not reply.
Question 5

The categories of this question were supposed to be the same as in question 4. This was true in the majority of the cases (see Table 2), however, the results show that for only 2 students out of 41 (categories Ia, II) we claim that they know the application for the definite integral for such a special function. For 6 students of our sample (category III) we cannot claim that but we cannot claim the opposite. About the rest (categories Ib, and those who did not answer the question) 33 students of our sample, we can claim that they do not know to apply the definite integral for the above function.

Table 2: Distribution (Number of respondents) of the Categories to Questions 4 and 5 (N=41).

When we analyzed the tasks in Questions 2, 4 and 5 we suggested that the students might be expected to give answers involving visualization (categories I, IV, IV respectively). Table 3 provides this information about our sample. It turns out that the visualization thinking is very weak in our sample.

Table 4: Distribution (of respondents) of students who did not answer Question 6 and answered correctly Questions 1-5. (N = 26)

Table 4 shows the responses of those who did not answer Question 6 but gave correct answers to Questions 1-5. The conclusion is that these students know what to do but they do not know to explain at the general level. However, our conclusion is not true when they face improper integrals or definite integral of modulus function (Questions 1 and 5).

Discussion

One of the goals of this study was to expose some common images of the definite integral of a function held by A-level high school students. This has a direct implication for teaching. If one wants to teach the definite integral of a function to a group similar to our sample, it is important to know the starting point of the students (Rasslan & Vinner, 1997). Taking into account the difficulties mentioned in this
study and also in Tall (1993) at least some doubts should be raised whether the given approach to the definite integral is the most effective way for teaching such a concept. If improper integrals, definite integrals of more general functions such as the modulus function or the integer-value function, are needed, we suggest that they should be introduced as cases extended the students’ previous experience. The pool of examples introduced to the students should include a variety of examples and students should be encouraged to express their ideas in ways which help them to build a more insightful concept. A similar conclusion was mentioned by Rasslan and Vinner (1997) according to other concepts, such as even/odd function.

The strategy applied by the School Mathematics Project is to introduce conceptual ideas through class discussion and then to experience them in use. The using of the ideas is a major part of the activity in a manner reminiscent of the ‘tool-object dialectic’ (Douady, 1986). The concept definition is essentially an incidental part of the process which is far more concerned in practice with developing experience and images of the concepts themselves. Students learn implicitly what they do. Ferrini-Mundy & Guardard (1992) have already illustrated that students who essentially practice routines in High School Calculus learn procedural techniques which may even be prejudicial to later developments at College. Here we have investigated students whose examination results are above average who are following a curriculum intended to be more experiential and conceptual. The majority do not write meaningfully about the definition of definite integral, and have difficulty interpreting problems calculating areas and definite integrals in wider contexts.

References

More and more research into student understanding is being undertaken, in which analysis of responses often involves the use of taxonomies to describe hierarchies. Recent use of the SOLO Taxonomy has identified that there can be cycles of levels within each mode in the hierarchy. Most recent research has involved qualitative description of these levels and identification of cycles based on subjective decisions. This report demonstrates how Threshold Values produced by Rasch Analysis can be used, as a quantitative measure, to justify the cycles of SOLO levels. The data used is from a study into statistical understanding, undertaken with Australian school students aged 12 to 18, in which the SOLO taxonomy was used as the framework for developing a hierarchy of student responses to open-ended questions.

INTRODUCTION

As more qualitative research is undertaken in the area of student understanding, hierarchies, expressed in levels, are increasingly being used as descriptive and assessment tools. Structure of the Observed Learning Outcome (SOLO), which has proved useful in a variety of disciplines, is one such taxonomy. A need was identified for some means of quantitatively justifying the cycles of levels that were observed, and discussed qualitatively, in more recent applications of the taxonomy. After outlining background information about the SOLO Taxonomy, the context of the study and the Rasch analysis used, ‘threshold values’ are defined. Discussion follows on how these threshold values can be used as a quantitative justification of cycles of levels. Some implications for future research are presented after conclusions have been drawn.

SOLO

SOLO originators, Biggs and Collis (1991, pp. 62-65), in a more recent description of the taxonomy, identify 5 basic levels in a learning cycle; prestructural, unistructural, multistructural, relational and extended abstract. Also identified were modes of representation within which students operate, ranging from sensorimotor, through ikonic, concrete-symbolic and formal to post formal. The learning cycle is repeated for each successive mode, the unistructural, multistructural and relational levels being within the mode, and prestructural and extended abstract levels belonging to the adjoining modes. However, more recently, researchers in a variety of disciplines are identifying more than one cycle
of levels within each mode. For example, Lawrie, Pegg and Gutierrez (2000) in geometry and Reading (2001) in data collection.

Most studies rely on qualitative justification of the levels in student responses. The levels are described, and cycles of levels identified, based purely on the researcher's subjective interpretations of student responses. This report demonstrates the use of Rasch analysis as a quantitative approach to justifying the cycles of levels identified.

CONTEXT

Discussion here is based on data from a study where 180 Australian students, aged 12 to 18, were given open-ended questions on statistical understanding covering four focus areas; Question 1 in the area of data collection; Question 2 in data representation; Question 3 in data reduction; and Question 4 in interpretation and inference. Each question had two parts. Question 1 Part I presented students with a general data collection question while Part II asked a more specific question, where part of the collection procedure had already been specified. Part II, with some prompting, was included to delve more deeply into the understanding of data collection. For Questions 2, 3 and 4, Part I and Part II asked similar questions except that Part I presented the data in a raw form while Part II presented graphed data. Two parts were included in these three questions to determine whether data presentation in raw form or as a graph influenced the level of understanding.

Student responses, including explanations of 'why' the particular response was given, were analysed to establish a hierarchy of eight levels, from Level 1 to Level 8. So few responses were recorded at Level 8 that this level does not appear in the following discussion. The SOLO Taxonomy was then used as a framework for describing these levels and dividing them into three separate cycles. Level 1 and Level 2 fell within the ikonic mode. The first cycle in the concrete-symbolic mode consisted of Levels 3, 4 and 5 and the second cycle, Levels 6, 7 and 8. For more detail about this study see Reading (1996), with specific discussions of each of the four questions in Reading (2001, 1999, 1998) and Reading and Pegg (1996), respectively. Rasch analysis, used to produce a measure of statistical understanding for each student, also produced threshold values for the various levels within each question.

RASCH ANALYSIS

The Rasch model was used to produce an estimate of statistical understanding on a logit scale, for each student, which incorporates the information from the questions covering all four focus areas (Reading, 1996, pp. 93-94). Masters' (1982, pp.157-
partial credit Rasch model for polychotomous data (where responses can be coded according to an increasing, or decreasing, degree of 'correctness') considers the individual difficulty of each successive step from one level to the next in the question, using a formula for calculating the probability of a student responding at a particular level of a particular question. The advantage of the partial credit model is that the parameters are separable, making it possible to produce sufficient statistics for person ability (understanding) and for step difficulty within each question. Masters (1982, pp. 163-166) used a maximum likelihood procedure to estimate the parameters, overall ability for each student and difficulty for each question, in the model. In the study, appropriate measures indicated that the questions were all consistent in testing the same underlying construct, 'statistical understanding', and that the data fitted the Rasch model well (Reading, 1996, p170). Although the study reported on measures of overall understanding, question difficulty and threshold values (Reading, 1996, pp. 170-190), this report only discusses the thresholds values.

THRESHOLD VALUES

Threshold values, produced by the Rasch analysis for the various levels in each question, were used to justify the arrangement of levels within the cycles described in the study (Reading, 1996, pp. 178-181). These values are estimates of the score a student would need to attain a 50% chance of having his or her response coded at that level. For example, the threshold value of 0.15, for Level 5 of Question 2 Part I, means that a response from a student with an estimate of statistical understanding of 0.15 has a 50% chance of being coded at Level 5 for that particular question.

The results are presented graphically in Figures 1 to 4. No threshold value is shown for Level 1 because there is no information about performance at a level below this to allow estimation of the better understanding needed to be able to be coded as Level 1. Each graph shows the threshold values for Part I and Part II of a question. In each graph, the trends as indicated by the shape of the graph, for Part I and Part II are similar. This reinforces the authenticity of the trend. Following is a discussion using these threshold values to justify the cycles of levels.

CYCLE JUSTIFICATION

The study provided insufficient responses at Levels 1 and 2 to make detailed judgements about SOLO levels, or cycles of levels, within the ikonic mode and so discussion is centred on the two cycles of levels within the concrete-symbolic mode. These corresponded to Levels 3, 4 and 5 within the first cycle, and Levels 6, 7 and 8 within the second. As previously mentioned, there were too few
responses at Level 8 to justify including the threshold values in the figures presented.

It was anticipated that once a student is able to function within a cycle there is not as great a change in the level of understanding needed to be able to progress from one level to the next within that cycle. This would be indicated by similar threshold values for the levels within a cycle, for example in the move from Level 3 to Level 4 and the move from Level 4 to Level 5. Then, with the move into a new cycle, presumably a complex transition for many students, the threshold values should be greater. Thus greater jumps in threshold values, indicated by steeper segments of the graph, would demonstrate movement from one cycle to the next. For example, with the Level 3,4,5 cycle, steeper segments would be expected from Level 2 to Level 3, moving into the cycle, and then from Level 5 to Level 6 moving out of that cycle into the next.

RESULTS

The threshold values for three of the questions (figures 2, 3 and 4) tend to confirm that cycles, indicated by flatter sections of the graph, exist but those for Question 1 (figure 1) suggest that all movements from one level to the next were reasonably complex for students, with no clear indication of cycles. Next is a consideration of the threshold levels in more detail.

![Figure 1 - Thresholds to Attain Levels - Question 1 - Data Collection](image)

As indicated earlier, the similarity of shape of the graphs for Part I and Part II in each question confirms the trends indicated, but what of the gap between the graphs for Part I and Part II? The threshold values for Part II of Question 1 are...
consistently lower, except for Level 2, than for Part I. This is not unexpected as some prompting as to the data collection details was given in the second part of the question.

Figure 2 - Thresholds to Attain Levels - Question 2 - Data Tabulation and Representation

For the other three questions (figures 2, 3, and 4) the threshold values for Part I and Part II are sufficiently similar to suggest that there is little difference between the results whether the data is presented in a raw form or in a graph. For Questions 2 and 3, the Part II thresholds are slightly higher suggesting that, for the tasks of data tabulation and representation and reduction, to respond at a certain level may require a little more understanding when the data are presented as a graph rather...
than in raw form. However, the differences between the values for Part I and Part II are only slight. For Question 4, Part I and Part II values are almost identical, suggesting that for interpretation and inference the form of presentation of the data does not appear to affect the level of understanding required to present responses at specific levels. How then does the shape of these graphs aid in the justification of cycles of SOLO levels?

For Question 1 (figure 1) there is a steady increase in the threshold value required to attain each of the levels. The threshold values are not necessarily supportive of the cycles identified by the study, although the Part II results do show some flattening out of the change in threshold values moving between Levels 3, 4 and 5. It is possible that these students find the progression through levels, even within cycles, difficult in the data collection focus area because in the Australian Secondary schooling curriculum there are fewer opportunities to engage in meaningful activities for data collection than the other three focus areas.

![Figure 4 - Thresholds to Attain Levels - Question 4 – Interpretation and Inference](image)

For the other three questions (figures 2, 3 and 4) there is a levelling off of threshold values within one cycle, especially apparent for the first cycle in the concrete-symbolic mode. For each question the threshold values moving from Level 3 through Level 4 to Level 5 only show a slight increase. This suggests that once a student can respond at Level 3 it is likely that they will experience little increase in complexity when responding at Level 4 or Level 5. Also, for each question, the step into the cycle from Level 2 to Level 3 and the step out of the cycle, from Level 5 to Level 6, are steep suggesting movement between two different cycles. These results help to confirm that the three Levels, 3, 4 and 5, are
in fact one cycle within a mode, in this case the first cycle identified in the concrete-symbolic mode.

In these three questions, the justification of the second cycle is not as clear. The threshold for Level 6, the entry level for the second cycle, is steep enough to indicate that the first cycle is complete and a new cycle is being entered. However, the increase in threshold value from Level 6 to Level 7, is still quite high in Question 2 and significantly higher in Questions 3 and 4. Although this suggests that the Level 6 and Level 7 are not within one cycle, it should be remembered that the second cycle actually had three Levels 6, 7 and 8 and that with limited responses at Level 7 and virtually none at Level 8, there is probably not sufficient data to confirm or deny the existence of the second cycle at this stage.

**CONCLUSION**

The use of threshold values has proved a useful tool in quantitatively justifying the previously qualitative arrangement of SOLO levels into cycles. Small differences in threshold values between levels indicate a movement between levels within a cycle while a large difference indicates a move from one cycle into the next. The similarity of threshold values for Levels 3, 4 and 5 suggests strongly the existence of a cycle of levels, at least for three of the focus areas. The jumps in threshold values from Levels 2 to 3, into the cycle, and out of the cycle, from Level 5 to 6, add to the justification of identification of a cycle of levels here. This is the first cycle within the concrete-symbolic mode as identified earlier.

The second cycle, coded qualitatively in the study, is not so clearly identifiable from the threshold values available. The increased thresholds for Level 6 demonstrate the entry point for the second cycle but the move into the next level in the cycle, Level 7, does not show the slight increase in threshold value, as expected. In fact, the threshold values show that in all questions, except Question 2, the step into Level 7 required even more understanding than the step into Level 6. However, as there were fewer responses at this upper end of the hierarchy, further research may help to clarify the existence and character of this second cycle in the concrete-symbolic mode.

**IMPLICATIONS**

Implications for future research of this quantitative analysis exist both within the narrower context of this particular study and within the broader context of the use of the SOLO Taxonomy. From this study, there are still many unanswered questions. Analysing responses from students younger than 12 would provide more information to describe the levels, and perhaps cycles of levels, within the ikonic
mode. Similarly, responses from students over 18 would help to clarify the second cycle in the concrete-symbolic mode. This would involve new studies at the Primary and Tertiary level of education. It is also necessary to delve more deeply into analysis of responses in the data collection area to clarify the cycle structure.

In the broader context, these threshold values should prove useful to those who want to justify cycles of levels identified when using the SOLO Taxonomy. Researchers should be aware, though, that this would not form part of the process when using the qualitative descriptions of the hierarchy to assess individual students. The relevance of this tool would be in larger studies when hierarchies are first being created and justification for the identified cycles of levels is needed.

DESCRIBING YOUNG CHILDREN'S DEDUCTIVE REASONING

David A Reid
Acadia University

This paper reports results related to the development of a consistent descriptive language for research on mathematical reasoning. Ways of reasoning deductively are highlighted, using examples drawn from observations of young students. One-step deductions versus multi-step deductions, known versus hypothetical premises, and single versus multiple premises, are used to distinguish different ways of reasoning.

This paper reports results related to the development of a consistent descriptive language for research on mathematical reasoning. These results arose out of a long term research project (the PRISM project [1]) aimed at elaborating and clarifying previous models and terminology for describing reasoning. The model now in use for this research project describes reasoning across five dimensions: need, target, kind of reasoning, formulation and formality; and has been used to describe reasoning of students of all ages (Reid 1995a,b, 1997, 1998, in press). In this paper one dimension, ways of reasoning, will be highlighted, using results drawn from observations of students aged about seven years.

THE MODEL

The PRISM project took as its beginning point a model for reasoning outlined by Reid (1995a, 1996b). It includes four dimensions for describing reasoning. Need includes the needs to explain and to verify mathematical statements and to explore to discover new statements. This dimension of the model was inspired by the work of Bell (1976) and de Villiers (1990). Kind of reasoning includes reasoning deductively, inductively and by analogy, and was inspired by the work of Polya (1954/1990). Formulation refers to the degree of awareness the reasoner has of their own reasoning. Formality refers to the degree to which the expression of the reasoning conforms to the requirements of mathematical style. The work of Lakatos (1978) and Blum & Kirsch (1991) inspired this dimension. One of the refinements of this model that has resulted from the PRISM project is the addition of a fifth dimension, target, that describe who the reasoning is for: a teacher, a peer or oneself.

This model of reasoning is compatible with those being developed by others. For example, Sowder and Harel (1998) have outlined a model describing what they call “proof schemes”. In terms of the PRISM model it offers additional detail concerning kinds of reasoning but is limited to those kinds of reasoning related specifically to the need to verify.
THE CONTEXT

The episodes of mathematical activity that will be described here were recorded as grade two students (aged seven or eight years) worked in small groups at their classroom mathematics centre, one of five learning centres that the students moved through on a weekly rotation. The regular classroom teacher supervised the other centres while another teacher, working as a research assistant in the class, supervised and interacted with the students at the mathematics centre. Mathematics centre activities included playing games, reading and discussing stories, and engaging in geometric activities with pattern blocks and geoboards.

The research assistant recorded the activities at the mathematics centre on both video and audio tape, and produced summaries of the students’ mathematical activity based on these recordings and her own observations. The author re-viewed the tapes, discussed the students’ mathematical activity with the research assistant and occasionally visited the classroom as a participant/observer.

The results below evolved through an enactivist research methodology (Reid, 1996a). In keeping with the enactivist position that all learning is structure determined, the learning of individual researchers concerning the data is acknowledged as being determined by the structure of the researchers. At the same time, the researchers’ structures co-emerge with their environments, which include physical artefacts (e.g., video tapes) that constrain the researchers’ learnings, and other human beings whose structures impose additional constraints, if the researchers wish to maintain communication with them. Enactivist research methodology seeks to build on this co-emergence, through the mechanism of multiple perspectives.

Perspectives can be multiple in several ways. Several observers will inevitably observe from their own perspectives, each of which has something to offer. One researcher reviewing a video tape on several occasions does so with different perspectives each time. Data represented on video tape, audio tape or in transcript affords further perspectives. All of these are ways of obtaining additional perspectives can be involved in enactivist research. In the case of the results reported here, multiple perspectives arose from the individual structures of the research assistant and the author, from multiple viewing of tapes, and from re-presentations of the data as video tape, audio tape and written summaries.

RESULTS

One of the aims of the PRISM project is to explore how the model must be adjusted when used to describe the reasoning of students of different ages. In the case of students in the first years of schooling, the dimensions of need and target require no adjustment. The dimensions of formulation and formality are not of much interest for this age as all the reasoning observed was unformulated and hence informal. It was found to be necessary to refine the description of deductive reasoning, in order to
capture any hint of such reasoning present in the students’ mathematical activity. For this reason the results described here focus on describing this dimension.

To describe deductive reasoning precisely it was found to be necessary to distinguish between one-step deductions and multi-step deductions. In addition the number and nature of the premises of the deduction were found to be useful for distinguishing kinds of deductive reasoning. The interaction of these two criteria and the descriptive categories arising from them is summarised in Table 1.

Table 1: Kinds of deductive reasoning observed

**Specialisation**

The most common type of deductive reasoning observed in the grade two classroom was *specialisation*. Specialisation is determining something about a specific situation by applying a general rule that applies to it. Specialisations can involve simple or complex general rules. Several specialisations from a general rule involving multiple attributes occurred when the children were playing Set. The game of Set involves determining if three cards satisfy the conditions that define a "Set." In the standard game those conditions are that the three cards be identical, or all different, in each of four attributes: colour, number, shading, and shape. In this case the children played a variation in which the striped shading was removed from the deck, and the open shading was treated as a fourth colour: white. The teacher defined a Set as three cards that were different colours, shapes, and numbers.

![Figure 1: 1 red oval, 3 green diamonds and 2 white squiggles make a Set. (In this game variant a set is defined as three cards of different colour, shape and number.)](image)

After playing for a while, the teacher asked the children to explain why 1 red oval, 3 green diamonds and 2 white squiggles are a Set (See Figure 1). Cynthia replied, "They’re all...different. They’re all different shapes. They’re all different colours." Alison added, "They’re all different numbers." And Jared summed up, "Different
colour, number and shape." Jared states the general rule that they are using to identify Sets, which he is applying to this specific case.

**Simple deductive reasoning**

Simple deductive reasoning is deducing a conclusion from two or more established premises. It can be one-step or multi-step, of which one-step is more common.

When a grade two student makes a simple one-step deduction it is not likely to be clearly stated. Following the reasoning can be difficult. For example, consider this statement made by Maurice when playing the game Mastermind with the teacher (See Figure 2).

"It's blue. Cause if there's three there. I changed the blue and I only got two."

Figure 2: The Mastermind board as it appeared when Maurice made his simple one-step deduction. (The object is to guess the colours and order in a four colour pattern picked by one's opponent. A white scoring peg indicates that one of the pegs in the guess is the right colour but in the wrong place.)

The teacher had asked Maurice if he knew anything new after receiving the two white pegs for his second guess. Maurice's response can be re-expressed as:

It's blue. Cause...

Blue is correct because:

1. Three of the colours in my first guess are correct

2. And the only relevant change I made in the colours from my first guess to my second guess was leaving out blue

3. And only two colours in my second guess are correct

He has taken three statements about the situation and concluded a fourth statement that follows logically from them.

While simple one-step deductions are the building blocks of proving, they need to be assembled into chains to make a proof. Reasoning with chains of deductions is called simple multi-step deductive reasoning. It is difficult to observe in early elementary classrooms, both because it is relatively rare and because young students rarely articulate their reasoning. It is sometimes possible, however, to conclude that multi-
step deductive reasoning has taken place by observing the conclusions students come to and the information they had to work with.

For example, when Maurice was playing Tic Tac Drop, a computer game, he made the comment, "If he don't put it next to me, I won," immediately after placing his first marker (Marked as O1 in Figure 3).

![Table](image)

Figure 3: Tic Tac Drop. The board after Maurice’s game with the computer. The object of the game is to get three of one’s markers in a row. Markers can only be added directly above the other markers in a column. O represents Maurice’s markers. The numbers indicate the order in which they were placed.

On a previous day Maurice had described a general rule he used when playing a related game, Connect Four, at home. That rule was: *If you have three markers in a row with both ends free, then you can win.* It depends on the winning condition of Connect Four, which is getting four in a row. Because the winning condition for Tic Tac Drop is different, Maurice’s general rule for Connect Four is not directly applicable, so he cannot be specialising from it. While we cannot know for sure how Maurice came to his conclusion that he would win if the computer did not place a marker next to his, it seems plausible that he deduced this new general rule either from the strategies he already knew from playing Connect Four or from analysing the new situation in terms of general features (e.g., two in a row with free ends). In both cases he would have had to make a chain of deductions to get from what he knew to his conclusion. As it happened, the computer played its marker in column six, and Maurice won.

Because of the emphasis on arithmetic in early elementary mathematics, the context in which students are most likely to evidence simple multi-step deductive reasoning is in the course of solving problems involving arithmetic. The following example occurred when the teacher posed the following problem to Maurice and Saul:

First there were 8 cookies. The children got four each. Then some more children came in. Then they got 2 each. How many people came in?

Both Saul and Maurice reread the question several times, which was written on a piece of paper. They tried to solve it with paper and pencil only. Saul circled the number eight in the question. Another boy, Ira, interrupted and stated, "Very easy!" but Saul disagreed, "No! Eight take away two is six. — First there were eight cookies. Then the children got four each. Oh! Let me see. First there were 8 cookies... — Four people!"
The teacher asked Saul, "Did four people come in? How many people were there at the beginning?"
"There were two."
"You think there were two people in the beginning and then four people came in?"
"No, then two more people came in. That made four. Because eight, — let me think about that again. — Um, this is hard. — I think there were four or six people."
The teacher asked Saul how he was going to figure out if there were four or six people, "Are there any parts that you can figure out?"
Saul drew a diagram on the bottom of the page showing eight cookies, in two rows of four. He circled the two groups of four. Then he drew a line through each group of four, creating four groups of 2. "There were four people in there." He said, and then he reread the question again silently.
Maurice agreed that there were four people. The teacher asked once again how many people came in. Maurice replied, "Two."
To solve this problem Saul and Maurice had to first determine the number of children originally present, then the number of children present after the new ones arrived, and then the difference between the two numbers. Each one of these requires a one-step deduction. It is the linking of them together that makes this an example of multi-step deductive reasoning.

**Hypothetical deductive reasoning**

Thus far the deductions we have seen involve reasoning from something that is known. In mathematics proofs however it is often necessary to reason from a hypothesis, something that is not known to be the case, either to show that it cannot be the case (as in a proof by contradiction) or to show that if it were the case for one number it would also be true for the next number (as in a proof by mathematical induction). Such reasoning, because it involves a hypothesis, is called hypothetical deductive reasoning. Although hypothetical deductive reasoning is often thought to be more difficult than simple deduction from known statements, it can be observed in the reasoning of early elementary school students, in both one-step and multi-step forms.

An example of a hypothetical multi-step deduction occurred during a game of Mastermind (See Figure 4). After giving Kyla two white pegs for her third guess, the teacher asked her which one she thought might have been in the right place. Kyla pointed to the blue in the first row and then changed her mind. "I never got a black one right there [pointing to the blue in the second turn]." She then indicated that green could not be correct either in the first try. "Cause on this one [turn three] I didn’t get a black." After that Kyla stated that orange on turn one must be in the correct spot but then realised it can not be. "Cause I got a black one right here — no! Oh my! It’s yellow." Kyla’s reasoning includes three hypotheses: That blue is in position three,
that green is in position four, and that orange is in position two. Having arrived at contractions from each of these hypotheses in turn she concludes that the one remaining case (yellow in position one) must be correct.

A white scoring peg indicates that one of the colours in the guess is the right colour but in the wrong place. A black peg indicates one of the colours is in the right place.)

SUMMARY

Describing the reasoning of young children is difficult. Quite often they do not articulate their thinking clearly, and they tend to make use of many implicit assumptions (Anderson, Chinn, Chang, Waggoner, & Yi, 1997). This makes it all the more important for researchers investigating children’s reasoning to be precise in their descriptions of that reasoning. For example, while of the reasoning described here is deductive, but there is a significant difference in sophistication between a specialisation and a multi-step hypothetical deduction. Omitting to note that difference would be a serious weakness in a description of a child’s mathematical activity. The distinctions I have made in this paper, along with the terminology I and others have outlined elsewhere, should help provide researchers with the tools they need to observe and describe children’s reasoning more precisely.

NOTES

1. The PRISM project is funded by the Social Sciences and Humanities Research Council of Canada, grant #410-98-0085.

Thanks to R. Hudson and B. Dowden for all their help.

REFERENCES

Proof is regarded to be an important aspect in the mathematics classroom. Nonetheless, it is difficult for students to give mathematical proofs. Our research aims at identifying important dimensions of proving abilities. In a study with 669 grade seven students, we investigated how mathematical knowledge, the ability to evaluate correct and incorrect proofs, and scientific reasoning influence the students' performance in proving. Our results give evidence that these aspects contribute significantly to students' abilities.

1. Theoretical Framework

Proof and logical argumentation are important topics in mathematics as a science, and mathematics may even be regarded a proving science. The role of proof in the school curriculum did not always reflect that importance. In the 1970s and 1980s, there was an intensive discussion whether proofs should be part of the mathematics curriculum. Mathematics educators criticized that proving in the classroom emphasized formal aspects but disregarded mathematical understanding (Hanna, 1983). This is still a consensus among many mathematics educators, but its consequences have been revised. Proof is considered as an important topic of the mathematics curriculum (NCTM, 2000) and as an essential aspect of mathematical competence. Nonetheless, proof is not used as a synonym for formal proof. In particular, researchers such as Hanna and Jahnke (1993), Hersh (1993), Moore (1994), Hoyles, (1997), Harel and Sowder (1998) have pointed out that proving spans a broad range of formal and informal arguments. Understanding and generating proofs is an important component of mathematical competence, and mathematical argumentation has been identified as an essential element of higher order mathematical competence in the TIMS study (cf. Baumert, Lehmann et al., 1997). The current discussion emphasizes the development of proof concepts (Boero, 1999), the continuum from exploration to proof (NCTM, 2000) and the role of reasoning and argumentation in finding a proof (Reiss, Klieme & Heinze, 2001). On the background of the PISA findings (Deutsches PISA-Konsortium [German PISA Consortium], 2002) the individual prerequisites for secondary school students' performance in proof tasks are of particular interest.

The Standards and Principles for School Mathematics (NCTM, 2000) call for a "focus on learning to reason and construct proofs as part of understanding mathematics so that all students

---

1 This research is funded by the Deutsche Forschungsgemeinschaft (RE1247/4).
recognize reasoning and proof as essential and powerful parts of mathematics;
make and investigate mathematical conjectures;
develop and evaluate mathematical arguments and proofs;
select and use types of reasoning and methods of proof as appropriate.”

The approach is applied to all stages of education from preschool to grade 12. In the early years informal inductive elements are underlined whereas the formal deductive elements become more important for older students.

This standard is the basis for our own work (Reiss & Thomas, 2000; Reiss, Klieme & Heinze, 2001; Reiss & Renkl, in press). With respect to the aspects described in this standard, we assessed students’ performance on mathematical proofs. We concentrated on

- students’ abilities for proving (i.e. the knowledge of mathematical propositions and concepts, its application to simple situations, understanding a proof, the ability to argue mathematically),
- their knowledge of proof methods and their evaluation of the correctness of proofs (cf. Healy & Hoyles, 1998),
- their abilities in the domain of scientific reasoning.

2. Design of the Study

The aspects described above were investigated in a study with students at the end of grade 7 and in the beginning of grade 8. In grade 7, students get an intensive instruction on geometry proofs and argumentation, which is continued in grade 8. The study was performed between January 2001 and February 2002. We will report on data of a pre-test, which was given to them in June 2001. The results presented here are based on the data of 669 students (363 female students, 306 male students).

We developed a test for the assessment of their abilities to prove which consisted of six items on basic qualifications and seven items on justification and reasoning. For assessing their knowledge of proof methods and their evaluation of the correctness of proofs we adapted a test constructed by Healy and Hoyles (1998). The students had to evaluate four solutions for a proof task: two incorrect ones (empirical, circular) and two correct ones (narrative, formal). In order to assess abilities in the domain of scientific reasoning we presented tasks which consisted of two parts, namely a reduction of a given problem space (Klahr & Dunbar, 1988) and ordering of information given. The test items were presented to the students as paper and pencil questionnaires in a classroom situation.
3. Results
The students performed quite well in terms of knowledge of mathematical propositions and concepts, and its application to simple situations. We observed more difficulties concerning their understanding of proofs and their abilities to reason mathematically. The variation within these components was considerable. Whereas most of the students had a basic knowledge of mathematical propositions and concepts \((M=7.4, s=2.5, \text{maximum number of points: 12})\), they scored lower with respect to items asking for mathematical argumentation \((M=5.2, s=3.7, \text{maximum number of points: 14})\).

Figure 1: Distribution of norm scores for basic mathematical knowledge (left) and mathematical argumentation (right)

When constructing the test, we applied Klieme’s (2000) model of mathematical competencies. The data show a close connection between this model and the actual students’ performance. The following table provides information on the students’ performance (table 1). According to the achievement we grouped the students into a lower third, a middle third, and an upper third and compared their performance with respect to the levels of competency.

In level of competency I, which was represented by five items, there is no formal mathematical reasoning required, just the application of concepts and rules as well as elementary inferences. In level II (three items) the students must have a sound knowledge of geometrical concepts and facts. They must be able to give a correct justification to given geometrical problems and to find an appropriate notation. In level III (four items) the students must be able to order their arguments in a meaningful way. A prerequisite for this is autonomous and creative problem solving and reasoning. Table 1 shows that the lower third of the students did not have any correct solutions in level III tasks whereas the upper third managed to solve 85% of the level I problems and 89% of the level II problems. Nearly all the other numbers are gradual increases or decreases between these extremes. This can be regarded as an internal validation of the test.

Table 1: Percentage of correct solutions

It should be mentioned that we found large differences between the 27 classes involved in the study. Their average scores ranged from very low (M=5.7) to appropriate (M=17.7) given a maximum of 26 points for the 13 items. In the three classes showing the lowest average scores the students achieved less than half of the possible points (with the exception of only one person). Accordingly, these classes lack of high achieving students, whereas in the classes with the highest average scores there was a wide variation of achievement levels. The high achieving classes solved the simple tasks in a good or even very good manner, the low achieving classes performed satisfactorily on these items. However, we found differences at tasks, in which argumentation skills were needed for the solution. The students of the low achieving classes hardly had any correct solutions with respect to these items. The responses show that the students had the declarative knowledge to solve these items, but they were not able to apply it correctly. These differences might be caused by teaching styles (cf. Baumert, Lehmann et al., 1997). We will investigate these differences in an ongoing video study.

Concerning the students’ knowledge of proof methods and their evaluation of the correctness of proofs, it can be seen that students have difficulties in identifying incorrect solutions as incorrect. It is significantly easier for them to classify correct solutions as correct (p<.001). Moreover, for the students it is easier to evaluate proofs than to formulate proofs by themselves. Concerning norm scores we found an average score of M=0.67 (s=0.33) for the knowledge of proof methods and the evaluation of the correctness of proofs. The norm score for the test items of level II and level III is M=0.37 (s=0.26). This difference is highly significant. Comparing the lower third, medium third, and upper third with respect to the achievement in the test on mathematical performance, there are highly significant differences concerning the
students' knowledge of proof methods and their evaluation of the correctness of proofs.

In the domain of scientific reasoning we found that students are often guided by plausible arguments even if these arguments are not logically consistent. A high proportion of the students could not solve tasks in which plausibility was not a hint for the solution (cf. table 2). If students could not solve a plausible task, they could not solve tasks presented in an unusual context either. On the other hand, if they could solve plausible tasks they had a high probability to solve tasks presented in an unusual context.

Table 3: Percentage of each level of competence dependent on the availability of formal solution strategies in tasks concerning scientific reasoning
The data show that students who are more successful using formal strategies (namely students who do not need a plausible context but are able to solve problems in an unusual context) have higher scores with respect to items of competency level II and competency level III.

Discussion
There are a number of abilities, which may enable students to perform proofs. In our study there is evidence that the following abilities play an important role in this context:

*Basic knowledge of mathematical facts and argumentation:*
The students need an appropriate level of knowledge about simple mathematical propositions and concepts. Most students have those basic abilities, although the level was quite different in the various classes investigated. Moreover, students need higher order skills in order to apply their knowledge in a proof context. This is more difficult for the students, thus only a few of them are able to apply their knowledge. These findings are in accordance with results of Klieme, Neubrand and Lütge (2001) within the PISA study. Moreover, our data could be validated by Klieme’s (2000) model of mathematical competency.

*Knowledge of proof methods and evaluation of the correctness of proofs:*
It was more difficult for the students to identify incorrect solutions as faulty than to identify correct solutions as being correct. This confirms findings of a former study with grade 13 students (Reiss, Klieme & Heinze, 2001) and findings of Healy and Hoyles (1998) as well as Küchemann and Hoyles (2001). Moreover, we found a correlation between this knowledge and the achievement measures on basic mathematical knowledge of facts and argumentation.

*Scientific reasoning:*
Plausibility may be regarded as guiding principle for scientific reasoning. Many students rely on plausible argumentation when confronted with reasoning tasks. The plausibility of propositions is more important for their argumentation than facts, which determine that a line of thought is logical or not logical. If students show a high level of scientific reasoning they usually show good achievement in proof-related tasks. Accordingly, scientific reasoning seems to be closely related to mathematical abilities.

These three aspects will only partly explain the interindividual variance in argumentation, reasoning, and proof. We could identify significant differences between mathematics classrooms. Accordingly, the differences in the students' performance cannot be explained by individual prerequisites alone. This is in accordance with Bronfenbrenner's theory of ecological development. Bronfenbrenner (1979) suggests, to take into account the context of teaching and learning, which includes the teacher and the
social context. Our findings suggest that a significant portion of achievement differences in the mathematics classroom will be explained by these variables.

Our future research (and the second part of the study described here) will concentrate on the influence of teachers and school variables in mathematics education with respect to argumentation and proof. Instruments will be questionnaires concerning the teaching styles, which are presented to students and teachers, questionnaires concerning the mathematical beliefs of students and teachers, and video observations of mathematics classrooms.

APPROACHING GRAPHS WITH MOTION EXPERIENCES

Ornella Robutti, Francesca Ferrara
Dipartimento di Matematica, Università di Torino

ABSTRACT

In this paper we report on a study about students' activity in interpreting their body motion graphs on a symbolic-graphic calculator connected with a motion sensor. This is done in the context of introducing functions, graphs and modelling at secondary school level, in order to teach algebra with a semantic approach (in which symbols are used not only in a pure syntactic way). We analyse the ways in which students build a meaning for the graphs, comparing them with the ways used by students who did not take part in the same experience. Finally, we try to interpret these differences, by comparing language and gestures of the two students' groups.

INTRODUCTION

In literature it is well-known that students have many difficulties in interpreting graphs, particularly those in which one variable is time-dependent, as for example space-time or velocity-time graphs. Researchers have identified some ways in which students misinterpret graphs. One is the graph-as-picture interpretation, in which students expect the graph to be a picture of the phenomenon described. In kinematics, this can result in the student interpreting a graph of space versus time as if it were a road map, with the horizontal axis representing one direction of the motion rather than representing the passage of time (Berg & Phillips, 1994; Clement, 1989). Another common misinterpretation is the slope/height confusion, in which students use the height of the graph at one point, when they should use the slope of the line tangent to the graph at a point, and vice versa (Thornton & Sokoloff, 1990).

Mathematics and Physics Education research tells us that microcomputer-based laboratory instruction with motion sensors is quite successful in supporting students to learn to interpret graphs, because of the help of the real-time display of graphs, together with the kinaesthetic experience of motion, that give students control over the data. Generally, all the experiences in which students can interact with a tool to create phenomena, help them to understand the mathematics connected with those phenomena (see e.g. Noble & Nemirowsky, 1995).

The ongoing research project we are involved in, is concerned with the students' cognitive behaviour when using a symbolic-graphic calculator, connected with a motion sensor. Secondary school students are first engaged with experiencing various body motions. Second, they are asked to interpret the graphs and tables containing the data related to their motion, using natural language first, then in terms of increasing/decreasing functions, and finally in terms of slope, calculated in some points (Arzarello & Robutti, 2001). The general research problem is the study of the
students' transitions from the perceptual level [1] to the theoretical one and backwards and the mediation of technology in these transitions.

In our investigation, we obtained the same results witnessed in literature, as regards the comparison of students who experience body motion with sensors and calculators (we will call them the experimental group of students) with students who do not participate in the experience and have to solve the same problem situation (we will call them the control group of students). Generally the students of the experimental group interpret the motion graph correctly, while the students of the control group reveal the kind of misinterpretations described in the introduction.

Our attention is focused on the ways the students of the experimental group construct the meaning of the graph they observe on the screen after the motion experience. In doing so, we analyse the students' language and gestures, which provide information about the students' cognitive activities, and compare them with those of the students of the control group, who observe the graph only on the paper, after a brief introduction made by the teacher. A crucial point seems to be the transition static-dynamic and backwards, namely when the graph is seen as a pure graphical sign, or is conceived as a time-dependent representation [2].

Our hypothesis is that, for the construction of a correct meaning for a graph, it is fundamental to make some transitions from a static to a dynamic interpretation of it and backwards. Two main theoretical ingredients are at the basis of this study, namely: the transformational reasoning (Simon, 1996) and the mental times (Arzarello, et al., in press).

METHODOLOGY

The activity described in this paper is part of a long-term teaching experiment carried out in a classroom of 25 first year students (the first set) of a scientifically oriented high school, [3] (9th grade) during the school-year 2000-01 in Italy. This activity lasted three hours, in which the students worked in small groups (three-four pupils each). Each small group used two technological tools: the CBR (Calculator Based Ranger, a motion detector which collects space-time data in real time) and the symbolic-graphic calculator TI92, for realising a motion in front of the sensor and then interpreting the space-time graph on the calculator. The small group activity was followed by a final classroom discussion, directed by one of the authors. Previous activities, specifically oriented to make students familiarise with the motion sensor and the gathering of the data in the calculator, have been submitted to the students belonging to the experimental group. At the moment of the experiment, the pupils did not know any algebra rules, the linear function and its representation, the equation of uniform or accelerated motions and the definition of velocity (in a few words, they had not been taught algebra, nor yet kinematics).

The students of the control group are those of another classroom (20 pupils in the same initial conditions as the first set), in the same school. Working in small groups,
they do the same kind of activity as the experimental group of students, without making the motion experiment and without using technology. They have to analyse the space-time graph of a body motion printed on a sheet of paper, and to answer the same questions as those of the first set, after an explanation led by the teacher about the way this graph has been obtained.

During the activity of both groups (experimental and control), four people were present in the classroom: two teachers (one of mathematics and one of physics), to observe the small groups; one University student, to videotape one small group and the final discussion, and one researcher, to observe the groups and guide the final discussion. The data consist of video-tapes and some written notes.

THE OBSERVED STUDENTS

In the experimental group of students we observed a small group of four pupils, three boys and one girl: Filippo, Gabriele, Fabio and Giulia. They are all medium achievers, but with different features: Filippo is a reserved, studious and thoughtful pupil, Gabriele is a discontinuous student, who prefers to go on with a personal rhythm, Fabio is a clever and intuitive boy, while Giulia is a determinate and studious girl, active in a collaborative group.

In the control group of students we observed a small group of three boys: Filippo, Francesco and Giorgio. Filippo is a meticulous and respectful pupil who obtains good results, Francesco is an extrovert and expansive boy who overcame some initial difficulties with good will, Giorgio is a student with discontinuous results.

THE ACTIVITY

The activity proposed to the experimental group of students is the following [4]:

*Walk or run in the corridor in order to make a uniform motion; when you arrive at the red line, come back with the same motion. The CBR will record your position with respect to time and will collect the data in a graph and in a table. The data are expressed in seconds [s] and in meters [m] respectively. Each 1/10 s a couple of data (time and position) are collected.*

*Describe the kind of motion you made in the corridor. Using the graph and the table, describe how space changes with respect to time (increase, decrease, ...). Analyse the graph (Is it like a line? Is it like a curve? Does that curve increase? Does that curve decrease?). Consider the ratio \( m = \frac{s_2 - s_1}{t_2 - t_1} \) and use it to describe mathematically the graph of your motion (\( t_1 \) and \( t_2 \) are two subsequent time data and \( s_1 \) and \( s_2 \) are two subsequent position data).*

PROTOCOLS

Experimental group of students

In the experimental group of students, each small group makes the experience of motion in the corridor. In the observed small group, the student who is running in the
corridor (from the sensor to a red line and back) is Fabio, while the other members are looking at the calculator. After the motion, they are all around a desk, to answer the questions. In this first excerpt, the students are exploring and describing the shape of the graph (Fig. 1) and trying to connect it with the motion.

![Graph Image]

**Fig. 1 - The graph obtained by the observed small group in the motion experience.**

74 Gabriele: *So, we started from a point and we made a motion...*[...]*

78 Gabriele: *And then, at the end, this line* [he is moving his pen on the horizontal stretch of the graph from left to right]

79 Fabio: *Here* [he is pointing at the starting point of the horizontal stretch], *here is when I got to the red line* [...]

81 Gabriele: *Here you stopped* [he is marking the same point on the graph with his pen]

82 Giulia: *...You came back* [she is pointing at the negative slope stretch] *and then you stopped again* [...]

91 Fabio: *The one who ran, uhm...* [...]

94 Fabio: *...He tried to take the steps always in the same...in the same time interval* [...]

112 Giulia: *He tried to keep the same pace there and back* [...]

116 Gabriele: *Walking always the same distance*

117 Fabio: *...During the whole, during the whole time in which I walked, I tried to, to make, to keep always the same velocity* [...]

123 Giulia: *Constant velocity!* [she is writing it]

The students go back and forth from the graph on the screen to the description of the motion experience. The way pupils are looking at the graph changes over time. At the beginning, they use the deictic function of language (Radford, 2000), to indicate some parts of the graph (e.g. #78 “this line”). This kind of language reveals a static approach to the graph. Two observations are important now: first, the students observe the graph dividing it into different parts, as already noticed (e.g. Monk & Nemirovsky, 1994), and they try to interpret these parts first separately and then together. Second, the cognitive pivot (Arzarello & Robutti, 2001) to interpret the graph is given by an event of the motion experience: Fabio’s arrival to the red line (#79). So, the deictic function is used together with the generative action function of the language (Radford, 2000), in order to link the graph with the motion experience (#79 “when I got”; #81 “Here you stopped”; #82 “You came back and then you stopped again”; ...). The generative action function, together with some adverbs
(e.g. "when") reveals a dynamic interpretation of the graph. This evolution from static to dynamic indicates the presence of a transformational reasoning: "... the ability to consider, not a static state, but a dynamic process by which a new state or a continuum of states are generated" (Simon, 1996, p. 201). At #91 a new phase starts, with new generative action functions. There is a mathematisation process, in which the language evolves and becomes more specific through consecutive refinements. The steps taken in the same time interval (#94), in fact, become, for Giulia (#112) "the same pace there and back" and then, for Gabriele, "the same distance" (#116). The students find a sort of motion rule: the presence of the adverb "always" (#94, #116, #117) reveals the generalisation of this regularity in the sentences listed above. This word, as observed by (Radford, 2001): "underpin the generative functions of language, that is, the functions that make it possible to describe procedures and actions that potentially can be carried out reiteratively” (p. 83).

In our opinion, there is something more in the information carried out by this term: the transition from the timed experience to a never-ending process, through the detimed rule describing the graph. So, there is a new transition, from a dynamic to a static interpretation of the graph, to produce a time-independent rule. This new static viewpoint is not to be intended at the same level as the first static one, but at a higher one, due to the presence of a new concept: velocity. So, the uniform motion becomes a motion with "constant velocity" (#123). The basis of this transition is a transformational reasoning, as in the previous excerpt. The mathematisation process in the interpretation of the graph evolves towards correct ideas, as noticed by other researchers (e.g. Monk & Nemirovsky, 1994). This evolution, in our opinion, passes from static to dynamic stages and backwards. All the previous observations refer to the physical time (Varela, 1999), while also the students' inner times (Guala & Boero, 1999) are involved in this evolution. In fact, the students act in the time of past experience, when they recall the kind of motion, and in the contemporaneity time, when they connect the motion with the graph (Arzarello et al., in press). Here the inner times of the students are very closed together, so the interaction among them is more productive than the situation of different inner times.

439 Fabio: ...I stopped and when I stopped...
440 Giulia: It goes on [she is pointing at the curve], doesn't it?
445 Gabriele: If you always go on at the same velocity, they [time and space] both increase [...]
448 Gabriele: Yeah, it [the curve] goes on in this way and then it goes down [with his pen he traces the consecutive slanted sides of an “open triangle”]
449 Filippo: Yeah, it is not a straight line. They are two half lines [...] 452 Giulia: Because if you did not, if you did not lose, let’s say, time for turning on yourself [...] 459 Fabio: I should have walked in a more uniform way, I did not walk...

In this excerpt, initially, the word “when” and the generative action function mark again a series of timed sentences (#439). Then, at #440, we can observe a dynamic
reading of the graph (when Giulia says that the curve "goes on" although Fabio stopped), which marks a transformational reasoning. At this point a new function of language enters the scene (#445, #452): it is the logic function, which appears in hypothetical expressions of the form: "if... then..." and reveals a conjecture or a deduction. The pupils evolve toward a more mathematical description of the graph in terms of increasing and decreasing functions. In doing so, the motion experience is linked to the shape of the graph (#452, #459): the students are in the time of past experience.

**Control group of students**

The excerpts listed below refer to the observed small group belonging to the control group of students. They have to describe the motion, referring to the graph of Fig. 1.

11 Francesco: *It [the graph] is uphill, therefore he is accelerating [...]*

19 Giorgio: *However he is going on at the same velocity [...]*

22 Francesco: *Then he suddenly slows down [he is moving his finger twice on the second slanted stretch] and... [...]*

26 Francesco: *Let's see: there is an increase of velocity and then, I don't know*

36 Francesco: *There is a moment [he is pointing at the horizontal stretch] in which the velocity is constant [...]*

42 Francesco: *Sorry, but here [he is pointing at the starting point of the decreasing slanted stretch] is he going fast? [he is moving his finger on this stretch] [...]*

46 Giorgio: *Then here [he points at the first slanted stretch several times] he is covering more space*

47 Filippo: *But here too [with his pen he is pointing at the second slanted stretch] theoretically [...]*

59 Filippo: *And then here [at the starting point of the second slanted stretch] he is stopping in theory, because, hum...*

60 Giorgio: *No [he is pointing at the higher horizontal stretch], he continues to go on at the same velocity [...]*

64 Francesco: *It is here [he points at the starting point of the graph]. Namely he starts here and then he comes back here [at the final point of the graph] [...]*

88 Giorgio: *This [the first slanted stretch] and this [the first horizontal stretch] are a straight line, all equal straight lines! [...]*

96 Francesco: *It is a curve [Filippo is writing it] which starts increasing and ends decreasing*

97 Filippo: *Increasing...then acceleration [...]*

99 Francesco: *...And ends decreasing*

100 Filippo: *Slowing down!*

The students misinterpret the graph, with a confusion between distance and velocity (slope/height mistake). For example, at #11 they think that the ascending part means an increasing velocity; at #19 the first horizontal part represents a constant velocity. From #42 on, the misinterpretation continues: for example at #46, where pupils refer
to a velocity. In all the dialogue there are many deictic functions of language and many pointing gestures, with the role of indicators of the graph (e.g. the word “here”, often used with a gesture, in #42, #46, #47, #59, #64, #88). Here, language and gestures are a kind of communication indicating a static interpretation of the graph which does not become dynamic. These students do not come to a correct interpretation of the motion represented in the graph, because they are not able to link the graph itself to a real motion. We think that they do not make a transformational reasoning, because they did not experience the motion, nor use the technology. Furthermore, these students' inner times are not so closed together, as those of the previous small group.

CONCLUSIONS

It would be too simple concluding that the motion experience, together with the use of a proper technology offering a powerful mediation for learning, is sufficient to construct a right meaning for a graph. The two observed small groups of students offer a significantly different approach to the activity, but it is also important to describe the general approaches of the two classrooms (the experimental group and the control group). In the first classroom, all the small groups were able to describe the graph in terms of motion, while in the second classroom, only one small group reached a correct interpretation, while all the others (5 small groups, for a total of 16 students) produced the misinterpretations described in the literature [5].

Our suggestion is that both the motion experiment and the mediation of technology (calculator and CBR), together offer a support to make the transitions from a static to a dynamic interpretation of the graph and backwards. These transitions help the students to evolve towards a correct meaning for the graph, linking it to the phenomenon which it describes. This fact appears crucial, insofar the technology used in this experiment supports both the use of transformational reasoning and the synchronisation of students' inner times. Along with Nemirovsky, when he says that "learning graphing entails the enrichment of a broad range of experimental domains, involving the refinement of visual, kinaesthetic and narrative resources" (Nemirovsky et al., 1998), we believe that this kind of activities is important for Mathematics Education research and practice, because they foster the passage from perceptual to theoretical thinking.

NOTES

1. As perceptual level, we mean using perception (e.g. seeing and touching, while moving). As theoretical level, we mean producing a conjecture in a conditional form and validating it with a proof.

2. It is important to underline that not only a graph of a time-dependent phenomenon, but also a graph of time-independent one, or a geometric figure, or a function and so on, can be conceived in a dynamical way.
3. It is a Liceo Scientifico. These students attend five mathematics classes and three physics classes per week.

4. The words written in italic type are not present in the activity of the control group of students: they are substituted by an oral description of the motion.

5. It was only after a discussion led by one of us, during which the actual motion was carried out, that these students were able to understand the shape of the graph.

COGNITIVE TENDENCIES AND THE INTERACTION BETWEEN SEMANTICS AND ALGEBRAIC SYNTAX IN THE PRODUCTION OF SYNTACTIC ERRORS

Eugenio Filloy, Teresa Rojano and Armando Solares, CINVESTAV, MEXICO

In Filloy and Rojano (1989) we introduced the use of concrete models for the teaching of solving linear equations and studied the abstraction processes that take place when such models are put in work by 12-13 year olds. In this paper we discuss M and V cases where, on the face of elements provided by the same "concrete" model for the operation of the unknown, the evolution paths of their use for the resolution of more and more complex equation modes are dissimilar (in fact, antagonic). However, in spite of this antagonism there is a common tendency to abbreviate the processes involved and this generates (in both cases) a number of well known algebra learning obstacles and syntactic errors.

The literature about algebraic errors in the learning of algebra is mainly focused in its syntactic component: Matz (1982), Kirshner (1987), Drohuard (1992). Few works like Booth (1984) and Bell (1996) situate this problematic component in a more general context, for instance, problem solving. In this paper we analyse the interaction between semantics and algebraic syntax as a source of syntactic errors, when this interaction takes place in teaching processes that involve concrete modeling. We argue that such analysis provides a perspective that allows us to give different explanations of the presence of some typical algebraic syntax errors.

Undertaking a semantic introduction to new algebraic concepts, objects, and operations implies selecting a concrete situation (i.e., a situation which in some context is familiar to the learner) in which such objects and operations can be modeled. With this approach it is possible to resort to previous knowledge, in order to accomplish the attainment of new knowledge. This is one of the driving principles of modeling, the strengths and weaknesses of which become manifest at the time a specific model is put into operation (see Filloy/Rojano, 2001, for a more detailed description). In the cases we report here (V and M cases) the concrete situation in question is a geometric model that was used as a semantic introduction to the operation of the unknown for the resolution of the first non-arithmetic equations. In this model, the translation of the proposed equation into equalities between quantities or magnitudes in a more 'concrete' situation permits to find out the numerical value of the unknown in the context of area comparison. The use of such a geometric model, then, presupposes a good handling of operations with areas. This handling, as can be verified in V and M's interviews, is a requirement that was covered in both cases. When this study was carried out, M and V showed to be highly proficient at school maths. They found no difficulties in handling the model during the instruction phase aimed at modeling the first non-arithmetic equations (equations of the form Ax+B=Cx, where A, B, and C are given positive integers, and C>A). It is in the
transition to more complex modes of equations that modeling and actions in the model, in turn became more and more complex. In contrast to previous explanations given with regards pupils' syntax errors, within the modeling realm it is possible to formulate explanations grounded on the nature of the model and the sort of cognitive tendencies displayed by the subjects.

THEORETICAL AND METHODOLOGICAL FRAMEWORK

In Filloy (1990) we introduced the methodological framework of local theoretical models in which the object of study is brought into focus through four inter-related components:

(1) Teaching models together with (2) models of cognitive processes, both related to (3) models of formal competence that simulate competent performance of the ideal user of a Mathematical Sign System (MSS) and (4) communication models to describe rules of communicative competence, production of texts, texts decoding, and contextual clarification.

The following scheme describes the rationale of the case study:

Results from the diagnostic test located V and M in the category of students with high proficiency in a) solving arithmetic linear equations; b) solving arithmetic word problems; and c) numeric skills. Before the interview, V and M had not been introduced to the learning of algebra. Once V and M got to solve the first non-arithmetic equations by means of the geometric model, they were faced with more
complex modes of such type of equations as it is shown in the lists of the interview items below. It can be noticed that the list of items differ from one case to another, due to the specific characteristics shown either by the “semantic” case or by the “syntactic” case during the interview.

THE INTERVIEW ITEMS

We will write IM.n and IV.n for the nth item of Sequence I Series in the interview.

ABBREVIATION PROCESSES

The development of the use of the concrete model is not uniform, it depends on the individual student’s tendency to choose a particular approach (Filloy, 1991; Filloy/Sutherland, 1996).

Two extreme cases were detected in the interview: In one case (V case) with an operative tendency, the development anchored to the use of the model context even when the equation types required very complicated modelling procedures. This is the semantic cognitive tendency case. In the other case (M case) there was a constant search for the syntactic elements present in the actions on the model as they were repeated in equation after equation and in type after type. The subject broke away from the semantics of the model with a more abstract language through the creation of personal codes, belonging neither to the model nor to algebra. This is the syntactic cognitive tendency case.

Notwithstanding the bias that the subject’s own tendency introduces in his or her use of the concrete model for the resolution of the new equations, there exists, as can be observed from these extreme cases, a common tendency. This tendency consists in abbreviating both the translation processes from the equation to the model and the actions performed in the model (or in the equation itself). In the following
In subsections, we discuss the abbreviation processes related to both cognitive tendencies, the semantic and the syntactic tendencies.

**A semantic tendency**

V, shows distinctive evolution lines with regards the abbreviation processes: on the one hand, 1) there are those of stability, progress and generalization of the graphic abbreviation, with the intervention of anticipatory mechanisms regarding the actions, and on the other 2) the transference and discrimination of strategies for area comparison, for each mode of equation.

V's resolution examples:

<table>
<thead>
<tr>
<th>IV.14 $x+5=2x$</th>
<th>The comparison of areas and the writing (and verbalization) of the simplified equation is done at the same time - without difficulty - without help.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Areas comparison</td>
<td>Construction of the simplified equation</td>
</tr>
<tr>
<td>V: &quot;We take away this piece of land (referring to the rectangle of 1 x 'x') and we are left with this which should be one(referring to the remaining front)&quot;: V only draws some additional lines for the comparison.</td>
<td></td>
</tr>
<tr>
<td><img src="image" alt="" /></td>
<td><img src="image" alt="" /></td>
</tr>
<tr>
<td><img src="image" alt="" /></td>
<td><img src="image" alt="" /></td>
</tr>
<tr>
<td>V: &quot;One by 'x' should be equal to five&quot;. At the same time writes, making clear the coefficient 1 of 'x': $1x = 5$</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>IV.27 $9x + 33 = 5x - 17$</th>
<th>Obs.: In the areas comparison V draws some more lines in the incomplete figure. This stage and the written form of the simplified equation are almost mixed up, due to the speed with which V completes them. From V's manner of writing the simplified equation, making very clear the coefficient 1 of 'x', it could be said that this equation is very close to the context of the model (1x represents an area). Very probably V solves this equation through a specific fact.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Construction of the simplified equation</td>
<td></td>
</tr>
<tr>
<td>V: &quot;Four plus seventeen&quot;. She writes $4 \times 17$.</td>
<td></td>
</tr>
<tr>
<td>V: &quot;... Times 'x'?&quot;.</td>
<td></td>
</tr>
</tbody>
</table>
Also, in M's performance with the model, abbreviation processes are observed, but in this case such processes tend to not merely automate the actions in the 'concrete' model (as is observed in V's case), but to extract the syntactic elements present in these actions, so they can, in turn, be modeled in a more abstract language and thus make it possible to detach herself from the semantics of the more concrete model.

A syntactic tendency

In M's case, her very concern about finding syntactic rules for the resolution of the new equations leads to a reflection on the actions that are always performed, one case after the other, and this presupposes (as in V's case) an abbreviation process of such actions. The search for syntactic rules is carried out, in this case, by describing the actions in a more abstract language: such a description requires a synthetic version of the actions.

This synthesis of the actions is achieved through an abbreviation of the resolution process, both in the concrete model and in her translation into the more abstract language. During this translation process, graphs are created (arrows as personal codes) that do not belong to either algebra or to the context of the 'concrete' model. These personal codes allow M to understand, orient, and represent the operations outside of the model, although it should be pointed out that such extra-model representations have the defect of not being adequate ways of representing the result of the operations. Such a representation appears in terms of the operations that led to a simplified equation, without making it clear that it (the simplified equation itself) is a final state of those operations. This situation (having in mind just the operations), very frequently leads to an aberrant operation between terms of different degrees.

M's resolution examples:

<table>
<thead>
<tr>
<th>IM11</th>
<th>$15x + 13 = 16x$</th>
<th>$15x + 13 = 16x - 15x$</th>
<th>Obs.: The fact of not registering 'x' as a part of the result of subtracting terms in 'x' (15x and 16x), leads M. to effect an aberrant operation between terms of different degrees: one (x) plus thirteen.</th>
</tr>
</thead>
<tbody>
<tr>
<td>M. &quot;Sixteen x minus fifteen x is one; then, one plus thirteen is fourteen&quot;</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>IM13</th>
<th>$129x + 51 = 231x$</th>
<th>$129x + 51 = 231x - 129x = 102x$</th>
<th>Obs.: M develops her own code of signals in order to leave written traces of those actions that have already been done, as well as those to be performed and of intermediate states in the resolution of the equation:</th>
</tr>
</thead>
</table>
Different Tendencies

The antagonism of these two tendencies (V’s and M’s) becomes clear by merely observing their respective interviews. However, from their comparative analysis a couple of remarks regarding the aspects that are common to both cases, deserve to be emphasised. On the one hand, 1) it can be seen that in spite of the aforesaid antagonism, there is a common tendency to abbreviate the processes (following, in each case, its’ own execution path), and on the other hand, 2) during such abbreviation processes a number of obstacles and errors, also common, are generated, and can be considered as typical in the later syntactic handling of symbolic algebra. In one case (V’s), the abbreviating tendency consists of trying to lighten the operations performed in the model, while staying within it. To this end, attention must be given to the actions (translation, comparison, etc.) that are performed again and again. This reflection, in turn, leads to an abbreviation process of such actions. It is through this abbreviation that some parts of the concrete model are lost. On the one hand, 1) the “bottom of the terrains”, (the linear dimension which corresponds to the unknown), is a situation that leads to hiding the operation of the unknown. On the other hand, 2) the area condition of the constant term is also lost, as well as its’ operative handling. This provokes a tendency of performing the addition of ‘x’ with the terms of degree zero, resulting in the aberrant operation that has been formerly pointed out between terms of different degrees.

SYNTACTIC ERRORS

The generation of the same type of syntactic errors in the two cases discussed here is not accidental and can be explained from a more general level of analysis. In teaching by means of models there is the danger that the main virtue of any concrete model (namely, that of seeking support in previous knowledge) becomes the main obstructor
in the acquisition of such new knowledge. In the cases of the children interviewed, whom are left to develop by themselves the use of the geometric model, it happens that the model component which tends to abbreviate, and therefore, to hide the operation of the unknown, will persist in both cases. In cases such as Vs’, subjects possessing a strong semantic tendency have this happen due to the fact that the automation of actions in the model weakens the presence of the unknown throughout the procedure. In cases such as Ms’, this tendency is due to the effects of the creation of personal codes, to register intermediate states of the originally proposed equation. Corrections, in each case, are of a local nature and according to the subjects’ tendency. Thus, when there exists a leaning towards staying in the model, the correction of the syntactic aberration mentioned above is performed in the model itself, for only the model semantics can make such an aberration evident. On the other hand, in the case of a syntactic tendency, the correction takes place currently with other events in the syntax, namely, an essential modification of the notions of equation and the unknown.

GENERAL DISCUSSION

By way of conclusion, the interaction between semantics and algebraic syntax which takes place along the abstraction processes of operations performed with algebraic objects (that have been given meanings and senses within the context of a concrete model) is modulated when learning the algebraic language by tendencies in the subject and by features of the specific model being used. There are, however, some aspects of such an interaction that remain constant when changing the subject’s tendency factor, or the type of model. These essential aspects in the relationship between semantics and algebraic syntax reflect, in turn, essential aspects of another interaction, the one occurring between the two basic model components: the reduction to the concrete, and the detachment from the semantics of the concrete. The transference of the problem, semantics vs. algebraic syntax to a level of model actions allows one to close the existing teaching gaps between these two algebra domains. The analysis of this interaction between semantic and syntax at this new level, points to the necessity of intervening through the teaching model at key moments at the beginning of algebraic language use.

In a forthcoming paper we will indicate how this dialectic semantics/syntax; the theoretical description of the relationship between the deep and superficial forms; the generative and transformational aspects to describe the grammar (see Kirschner, D. 1987 and Drouhard, J. P. 1992) of algebraic mathematical sign system syntax, can be linked with the explanation of why errors are committed when following a rule is needed to utilize one or more previous and competently used rules.

Abstract:

This paper describes a study in progress that examines development of the teacher’s proficiency in managing a whole-class discussion in the context of her experience of teaching students in an inquiry-based learning environment. Discussion segments of two lessons by one teacher with the same class, which were conducted a year and a half apart, are analyzed. We suggest elements of a structure for discussion orchestration. Using these elements for the micro-analysis of the lesson segments we demonstrate a possible evolution of teacher proficiency.

BACKGROUND

The study presented in this paper focuses on the development of the teacher’s proficiency in managing a whole-class mathematics discussion. This type of teachers’ endowment is central for many reform-oriented curricula that establish, strengthen and broaden conjecturing, exploration, and investigation procedures in the mathematics classroom (e.g., Ball, 1992; Lampert, 1990; Lampert, 2001; Schifter, 1996; Yerushalmy, Chazan & Gordon, 1990). Teachers are no longer considered the central source of mathematical truth, but rather act to support students by creating problem-solving situations, to acknowledge the value of students’ ideas and to respond to them. As the nature of the mathematical task moves towards exploration, the structure of a whole-class discussion changes as well.

In such a classroom students and their teacher share their roles in the classroom, i.e., the teachers and the students listen to each other, reflect on and clarify others ideas, perform representation translations, and provide explanations (Lampert, 2001; Forman & Ansell, 2001). We believe in the possibility of (almost) symmetrical roles of teachers and students in classroom discussion, however we assume that sharing roles between a teacher and the students depends heavily on the teacher’s proficiency. We assume that a teacher without an experience in orchestrating a classroom discussion would be more dominant and less open to students’ needs. This study stems from the standpoint that teaching provides many important opportunities for professional development (e.g., Ma, 1999) and examines how discussion orchestration changes through teaching experience.

In their analysis of the discussion orchestration Forman & Ansell (2001) demonstrated that I-R-E (initiation-response-evaluation) social participation structure of the traditional classroom suggested in the 1970s (e.g., Mehan, 1979) does not reflect the structure of discussion orchestration. A discussion can contain several different patterns of interaction, so that there may be several possibilities with respect to IRE structure (e.g., it
Variations in discussion structure are closely connected to the variations in roles of students and teachers in such a discussion. In inquiry-based discussions there are shifts toward teachers' reflectivity and flexibility. In this study we try to detail these shifts in terms of teacher's discussion actions.

Research on mathematics teachers' education demonstrates the importance of flexibility, deepness and connectedness of teachers' mathematical knowledge (e.g., Ball, 1992; Lampert, 1990; Schifter, 1996). Ball (1992) establishes teacher knowledge about the nature and discourse of mathematics as essential part of teachers subject-matter understanding. Jaworski (1992) defines the essence of mathematics teaching as being placed in three domains: the management-of-learning, sensitivity-to-students, and mathematical-challenge. This study tries to analyze development of teachers' proficiency of managing the whole-class student-sensitive discussion through presenting students with challenging mathematical questions.

THE PURPOSE AND THE QUESTIONS

The purpose of the current study is to characterize teacher's actions in the inquiry-based classroom discussion and to analyze changes in the teacher's actions over time in order to identify what kinds of teacher behavior makes discussion more effective, reflective and flexible. In this paper we focus on two questions:

(1) What are the main types of teacher actions in the inquiry-based classroom discussion?
(2) How do these actions change in the course of teaching practice?

METHOD

The teacher: Shelly -- the first author of this paper -- was a beginning teacher, having graduated with her B.Ed. three years before the experiment in her classroom started. During first three years of her teaching career she took part in a professional development program for elementary school mathematics teachers. The course was focused on inquiry-based learning of mathematics. During the second and the third years of the professional development program she joined a development team that specialized in materials for an inquiry-based mathematics classroom (Fridlander, 1997; Fridlander & Rota, 1996). At the end of the professional development program, Shelly started experimental implementation of the new learning materials. Our study considers Shelly's teaching experiment (Cobb, Wood & Yackel, 1990) during two years and the development of Shelly's proficiency through teaching.

The data: Overall about 20 of Shelly's lessons were videotaped during the two years of the experiment for the purpose of the formative evaluation of the teaching materials. Thus at that time she was not aware of the possibility of using these data for the purposes of the current study. For the purposes of this study, three of 20 lessons with the same group of students and very similar in their structure were chosen. This paper presents analysis of teachers discussion actions during these three lessons and analyzes changes in the teacher's actions using 10-minutes segments from two of these three lessons, which were 1.5 years apart. The first lesson took place when the students were in the middle of the 2nd grade (January, 1993), the
second lesson took place when the students were at the end of the 3rd grade (May, 1994).

**Lesson structure:** As noted above, the two lessons have very similar structure including three main stages: Introduction, Inquiry, Summary-discussion. In the very short introduction stage Shelly presented students with the problem. During the inquiry stage the students worked in small groups and Shelly helped them to progress in their investigation when the help was needed. The last stage of the lesson, which is under investigation in this paper, is the whole-class summary-discussion. During this stage the students from the small groups shared results of their investigations with the whole class, they made conjectures, discussed them, compared different solutions of the problem and tried to come to a conclusion. The teachers’ role in this setting was helping students make progress in their presentations, generalize the results and finish the lesson with shared mathematical meaning. Mathematical tasks for both of the lessons included series of questions that were under students’ investigation. Below we present mathematical tasks that were at the focus of the discussion in the segments of the lessons considered in this paper.

**Task for the segment from the first lesson:** In this task (from Dice activity: Fridlander & Rota, 1996) the children investigated the relationship between a graph and the common property of the points in the graph. In this paper we refer to the part of the Discussion that was dedicated to the following questions (Figure 1).

![Figure 1: Task for the segment from the first lesson](image)

**Task for the segment from the second lesson:** In this task the children dealt with an unknown number of matches that satisfy a given condition (from Matches activity: Fridlander & Rota, 1996, see Figure 2).

![Figure 2: Task for lesson 2](image)

**DATA ANALYSIS AND RESULTS**

We would like to be precise in the description of Shelly’s flexibility. Thus, first we present main types of the teacher’s actions in her classroom and then analyze the changes that were found in Shelly’s discussion orchestration.
Main types of teacher’s discussion actions: During whole-class discussion Shelly performed different actions that composed her discussion orchestration. While students’ learning activities were mainly focused on solving a mathematical problem and were aimed at constructing students’ personal mathematical meaning, Shelly’s activity was mainly focused on solving teaching problems and on supporting students’ construction of the mathematical meaning. Based on Forman & Anse11’s (2001) statement that both the teachers and the students are “involved in revoicing each other and listening to, reflecting on, clarifying, expanding, translating, evaluating and integrating each other’s explanations”, we tried to zoom in the transcripts of the discussions and to identify precisely main teachers’ and students’ discussion actions. We first defined three main classes of the discussion actions: class of Stimulating Initiation including actions that begin discussion of a new mathematical question; class of Stimulating Reply including actions that stimulate continuatioin of a discussion and are connected to prior utterances; and class of Summary Reply including actions that finish discussion of a particular question. Second, based on our analysis of the transcripts of the three lessons, we defined possible teaching discussion actions. We (the two authors of the paper) defined these categories of actions independently, discussed the terminology and agreed about the following categories to be used in the further analysis. Note, that in this paper we present the part of the study that analyses teacher’s discussion actions only.

Questioning: In this category we included utterances in which Shelly presented students with a problematic situation and invited students to find a solution to this situation. In other words, posing a problem, starting a new stage of the discussion, changing a problem under consideration were all attributed to the questioning category. A teacher may ask a question that was planned or may refer to (reflect on) a student’s conjecture, statement, or difficulty. Thus, questioning category was subdivided into different sub-categories according to their purposes in the course of the discussion (e.g., Opening questions, like “Who is ready to present his solution?” Promoting questions, like “And then what did you do?” Clarification questions, like: “Why did you take [this numbers] one and two?” or “What can you tell about the points on this diagonal line?” or “Let’s check whether this results is correct.”). Note here that the teacher’s utterance was categorized as questioning without relation to its semantic structure. Mainly questioning appeared at the two stimulating stages. Note also that in our segments “Stimulating Initiation” appeared in questioning form only.

Translating a representation: Teacher’s action in which she performs symbolic or graphical representations of students’ utterance, like writing and drawing on the board were considered as performing translation between representations. In our segment this category was usually accompanied by constructing a logical chain.

Constructing a logical chain: These teacher’s actions include a chain of the type “if – then”. Initially, this category was considered a complex explanation but at the later stage of the analysis complex explanations were subdivided into translating representations and constructing logical chains.

Repeating students’ utterance: A teacher repeats exactly what a student said. This action was performed for different purposes, e.g., to continue discussion, to stress the student’s
idea, to invite students to think about the correctness or the conjecture. Thus according to
the purposes of the repetitions they were subdivided into other subcategories.

**Hinting:** In some situations, when Shelly felt that the discussion was stuck, she tried to
help students to move forward in their reasoning mainly by means of *connections* with
other similar cases in which they applied a similar problem-solving strategy or algorithm.
For example: “Think how I usually write this”.

**Stating a fact:** In this category we included teacher’s statements of mathematical or
metamathematical facts.

**Providing feedback:** Teacher’s reflective evaluation of students’ solutions was included in
this category of teachers’ actions.

Figure 3 demonstrates the coded transcript of the segment of discussion in the second
lesson.

Figure 3: Example of the coded transcript (from discussion in lesson 2)

**Changes in teachers' actions over time:** After defining the categories we turned back to
the transcripts and coded teachers’ actions in the two transcript segments (each 10 minutes
long) independently (see example in Figure 3). Ninety-three percent of discussion actions
(of the total number of teaching discussion actions) were coded identically by the two
coders. The other seven percent were discussed in order to achieve an agreement on the
coding. We applied the Shoenfeld (1985) analysis schemes to solving the teaching
problems. Figure 4 presents micro time-line analysis of Shelly’s discussion actions
embedded in the transcripts. The scale along the horizontal axis indicates time. Ten
minutes of each segment were divided into 300 units of two seconds. The labels along the
vertical axis indicate different teachers actions at the different stages of the discussion.
Figure 4 provides visual support for our suggestion about development of teacher’s proficiency in managing a whole-class discussion. We may see that during the second lesson Shelly was listening to the students more while the students were more active participants of the discussion. We may see that Shelly is less active at the stage of stimulating initiation thus we may suggest that students had more possibilities to initiate discussion. We see only a few summarizing actions that Shelly performed during the second lesson discussion. The nature of the actions at this stage also changed. At the stage of summarizing reply during the first lesson Shelly repeated students’ utterances, translated representations and stated facts whereas in the second lesson she mostly provided (positive) feedback to students’ actions. At the stage of stimulation reply during the second lesson Shelly provided fewer hints and asked fewer questions than in the first lesson. At the same time Shelly repeated students’ statements, and provided more feedback as stimulating reply. In her reflective analysis of the lessons Shelly points out that during the second lesson she felt more secure in basing the discussion on students’ conjectures whereas during the first lesson she felt she needed to proceed according to her initial planning.

Overall we found that Shelly was much more flexible during the second lesson; she was able to change her initial plans in terms of ideas the students presented, and was able to show more trust in her students. This changes in flexibility we describe in terms of discussion actions that were differently distributed between and within the three main classes of actions.
We defined four large categories of teachers discussion actions that we referred to as classes of actions. Two of these classes were subdivided into seven categories of teacher's actions (see Figure 5). Our categories are consistent with Lampert's (2001) description of management of a whole-class discussion in which she divided her lesson into episodes according to the teacher's roles in the discussion and with Forman and Ansell's (2001) social participation structure of the classroom. In terms of Lampert all these teacher's actions were aimed to lead students into new mathematics territory (see Figure 5). As noted earlier, we consider teacher's and students' roles in the inquiry based classroom to be almost symmetrical, thus in Figure 5 all the actions are attributed both to teachers and to students.

Figure 5: Discussion actions

We provided a microanalysis of the structure of the discussions in two lessons by the same teacher with the same students one-and-a-half years apart. These micro-pieces of the discussion actions were integrated into the whole picture for the further analysis. During the first lesson the teacher was at the beginning of her experience of managing the whole-class inquiry-based discussions. Development of the teacher's experience of managing the whole-class discussion developed in the course of her teaching experience without any professional-development intervention. Thus we consider our findings to be an indication of the act of teaching being an opportunity for teachers' professional development. The type of analysis that we suggested in this paper provides additional evidence of how teachers may orchestrate classroom discussion. We tried to describe what it means that the teachers become more reflective and more flexible when orchestrating the whole-class discussion.

In this study we applied Schoenfeld (1985) schemes of analysis of solving mathematical problems to solving teaching problems (in terms of Lampert, 2001). Furthermore we would like to pose the following analogy between mathematical problem solving and teaching problem solving. As Schoenfeld (1985) found that one may effectively teach algorithms whereas it is difficult to teach the heuristic for when to apply the proper algorithm. This
use of heuristics distinguishes the expert problem-solver from the novice. We suppose that teacher actions may be teachable; however, it may be difficult to teach a teacher when to apply a particular teaching action. In this sense we would like to speculate that teacher actions are of heuristic nature, i.e. are not describable by algorithms. At the same time we suggest that our categories may serve as benchmarks in planning and analysing discussions and may be useful in different professional development programs for mathematics teachers that focus on the issue of whole-class inquiry-based discussion.

SOLUTION OF WORD PROBLEMS THROUGH A NUMERICAL APPROACH. EVIDENCES ON THE DETACHMENT OF THE ARITHMETICAL USE OF THE UNKNOWN AND THE CONSTRUCTION OF ITS ALGEBRAIC SENSE BY PRE-UNIVERSITY STUDENTS

Guillermo Rubio
Universidad Nacional Autónoma de México. CCH Sur.

In this document, a didactical proposal based in a method to solve arithmetic – algebraic word problems which uses a numerical approach is showed. The method serves as a mediator between the arithmetical and algebraic methods revealing three different uses of the unknown, namely: the "arithmetical unknown", the "numerical unknown", and the "algebraic unknown." Evidences obtained in a case study are shown, and such evidences present the need to make pre-university students face problems conveying to the use of a "numerical unknown." Then, students can achieve the detachment of the arithmetical use of the unknown, construct its algebraic sense and move forward in the competence of solving word problems through algebra.

This investigation is part of a more than 10 years project in which a problem solving approach to pre-university algebra it has been fostered. Some others results can be observed in (Rubio, 1990; Filloy & Rubio, 1993; Rubio, 1994; Filloy, Rojano & Rubio, 2001). The evidences presented hereby are linked to the performance of 15-16 year-old students in tests, clinic interviews and their work in the classroom by using a didactical proposal based in a successive explorations method to solve word problems where numerical values are assigned to the unknown. The purpose of the use of numbers is that they serve the student to: a) facilitate the analysis of some families of problems; b) detach the sense of the arithmetical use of the unknown that students tend to use when solving word problems; and c) advance in the construction of the algebraic use of the unknown through the use of a method that allows the student to give sense to the operation of the unknown of a problem, following a process in which it is operated with a numerical representation of the unknown in the first place, and then with a letter, as specified by the algebraic method to solve problems. It is considered that an unknown has an algebraic use sense when it is operated with the letter it represents.

The numerical approach used by the successive explorations method does not have as central objective that one student must solve a problem with numbers, but to facilitate its analysis, help to construct and give sense to the operations between the elements of the problem, and achieve its representation and solution algebraically. The method was conceived as a didactical device from which the student is detached as it acquires greater competence in more abstract uses of the algebraic language. In fact, it can contribute with elements to close the gap existing between the syntactical...
development of the algebraic language – to which one generally tends in teaching – and the semantic one.

**REFERENTIAL AND THEORETICAL FRAMEWORK**

In order to structure the didactical proposal, central aspects of the false position method were taken into account (Bruno, 1939; Vallejo, 1835), as well as the stages established by Piaget (1979) in relation to the assimilation process of the real facts to the mathematical-logical structures in the development of theories constructed from the physical experiences verified by such theories. Besides, the successive explorations method in which the didactical proposal is based, the trend observed in many students regarding the spontaneous use of non-algebraic methods were taken into account, such as the trial-and-error method to undertake several families of arithmetic/algebraic word problems.

The numerical approach of the method is connected from an epistemological point of view with: a) the two first stages described by Piaget (1979) and; b) the first indications about the actions to be made in order to apply the false position method (*Regula Falsi*). Piaget argues that those stages precede the data translation to the system equations (stage 3). The first one, the establishment of facts or data from the real world is not independent of mathematics modeling such as: classification, relationships, correspondences, measurement, etc. The second one is oriented to the search of an explicative model of the facts or data of the actual world starting from the construction of an intuitive and qualitative scheme. The numerical interpretation of the method captures both stages and its main purpose is to facilitate the settlement of the relationships between the elements of the problem, before translating the data, and its relationships to the equation representing the problem.

A critical historical analysis of the use of the *Regula Falsi* to solve problems in old text books was useful to incorporate its central ideas to the phases of the successive explorations method, which central aspect is the analytical intention of the use of numerical values to unchain the solution of a problem. The study of some of the problems solved with the *Regula Falsi* led us to conclude that its importance is due to the fact that it has an objective very similar to that of the algebraic method, which is to facilitate the analysis of problems and treat all of them in a similar way, as if they were the same problem (different to the arithmetical method in which each problem is analyzed case by case, in a particular way). The *Regula Falsi* (e.g. Bruño, 1939) starts by considering the problem as solved, but instead of using a letter to represent to unknown as in the algebraic method, a numerical value is proposed as a possible solution, using it later to make all the operations indicated in the problem; finally the *Regula Falsi* ends with the settlement of a proportion that leads to the solution of the problem. This last aspect was not incorporated in the explorations method.

**METHODOLOGY**

The general project contemplated in its first stage an initial study during one school year in which the use of the method was observed in the classroom with 15-16 year-
old students and through the clinic interview of one girl student of the same age and school, but from another group. The main objective of this study was to improve the teaching model based on the successive explorations method. In the second stage of the project, a Case Study was carried out composed by six students whose clinical interviews were videotaped. Such students were chosen among 35 (15-16 years old) through a classification in classes based on their performance in three tests linked to three areas of competence: arithmetical problems; algebraic problems and solution of equations.

THE STUDY

The empirical investigation was focused in the study of meaning processes given by pre-university students to the unknown when they face some families of arithmetic / algebraic problems. The case study tried to find evidences regarding the changes of the use that students give to the unknown when facing problems which nature is "more arithmetic" than algebraic or vice-versa. The empirical work revealed the need to distinguish three different senses of use of the unknown: "arithmetical unknown" when given an arithmetic use, that is, when not operating with it; the "numerical unknown" when it is assigned a numerical value and when operations involving this value are accomplished and the "algebraic unknown" when it is represented with a letter and it is operated with the latter.

It was observed that in order to construct the algebraic meaning of the unknown it is required that the student is successively detached from the senses of the arithmetical and numerical uses of the unknown, considering that there is a detachment in the sense of the arithmetical use, when in the solution of a problem it is used a representation of it (either a number or a letter). The study proved that in order to propitiate such a detachment, it is required to face the student to problems which arithmetical solutions are complex or need a competence in arithmetic at an expert level. On the other hand, the detachment from the numerical use of the unknown is induced by the whole structure of the successive explorations method, where one starts operating with the "numerical unknown" and ends with the algebraic solution of one equation where the letter representing the unknown of the problem is used.

Briefly, in the study we try to evidence that the use of a "numerical unknown" can propitiate that the student detaches from its arithmetical use and begins the construction of the "algebraic unknown". It is thought that this is due since the "numerical unknown" facilitates the analysis of problems, where the relationships between their elements are established between numbers and where it can be seen that the numerical relationships between the elements of the problem not only have more semantic load than the algebraic ones, but also that one can use the unknown in them, although such unknown is "numerical", within an analysis process "moving forward" as in the algebraic method where one operates with a letter.

The observation of the solution processes in the case study allowed us to obtain evidences about the moments and situations conveying the student to leave the
arithmetical use of the unknown and those situations in which the student constructs a pre-algebraic or algebraic use. The latter was achieved by facing the student to problems of such nature that their arithmetic solution is complex, but by also giving him/her a way that leads him/her to the algebraic use. In the study can be seen that the use of a "numerical unknown" helps to fulfill the aforesaid since it facilitates the analysis of the problems and the settlement of relationships between their elements by operating first with numbers and then with the "algebraic unknown" when solving the equation obtained in the last phase of the successive explorations method.

It is also evidenced that in order to achieve that one student be competent in the algebraic method it is not enough that he/she detaches from the arithmetic and algebraic uses of the unknown, and that even he/she represents a problem with an equation, but that it is also required that he/she progressively advances in the competence to solve algebraically the equations that arose by following the phases of the successive explorations method and then, progressively, of the algebraic method.

THE SUCCESSIVE EXPLORATIONS METHOD

The method consists in six phases, each one with an objective of their own. The first three are basically pre-algebraic and have as paradigm the false position method (Bunno, 1939; Vallejo, 1835). With them, it is intended that the student: a) recognizes that in the problematic situation exists the presence of something unknown that can be determined by considering the limitations of the problem; b) uses a "numerical unknown" to settle the relationships between the elements of the problem through a numerical operations; and c) compares two amounts representing the same thing in the problem in order to construct the sense of the algebraic use of the equal sign (Kieran, 1981). The objective of the other phases is the construction and solution of the equation representing the problem.

To represent its phases we will use an episode of Maribel's interview, a student that was not competent in the solution of problems with the arithmetical method, but that was competent in the solution of some families of problems with the algebraic method and others with the successive explorations method. It was observed that she was using this method when she was not able to understand the relationships between the elements of the problem and, regarding this, Maribel says in one part of the interview: "...when I find it difficult to understand things...I start to use ...to use the method that I took... thus I find out what is happening in the problem...".

The episode begins by showing an algebraic problem, the Problem of the Bottles: "350lt. of liquor must be bottled in 500 containers, some of them of 3/4 lt. and others of 1/2 lt. How many bottles of each type were used?"

Phase 1 demands that the unknown must be explicit. This is illustrated in the next:

Maribel: "...Yes...now I am taking out...which are our unknown quantities...[She writes one below another of the unknown quantities: No. of 3/4 lt. bottles and No. of 1/2 lt. bottles]."
Phase 2 asks for the assignation of a numerical value to the unknown as a hypothetical solution of the problem, which allows the generation of the problem’s operations. Let’s see this:

Maribel: ...Now I am going to...suppose...a value...to see if from there...I can go to one equation.
Interviewer: ...What are you going to do?
Maribel: There are 500 containers...I guess we have 200 here... [She uses this number as a “numerical unknown” and points out where she wrote “No. of 1/2 lt. bottles].

The use of a “numerical unknown” is now helpful to Maribel to construct and give sense to the relationships between the elements of the problem as follows:

Maribel: ...I multiply 200 containers by 1/2lt...and I have ...100 litres...[This represents the litres in the 200 bottles]. Then she adds: ... I have 500 containers...then...there must be here...300 of...[She points out the other unknown: No. of 3/4 it. bottles]

Interviewer: That’s it...How did you get it?
Maribel: I got it from...subtracting 200 from 500...then multiply 300 containers by 3/4 lt. ...that would be...75lt...[This value representing the litres in 300 3/4 lt. bottles, but she forgot multiply by 4].

Phase 3 prepares the path of the equation. It requires the comparison between two amounts representing the same thing in the problem. In the interview,

Maribel: ...They are 175 litres...which is not the same to 350... [Maribel compares two amounts representing the total of litres to be bottled in 500 containers].

Interviewer: ...Isn’t it the same?
Maribel: ...No...then I get from there my comparison ... [She writes: 175lt. = 350lt? and below each of these numbers their meaning in words.]

Phase 4 indicates that it is necessary to work backwards starting from the comparison: A=B? recovering the operations made with the purpose of getting a “numerical pattern”. Let’s illustrate it:

Interviewer: Now...What do you do?
Maribel: ...I recover operations...the 175 came out...of the addition of 100 plus 75...the 100 came out of...200...which is the value I supposed by...1/2 ... and the 75 came out of ...300 by...3/4...[While speaking, she wrote the operations and obtained the numerical expression: 200×1/2+300×3/4=350?]. After reading what she wrote Maribel adds: But the 300 came out of...the subtraction of 200...minus...well...500 minus 200... [When saying this, the student wrote the numerical pattern: 200×1/2+(500-200)×3/4=350?]

Phase 5 requires the use of a letter in order to represent the unknown, as well as the construction of the equation of the problem from the numerical pattern obtained in the previous phase, as follows:

Maribel: In order to get the equation...we say that “x” is equal to the 1/2lt. bottles that...are used...and we substitute the supposed value... [We can see that the letter is used here as a name]
Interviewer: That is...the “x” is the same as the supposed value?...
Maribel: You can say so, yes, because...with the “x” we are giving...a supposed value
Interviewer: The “x” is two hundred?
Maribel: No...
Interviewer: So? ... the “x”...What is it?...
Maribel: The “x” is the exact 1/2 lt. bottles used to bottle one part of the 350 litres ...

When saying the abovementioned and writing: \( \frac{1}{2} x + (500 - x) \times \frac{3}{4} = 350 \), Maribel is detached from the sense of the numerical use of the unknown that fosters the successive explorations method.

**Phase 6** asks to solve algebraically the equation obtained. In the interview:

Interviewer: ...What do you do to find out the value of “x”? She says:
Maribel: The “x”...I solve the “x” to know its value...that is to say...I solve the equation

### THE “ARITHMETICAL UNKNOWN” AND “NUMERICAL UNKNOWN” IN EDGAR’S INTERVIEW

**The use of an “arithmetical unknown”.** This student was chosen because he showed competence to solve some families of problems with the arithmetical method and others with the algebraic one. Besides, it was observed that even though he didn’t use the successive exploration method’s phases systematically; he supported himself above all in the numerical exploration to unchain the analysis of complex problems. An episode of Edgar’s interview is shown as follows, where we can see the solution of a problem, through the arithmetical method and the arithmetic use of the unknown, (“arithmetical unknown”).

The episode begins showing the Perfume Problem: "How many millilitres of perfume essence must be added to 60 millilitres of alcohol to get a lotion with 70% of perfume?". Once Edgar has read it he says:

Edgar: ...We have 60ml. of alcohol...and we need it to have 70% of perfume...then the other 30% missing here...it is supposed to be covered by alcohol...then...because there are 60ml...they are divided by 3... [Edgar writes: 10% — 20ml] ...each 10% of the mix...they will be 20ml...then...a 30% is 60ml...a 10% will be...20ml... Then...I need them to be 70% of perfume...I multiply 20 by 7 ...it will be 140....millilitres...of perfume [This is the value of the arithmetical unknown. It is observed that Edgar does not operate with such unknown].

**The use of a “numerical unknown”.** In the following episode of the interview it is observed how Edgar detaches from the arithmetical use he was giving to the unknown in the Perfume Problem presented to him a few minutes earlier by posing him a problem which complexity leads him to use one “numerical unknown” to facilitate its analysis and where he uses numbers with this representation of the unknown to obtain the relationships between the elements of the problem. Then, the
The student supports himself on the numerical representation of the problem to give an algebraic sense to the unknown and to get the equation representing the problem.

The episode begins by presenting the student the Problem of the Perfumes' Factory: "In one perfumes factory are two containers, one with 18% concentration of Chanel and the other with 43% concentration of Chanel. How many millimetres from each container must be used if a 12ml bottle is needed and which must have a concentration of 36% of pure Chanel?"

In the study of cases, it was observed that when the student always expressed explicitly the unknown quantities of the problem, it was the first signal that he/she was not going to use an "arithmetical unknown" to solve it. This is evidenced when Edgar draws three containers and says:

Edgar: ... How many millilitres... will be taken out from each container to fill this one...Right?...[He points out the 12ml bottle]...once again we do not know how many millilitres are here...[He points out the containers with 18% and 43% of perfume]. Then, Edgar adds: ...We have to pour from both containers...but they are in different concentrations...then...they are 12ml...let us suppose...if we pour half of it there will be...18% from the first one and 43% from the second one...then...out of this 12ml...we will take 6ml of each container...right?...

Edgar: Yes...half and half...then...of the first container, from the six millilitres ["numerical unknown" value] we took...we know that...one 1.08 [He multiplies the "numerical unknown" value by 0.18]...will be perfume and from the second container...2.58ml. [He multiplies 6 by 0.43]...will be perfume...then...once putting together what was taken from both containers...there will be...3.66m1. of perfume...in the 12ml bottle we are going to fill...

Interviewer: Is there anything else you have to do?
Edgar: Now...we have to see if this...[He points out the 3.66m1 of perfume] is the 36% of this amount...[He points out the 12ml bottle]...now...we will get the 36% of 12...we see that...it is 4.32...which is incorrect...because it must be 3.66...[3.66m1 is compared to 4.32m1 which are the two amounts representing the same in the problem, phase 3 of the method].

After doing this, Edgar assigns other values to the "numerical unknown" and gets the pattern: 8×18/100 + (12-8) × 43/100 = 12×36/100 and as of such pattern he constructs the following equation: x×8/100 + (12-x) × 43/100 = 12×36/100. It is observed that in a first moment, the "x" is used as a name, but already being under tension with an algebraic use since the letter arose from a "numerical unknown" which has been operated. The tension ends with the algebraic solution of the equation.
CONCLUSIONS
As it can be observed in the episodes of Maribel’s and Edgar’s interviews, the numerical approach to solve algebraic-arithmetic word problems proposed can be used as a bridge between the arithmetic method which is tended to be used even in the university level (Ursini & Trigueros, 1997) and the algebraic method. The use of the successive explorations method revealed several aspects: a) the need to distinguish and characterize three senses of use of the unknown (“arithmetic unknown”, “numerical unknown” and “algebraic unknown”); b) the need to pose problems propitiating the student to detach him/herself from the use of an “arithmetical unknown”; c) the possibility to achieve this by using one “numerical unknown”, since this unknown is less abstract than the algebraic one; d) the possibility to unchain the analysis of some families of complex problems by making easier the settlement of the relationships between the elements of the problem with the use of numbers instead of letters; and e) the possibility to prepare the construction of the algebraic use of the unknown and of the algebraic method by connecting them to the syntax of the algebraic language.

Abstract
In this paper, the authors propose constructions in the Cabri-Geometre environment to approach activities of proportionality. The proposal builds upon a prior experience with students in México who had completed elementary education. Those students worked on the topics of ratio and proportion through teaching models that had been designed based on recognizing some cognitive components. We attempt to translate our reflections to the role that dynamical geometry can play in the teaching of notions such as ratio and proportion.

Introduction: Proportionality in basic education research
The themes of ratio and proportion are fundamental in school teaching. Hence, these topics have been subjected to study by different educational researchers. In spite of advances in this area of educational research, it is necessary to go deeply into its study, especially in relation to the implementation of new technologies in the mathematics classroom.

Piaget explored proportional thinking. He conducted longitudinal studies of the stages of cognitive development through the stage of formal operations. Specifically, Piaget’s findings led to understanding the foundations of the treatment of the ratio and proportion themes. Piaget (1978) pointed out that individuals could construct the scheme of qualitative proportionality when they understand that an increment in an independent variable yields the same result as a decrement in the dependent variable. That is, when subjects realize that an element of counterbalance is required.

Other research studies focused on the needs of instruction. For instance, Hart (1988) pointed out that proportional thinking is present in the adolescent and that its most advanced level is accomplished once the adolescent has constructed certain concepts. For Hart, some levels of generalization, such as the handling of ratios or ways of generating equivalences, occur when multiplicative strategies are used. Moreover, Freudenthal (1983) and Streefland (1984, 1990 and 1991) combined didactical aspects with the mathematical reflection about ratio and proportion. These researcher reports allow us to contemplate their contributions to these fields. Based on the cited studies, it is possible to create an instruction design under a constructivist approach.

Proportionality and curriculum: The contribution of the new technologies
It is necessary to analyze and classify the areas of knowledge, mathematical and transversal to the discipline, on which the understanding of the concepts of ratio and proportion exercises a direct or indirect influence. Thus, it is very important to focus the theoretical reflections about those concepts from a curricular and formative viewpoint. In the light of that type of analysis, we can justify the importance of
teaching the topics of ratio and proportion by reasons such as the following (Fiol & Fortuny, 1990):

1. From the intermediate courses of elementary education (grades 4-6) throughout lower secondary education (grades 7-9), proportionality is the core for the unification of trends of notions in the learning of mathematics. Such notions include, among others: fraction and rational number, changing units of measurement and scale, distribution problems, percents, probabilities, graphs of linear functions, geometric theorems and similarity of figures, and the number π and the golden ratio.

2. Many concepts in physics and chemistry are associated to relations of proportionality. These concepts include nouns such as velocity, acceleration, density, and dilatation, and the formulation of laws such as Ohm’s law, Hooke’s law, or Proust’s law.

3. The notion of proportionality is also present at the end of elementary school in the programs of social sciences or geography under the form of population density, birthrate, reading of maps, and so on.

4. Proportionality also appears, as we have cited above, outside the realm of the sciences in specialties such as genetic epistemology (Inhelder & Piaget, 1955) and in the studies related to cognitive development.

In this same trend, other researchers such as Lesh, Post, and Behr (1988) emphasized that the teaching of ratio and proportion starts in elementary school and serves as a basis for the understanding of other concepts. Very often, it is necessary to resort to the recognition of similar patterns or structural similarity in different situations. Many of those later concepts are critical in fundamental knowledge of the sciences and mathematics, as well as for the solution of daily life problems.

The increment of the number of educative projects that include the use of a technological component is impressive. This situation motivates teachers and researchers to include new technological devices in their teaching activities. Hence, the translation of our reflection to the role that these devices can play in the teaching of notions such as ratio and proportion is immediate (Lupiáñez & Moreno, 2001). In this paper, we introduce some activities in the Cabri-Geometre environment of dynamical geometry. The designing of these activities was based on observations in a previous experience (which is described below) with students of elementary education.

A previous experience with elementary school students
The didactical program of the prior educational experiment initiated in January and finished in June of 2000. The problem situations that formed part of this proposal were associated to teaching model\(^1\) (Ruiz, 2000), which were experimented at different moments, as required by the development itself of the research study

1 Figueras, Filloy, & Valdemoros (1987). A teaching model comprises meanings—in the technical as well as in common language,— didactical treatments, specific modes of representation, and the relationships among them.
implementation. From two to seven working sessions were carried out per month, depending on the progress shown by the students and on factors external to the program implemented by the researcher. Each session lasted from one hour and a half to three hours; including the complementary activities, 25 sessions were necessary. The scheduling of the sessions is shown in Table 1 below.

The teaching proposal departed from qualitative aspects. Qualitative aspects are those based on linguistic recognitions for the elaboration of comparison categories, such as “big” or “small.” The intuitive component, which is the piece of information based strongly on experience, on practice, on the senses, is a part of the qualitative aspects. This approach was used so that the students could give meaning or signification to the concepts of ratio and proportion, and could make the transition from the qualitative thinking to the quantitative thinking gradually, without completely abandoning the qualitative aspects. This transition process was traversed by means of different situations and at different moments. Similarly, Kieren (1988) emphasized the transition from the concrete to the abstract: he pointed out that the intuitive component is not completely abandoned.

After that, an ordering appeared: when students made comparisons, they used the phrases “greater than” and “less than.” In the matter, Piaget (1978) pointed out that when the idea of order appears in the transition from the qualitative to the quantitative thinking, the concept of quantity is not yet present—what he called
intensive quantifications. Later, the pupils used measurements when doing comparisons. First, they contrasted parts of the body with objects, they superimposed one figure over another, and then they used a measuring instrument (conventional or unconventional). In terms of Freudenthal (1983), comparers can be classified in two modalities: direct or indirect. The direct modality of comparing occurs when an object is superimposed over another object, while the indirect modality occurs when there are two objects (A and B) and a third element (C) to make the comparison. Thus, a great step forward to come close to quantification was that students started to measure using natural numbers when doing comparisons. Measuring became a significant prerequisite for the use of multiplicative operators.

At a later moment in the development of the didactical experience, students established relations among magnitudes, worked in the set of natural numbers, and used fractional expressions as well. Thus, they started to work in the field of rational numbers in an elementary way. Eventually, students characterized “ratio” as the relation between two quantities, expressed as the quotient of one divided by the other, and “proportion,” as the equality between two ratios. This outcome coincides with the definitions given by Hart (1988).

Independently of the model under treatment, we gave special attention to the different modes of representation that students used when they were confronted to the proposed situations. We attempted that students could use any of the following three modes of representation indistinctively: pictorial, tabular, and numerical. For the purpose of illustration, in the following section we describe one of the models used; it was composed of two activities and was developed through several sessions with a sixth grade class of elementary education.

Activities of the model: “Soccer competition” and “Building your own football soccer field”

The first activity is to determine the ratios of different measurements of three football soccer fields in relation to the authorized measurements of a football soccer field, some values being given. That is, in the activity of the Soccer competition, students have to find out the measurements of three soccer fields given the length of one of them and the measurements for an official one, so that the four fields are proportional to each other.

A maxima problem is posed in the second activity: to construct the greatest possible soccer field in the playground of the students’ school so that it is proportional to an official soccer field. For this activity, Building your own football soccer field, students know the measurements of an official football soccer field and the actual measurements of the playground in their school.

In the two tasks, students determine proportions by working with the ratios they find. The dynamics of work varies as each activity develops: students are required to work individually or collectively. However, they always have worksheets where to make computations and write down their results.

The analysis of the activities allowed observing that the students could remember the authorized length and width measurements of a soccer field. They used a process of
halving these measurements, wrote the obtained quantities on the corresponding sides of rectangles they had drawn, and tabulated those same values. By contrasting with the measurements of their playground, they realized that it was possible to lay out on it different soccer fields proportional to an official one. Then they read the directions for this activity carefully and noticed that in addition to being proportional to an official soccer field, the one to be built in the playground of their school should be the greatest possible. They knew that the required values could not be greater than the measurements of the playground. After several trials, they found out that the greatest soccer field would be one with dimensions equal to the fifth part of an official one.

For their arguments, students made use of the three registers of representation mentioned above: they placed the obtained data in tabular form and drew rectangles. Students asserted that the rectangles they drew were similar because the ratios of their measurements were proportional. They handled ratio as a relation between magnitudes, using fractional expressions, and handled proportions as equality relations of ratios. They also used equivalent fractions to determine proportionality. They did not use the rule of 3: this rule was not taught by the researcher during the didactical sequence, neither by the teacher because it is not included in the official program of school mathematics.

**Activities of proportionality in Cabri-Géomètre**

Students in the last grades of elementary school have potentiality for the acquisition and handling of the notions of ratio and proportion, in a context coherent with their prior mathematical knowledge. This potentiality showed clearly in the light of results obtained throughout the development of the teaching proposal. Our proposal provides the setting for the activities described in the next paragraphs. Our aim is that students complement their learning with the observation and manipulation of representations made available by the dynamical geometry environment of Cabri-Géomètre. However, some of the tasks are better adapted for a continuation of work at the beginning of lower secondary education (grades 7-9), not for the level of elementary education (grades 1-6). We assume that students in both levels of education have acquired the basic skills for handling this software.

**Recognition of patterns.** In this first activity, students are shown a family of rectangles. These rectangles can be moved and superposed without deformation in the screen. Students are asked to pair rectangles of the “same shape,” no matter if these are of different size. Although this activity is clearly related to similarity of figures, the term “similarity” is not used.
The objective is that students arrange the rectangles according to their visual perception, and once they have done this, the measurements of the rectangles can be shown. After discussing whether there is a relation in the simple cases, such a relation can be generalized to all cases.

First measures. Computation of ratios. The objective of this activity is that students get to know the basic tools of the Cabri-Géomètre software and use them to work with ratios. For this purpose, students can draw line segments, measure them, and find out the ratios between their dimensions. Starting with these simple manipulations, important aspects of the system are brought into operation: taking measurements, manipulating units of measurement, and the possibilities of computation.

Construction of proportional and unproportional figures. The purpose of this activity is to introduce a criterion for the construction of rectangles proportional to each other. The rectangles must be constructed so that they share one vertex and their diagonals through it lie on the same straight line (Figure 2). If we move the vertex F on that straight line and keep record of the different measurements in a table, we can verify that the resulting proportion does not change, obtaining thus a whole family of similar rectangles. Likewise, in Figure 3 we can check that by adding the same constant to the dimensions of the sides of a rectangle, we do not necessarily obtain a rectangle proportional to the original one. After developing this task, it is now possible to confront the activity of the Soccer competition by implementing these criteria.
Another interesting method for finding a rectangle proportional to a given one is by using the center and the diagonals of the latter one. If the new rectangle has the same center and its produced diagonals coincide with the extended diagonals of the first one, both rectangles are similar, that is, the sizes of their sides are proportional.

Moreover, this type of constructions yields a variety of figures that remain equal to each other although proportions change, and many new possibilities of study arise.

*Similarity and homothesis.* In the first courses of lower secondary education, it is possible to introduce the invariance of similarity of figures under homothesis. This topic becomes especially easy and at the same time very illustrative in the Cabri-Géomètre environment: it is very interesting to see how moving the point $P$ generates families of similar figures (see Figure 7).
Conclusions
There are different activities for enriching and widening students' knowledge about the notions of ratio and proportion. The representation and visual verification of Tales theorem, the study of linear functions, and the computation and graphic representation of constants like π or the golden ratio can be used for those purposes. Additionally, some of those activities can serve as potent elements for motivation.

A PRACTITIONER MODEL OF THE SUCCESSFUL USE OF COMPUTER-BASED TOOLS AND RESOURCES TO SUPPORT MATHEMATICS TEACHING AND LEARNING

Kenneth Ruthven and Sara Hennessy
University of Cambridge Faculty of Education

This study analyses the pedagogical ideas underpinning teachers' accounts of the successful use of computer-based tools and resources to support the teaching and learning of mathematics. These accounts were elicited through group interviews with the mathematics departments in seven English secondary schools, conducted in the first half of 2000. The central themes are organised to form a pedagogical model, capable of informing use of such technologies in classroom teaching, and of generating theoretical conjectures for future research.

RESEARCH INTO COMPUTER USE IN SCHOOL MATHEMATICS

Although there has long been interest in the potential of computer-based tools and resources in school mathematics, their use has only recently become more established in mainstream practice. An indication of the extent of such use is provided by the recent international surveys (Beaton et al. 1996; Mullis et al., 2000). In the first, England was the system with easily the largest proportion of students reporting computer use. In the second, England was joined by Singapore, the system showing by far the most marked increase over the intervening period. Typically across systems, however, computer use remains low, and its growth slow. Against this background, it is not surprising that focused studies of computer use in school mathematics have largely examined explicitly innovative situations, usually linked to development projects of some type.

More recently -and very predominantly in the United States- studies have started to examine the evolution of computer use beyond situations of innovation, in circumstances where it has become more ordinary than innovatory, more established in operation than consciously under development. Surveys have provided a simple profile of the forms of computer use taking place, and of pedagogical orientations associated with them (Becker et al., 1999; Niederhauser & Stoddart, 2001). However, the reports of these surveys themselves highlight some of the limitations of employing preconceived models and questionnaire items to capture teachers' perspectives and practices. Case studies based on interview and observation have offered a useful complement to such surveys, providing more naturalistic and holistic accounts of the perspectives and practices of individual teachers (Myhre, 1998; Doerr & Zangor, 2000). However, the focus on individuals restricts the capacity for analysis across cases, and thus for building theories and models with stronger potential for transferability and generalisability.
DESIGN OF A STUDY OF TEACHER CONCEPTIONS OF ICT USE

The study to be reported here develops this line of enquiry into how teachers conceive their incorporation of use of computer tools and resources into mainstream mathematics teaching. It complements previous studies by extending such research to England, where the use of computer-based tools and resources, commonly referred to as information and communications technology (ICT), has been a component of the national curriculum for over a decade; and by following a somewhat different theoretical orientation, and employing correspondingly different methods.

Two intellectual traditions have influenced the theoretical orientation of this study. The first is a naturalistic tradition of research into teaching which has insisted on the necessity of attending to teacher thinking, not just as an important component of the phenomenon under investigation, but as a crucial source of constructs with which to build more potent theories (Brown & McIntyre, 1993; Cooper & McIntyre, 1996). The second tradition is a cultural psychological one concerned with collective systems and inter-subjective processes of thought, which emphasises not only the social dimension of thought, but the distinctive forms of everyday thinking (Moscovici, 1981; Wertsch, 1991). The concern here is to explore the content and form of ‘common sense’ thinking, focusing on public norms over personal variants.

The contemporary circumstances of teaching accentuate this stance. In England, the subject department acts as a basic unit within secondary schools for the formal organisation of teaching and the informal association of teachers. Recent educational reforms, too, have led to departments playing an active part in mediating between national regulations and classroom teaching, through the development of schemes of work. Hence, the unit of observation for this study was the school department, and the concern with shared systems of ideas.

The study drew on group interviews held with the mathematics departments in seven non-selective schools working in an established partnership with the university. Access to ICT in these departments varied considerably, but all made some use of it in their teaching. The interviews proceeded from a positive stance, with the main prompt requesting examples of ICT use which participants felt had been successful in supporting teaching and learning. The audio-taped sessions were transcribed and edited, and the resulting transcripts imported into a computer database to facilitate a recursive process of thematic organisation through constant comparison. This led to the construction of prototypical categories, grouping together related material. The goal was to identify well developed themes running across transcripts, and relationships between them.

THEMATIC ANALYSIS OF CONCEPTIONS OF SUCCESS

Initial analysis focused on the success themes which were explicit or implicit in teacher accounts. It appeared that these themes could be conceptualised in terms of three related priorities, concerned with securing and enhancing the participation of students in classroom work, the pace and productivity of such work, and the
progression in learning arising from it. Two quotations will be used to illustrate these success themes. The choice of these particular quotations reflects an emphasis on the part of the teachers. Although they referred to a range of ICT tools and resources, it was the use of various forms of calculator or computer graphing which attracted a disproportionate amount of comment. Equally, these particular quotations illustrate how these references to use of graphing technology covered the full age and ability range at secondary level: from the academically lowest class in the youngest age cohort; to the academically highest course in the oldest age cohort:

We've used spreadsheets in Year 7 and 8, to enable them to look at handling data, because they can quickly get tables and produce charts that are much better quality than those that they can produce themselves. I've got the bottom set in Year 7 and it can take them the whole lesson to draw a bar chart. So it's particularly successful from that point of view... because they don't have to draw all the axes so much, and it doesn't take them so long to develop the ideas because they're not having to spend a whole lesson drawing something. They can draw twenty graphs in a lesson and actually see connections, rather than spend twenty minutes drawing the axes and then twenty minutes talking and then twenty minutes drawing all the graph. [VC]

It saves a lot of time as well with the Further Maths and the graphing that we did. It would have taken forever to actually plot all the points and see what happens when you transform certain shapes. Whereas it was done in a flash and they could see and they learnt an awful lot. So then they were ready and they'd accepted it because they'd seen it happening... Whereas it would have taken many lessons if we'd actually plotted all these graphs, they'd have just got bored by it. So that definitely helped, just kept the pace going. [MC]

Both these quotations appeal to comparisons with similar activities conducted without access to computer graphing tools. Issues of participation are framed in terms of avoidance of disengagement ('twenty minutes talking') and demotivation ('just getting bored by it') on the part of students. Issues of pace and productivity are framed in terms of time saved and pace maintained ('it doesn't take them so long'; 'it saves a lot of time', 'it would have taken many lessons', 'just kept the pace going') and work produced ('they can draw twenty graphs in a lesson'). Issues of progression are framed in terms of ideas being formed ('actually see connections'; 'see what happens when you transform certain shapes') and embraced ('they'd accepted it because they'd seen it happening'), and in more general terms of development and learning ('to develop the ideas'; they learnt an awful lot').

**THEMATIC ANALYSIS OF CONCEPTIONS OF PROCESS**

These success themes provided a useful basis for further analysis to identify the technological affordances and mediating processes which teachers saw as underpinning these forms of success. From this further analysis, ten process themes emerged as prominent across the departmental interviews. These will now be outlined and sparingly illustrated (due to limitations of space).
The theme of Ambience enhanced associates ICT use with change, difference or variety in working ambience. This was sometimes a matter of change of working location -from ordinary classroom to computer classroom- and correspondingly of work organisation. Where technology use was seen as something of a break from 'routine', such motivational effects could be attributed to the novelty of the situation, or to the conferment of privilege. Typically, too, work in the computer classroom involved students interacting directly with a machine; but also, given the normal situation in which the number of class members was around double the number of machines available, students often worked not individually but in pairs. But even in an ordinary classroom, with teacher-led activities directed at the whole class, an interactive style of ICT use created a distinctive feel:

I've only this week been using a program, just a short one, for the students to input a number, which it then outputs following a rule, so they can try and spot the rule by choosing different inputs and seeing what the outputs are. They quite enjoy seeing things done in a different way. [VC]

It seems that it was such exploratory, interactive styles which led to ICT use sometimes being characterised -in a wholly unpejorative way- as ‘playing around’ and the devices themselves as ‘toys’. Teachers talked of the ‘variety’, of the ‘difference’, even of the ‘other dimensions’, associated with ICT use, and related these to securing and enhancing student participation in classroom activities:

The theme of Restraints alleviated associates ICT use with the alleviation or mitigation of factors restraining or inhibiting the participation of students in classroom work. One important sub-theme (related to the ‘play’ sub-theme of Ambience enhanced) concerned the capacity of ICT use to prevent ‘work’ becoming ‘drudgery’. A further sub-theme focused on the way in which ICT use is often associated with a reduction -or removal- of the writing demands -physical and intellectual- of much conventional classwork; demands which may deter or challenge some students. Another specific area where weakness in student capacity was seen as alleviated by access to technology was the drawing of graphs: A final sub-theme concerns the way in which ICT use changes the status of mistakes, not only by facilitating their correction, but by removing evidence of them which might attract unwelcome -and demotivating- attention from the teacher:

They don’t seem to mind getting things wrong either. Whereas, if they got it wrong in their book, particularly children who are already feeling a little bit, lacking confidence let’s say, mathematically. To get something wrong in their book often results in ‘Oh, I'm not doing maths.’ But if they get it wrong on the screen, okay and they just go back to the drawing board and do it again. And they will do it over and over again. / If it is deleted on the screen and it is not there anymore, it is forgotten. / And you don’t write all over it. [LC]

The theme of Tinkering assisted focuses on how this provisionality of many ICT results assists forms of tinkering to improve them. The most basic of these forms is
self correction by students, typically following on from a direct check of a result, sometimes made vivid by the technology, occasionally prompted by an evaluative feedback mechanism. Whereas such ‘checks’ are applied to what are intended as definitive solutions to a given problem, the provisionality of ICT facilitates ‘trials’ of more tentative solutions, and hence a corresponding shift in strategic logic. The idea of ‘trial and improvement’ strategies formed part of the national curriculum being followed by these schools, and teachers made reference to the way in which use of ICT supported such strategies. More generally, they pointed to the way in which use of ICT afforded a more experimental approach to tasks (related also to the invisible mistakes sub-theme of Restraints alleviated):

They are more prepared to have a stab at something and get it wrong because not everyone can see it’s wrong and they’ll keep trying until they can get it right. [VC]

Arguably, it is awareness of this tinkering style of ICT usage which underpins earlier comments about students ‘playing on a computer’ or ‘playing around on the calculator’, under the Ambience enhanced theme.

The theme of Motivation improved associates ICT use with the motivation of students towards classroom work. Teachers commented on what students ‘love’, ‘like’ and ‘enjoy’ in relation to using ICT; likewise on what ‘motivates them’, on what they ‘respond well to’, and on what they are ‘quite taken by’. One further sub-theme suggests that by assisting or permitting students to display -and to be seen to display- greater capability, use of ICT can help build their self-confidence. Across more extended sections of transcript, this idea was associated with the earlier themes of Restraints alleviated and Tinkering assisted:

I think they can then start to feel more positive about themselves and their work, because often they can just get worse and worse with their untidiness because they know they can’t do it so they can’t be bothered to try. If they see what ICT can help them do then they might be encouraged to try it a little bit more themselves and then try to improve their own work to that standard. [VC]

The theme of Engagement intensified associates ICT use with deeper and stronger student engagement in classroom work. Clearly this theme is closely related to Motivation improved. Teachers noted students being ‘more prepared to have a stab’, to ‘put in more effort’, to ‘keep trying’. The following quotation draws together many of the ideas associated with this theme -good behaviour, attention to classwork, and a degree of independence and persistence in it:

They are working more, they’re not wasting so much time, they actually do get on with it, the majority of children will get on with it, rather than do one question, turn around and I’ve got to tell them what to do so they are learning something. [CC]

The theme of Routine facilitated associates ICT use with facilitation of relatively routine components of classroom activity, allowing them to be carried out more quickly and reliably, with greater ease, and to higher quality. In this respect, aspects of Routine facilitated underpin some of the phenomena already noted under the
theme of Restraints alleviated, and there was a clear intertwining of these themes in some sections of transcript. What characterises Restraints alleviated, however, is a focus on particular factors inhibiting the participation of persons, whereas Routine facilitated focuses on factors supporting the execution of tasks. The sub-themes of speed and ease were the most prominent. Such use of ICT was seen as particularly important in supporting the more extended project tasks which older students tackled as assessed coursework for the GCSE examination. An example illustrates how use of ICT tools facilitated routine components of such tasks, highlighting the removal of important constraints on the strategies which students could pursue:

I've just worked this year using draw commands in Word for a bit of coursework called 'Square Moves' where they have to move counters around, and part of the coursework is to show their strategy for moving the counters, and I did it with a low ability group, and we got far better results I feel, because I showed them how to draw circles, and get the sizes right, fill them in different colours, and then once they'd set up the basic grid they could copy and paste the whole grid however many times they wanted, and then they just moved the individual counters around, and as a result of that they did far more work than with the old style of always drawing them out. [TC]

The theme of Activity effected associates ICT use with securing and enhancing the pace (‘rather than someone poring over a page... they were able to do this in no time’) and productivity (‘far better results’, ‘far more work’) of classroom activity as a whole. The following quotation illustrates the linkage of Routine facilitated to the pace aspect of Activity effected:

We've got a graph plotting package which isn't particularly sophisticated... but it makes it nice and easy for the kids to use... Actually drawing a graph and seeing it on the screen, they can very quickly see what's happened to the graph. So using IT in that respect, it makes a significant difference in the depth of understanding and the speed in which it takes to learn skills... You may get there in two lessons rather than three, so you can gain a lesson. [TC]

The theme of Features accentuated associates ICT use with the provision of vivid images and striking effects through which features of mathematical constructs -or relations between them- are accentuated:

The actual immediacy of it and also the fact that it's living, it moves. [VC]

This 'immediacy' of response was one of the important sub-themes to emerge. Likewise the power of 'visual' representations, and the dynamic of actions and their effects:

So you quickly see what is happening to the gradient and what is happening to the intercept. [LC]

The theme of Attention raised associates ICT use with reducing or removing the need for attention to subsidiary tasks, and with avoiding or overcoming related obstacles, so as to better focus students' attention on overarching ideas and processes.
The following quotations bring out the way in which processes already alluded to under the head of Restraints alleviated and Routine effected clear and smooth the way so as to raise and focus students' attention:

The key thing about the calculators or any ICT applications being able to take away the drudgery out of doing the calculations, so that you can start to access a higher learning point without the problems of making mistakes along the way, clouding the issue. [SC]

The theme of Ideas established associates ICT use with the formation and consolidation of ideas through their being 'seen', 'understood', 'accepted' and 'remembered' by students. The following quotation illustrates the association of both Features accentuated and Attention raised with Ideas established:

When we're using Coypu [graphing package] for shifting curves, and that shows them very easily what altering the equation does to the curve, and that does help them tremendously. / ...It's a very, very difficult topic and so you can just actually get them to draw various curves, and show them what happens when you start altering the equation... Just the immediacy of it, actually means that it hangs together better, because if you see these results and then spend another 15 minutes drawing a graph, the whole thing just feels nothing much, so it's just not better efficiency, but also it is actually sounder for the brain really, if it can see things more immediately. [TC]

CONCLUSION

This study has elicited from practitioners a model of the successful use of ICT to support classroom teaching and learning in mathematics. The model is organised as a system of themes identifying key processes and critical states. Four themes depend most directly on exploiting affordances of ICT: Ambience enhanced in changing the general form and feel of classroom activity; Tinkering assisted in helping to correct errors and experiment with possibilities in carrying out tasks; Routine facilitated in enabling subordinate tasks to be carried out easily, rapidly and reliably; and Features accentuated in providing vivid images and striking effects which highlight properties and relations. Three further themes depend in turn on these processes: Restraints alleviated in mitigating factors inhibiting student participation such as the laboriousness of tasks, the requirement for -and the demands imposed by- pencil-and-paper presentation, and vulnerability to mistakes being exposed; Motivation improved in generating student enjoyment and interest, and building student confidence; and Attention raised in creating the conditions for students to focus on overarching issues. Three final themes depend again on preceding processes: Engagement intensified in securing the commitment, persistence and initiative of students in classroom activity; Activity effected in maintaining the pace and productivity of students within classroom activity; Ideas established in supporting the development of student understanding and capability through classroom activity.

This model is intended to serve as a helpful abstraction, providing a generic scheme for conceptualising use of ICT to support classroom teaching and learning in
mathematics. In any actual instance of classroom activity, of course, certain components of the system may assume more prominence than others, and those operative components of the scheme must be filled out more concretely according to the particular circumstances. Nor is the model a deterministic one. Rather it highlights key processes and critical states which require active -and reactive- planning and management on the part of the teacher for ICT use to successfully support teaching and learning. Finally, the model is a tentative one. It is based only on teachers' somewhat decontextualised accounts of successful practice, elicited through group interview; rather than on more strongly contextualised accounts of specific instances of practice, supported by examination of actual classroom events. Nevertheless, earlier variants of this model have already proved their worth in subsequent work with teachers, in helping them to articulate their conceptions of how particular forms of ICT use support teaching and learning.

Our general concern is to investigate the role that new technologies play in the development of processes of proof. We use Balacheff's work (1987, 1999) to talk of pragmatic proofs vs. intellectual and formal proofs. We present part of a case-study from a larger research where students used a Logo-based microworld for the exploration of infinite sequences and series, to illustrate how some of the elements that computer microworld explorations, activities and visual means bring, can lead to a process of discovery and acceptance of mathematical results, and create stepping-stones (pragmatic proofs) in the development of mathematical proofs.

INTRODUCTION AND THEORETICAL FRAMEWORK

We are interested in investigating the role that new technologies play in the stages of proving in mathematics education. Research in this direction is often related to geometry and the influence of dynamic geometry systems on the learning of mathematical proof (Hoyles & Jones, 1998; Villiers, 1998, Balacheff, 1999). However, in this paper we draw data from a different kind of study where students used a Logo-based microworld for the exploration of infinite sequences and series. We aim to illustrate how the environment and its tools gave students enough means of mathematical exploration and expression through which they could discover patterns, make generalizations and conjectures, and validate their results.

We begin with a brief discussion on the function of proof as a means of understanding, and the role of technology for developing a sense of proof and intuition before a formal proof is presented. We then present a brief summary of some important concepts developed by Balacheff (1987, 1999) that will serve as part of our theoretical framework. Finally, we present sample data from our study to illustrate the ways in which computational experiences can function as a means of creating understanding and acceptance of mathematical results, thus constituting processes of proof.

The construction of meanings through proofs, and the role of technology

The function of proof as "a key tool for the promotion of understanding" has been stressed by Hanna (1995). While Hanna defends the value of formal proof, she also makes a distinction between the function of proof in mathematics and that in mathematics education:

while in mathematical practice the main function of proof is justification and verification, its main function in mathematics education is surely that of explanation ... It might be a calculation, a visual demonstration, a guided discussion observing proper rules of
argumentation, a preformal proof, an informal proof, or even a proof that conforms to strict norms of rigour ... Clearly the challenge is to have [students] understand why [results] are true. (p. 47)

Other studies have highlighted features that are making clear the complex field of mathematical proofs: the role played by empirical evidence in contrast with deductive arguments (Chazan, 1993); the difference between argumentative reasoning and deductive reasoning (Duval, 1991); and students' proof schemata (Harel, 1996).

With the advent of new technologies, the empirical methods of mathematics research have been revitalized. Mathematicians themselves are recognizing that technology is changing the way we approach proving. Thurston (1994), who analyses the nature of proof and of mathematics itself, also emphasizes that it is a search for understanding which is at the basis of the exploration and logical processes leading to a proof; and he advocates the use of computers for exploration and discovery of mathematical ideas, giving priority to what he calls "humanly understandable" proofs over formal proofs.

Other authors and researchers have investigated the role of computer-based explorations and visualization to develop a sense of proof and give intuition for formal proof (for instance, by building up an overall picture of the relationships involved), considering these important complementary elements to mathematical proofs (e.g. Barwise & Etchemendy, 1991). Among those are Cuoco & Goldenberg (1992) who consider that the activity of constructing proofs involves a research technique where conjectures arise through the combination of experimentation and deduction.

One of the difficulties with proving in school mathematics is that concepts which expert mathematicians regard as intuitive are not intuitive to students since intuition depends on previous experience (Tall, 1991). To overcome this, Tall (op.cit., p.118) considers that:

by introducing suitably complicated visualizations of mathematical ideas it is possible to give a much broader picture of the ways in which concepts may be realized, thus giving much more powerful intuitions than in a traditional approach. ... intuition and rigour need not be at odds with each other. By providing a suitably powerful context, intuition naturally leads into the rigour of mathematical proof.

The components of proving

Balacheff (1987, 1999) has introduced certain ideas that we consider important for our analysis. He distinguishes between pragmatic proofs and intellectual proofs; emphasizing the role of language in the passage from the former to the latter. Pragmatic proofs are those based on effective action carried out on the representations of mathematical objects. They lead to practical knowledge that the subject can use to establish the validity of a proposition. Intellectual proofs demand that such knowledge is reflected upon, and their production necessarily requires the use of language that expresses (detached from the actions) the objects, their properties and their relationships. In other words, pragmatic proofs are based on action, while the use of a functional language (which includes a specific vocabulary and symbolism) and a "mental
experience" (where actions are interiorised) characterize the transition to the intellectual ones. The transition from pragmatic proofs to intellectual proofs culminating in mathematical proof, involves three components: the knowledge or levels-of-action component (the nature of knowledge: knowledge in terms of practices — "savoir-faire"; knowledge as object; and theoretical knowledge); the language or formulation component (ostentation, familiar language, functional language, formal language); and the validation component (the types of rationale underlying the produced proofs: from pragmatic, to intellectual, to mathematical proofs).

COMPONENTS OF PROOF IN A LOGO MICROWORLD

Here, we present an example to illustrate how certain computational activities constitute pragmatic proofs, with progress on the level of the first component (knowledge), and some progress in the other components. Although we cannot provide evidence on how computational activities can lead to the development of more rigorous intellectual proofs, we believe that progress achieved in earlier stages constitute suitably powerful experiences that create familiarity and understanding of the problem (an intuition) necessary for transition to the latter (cf. Tall, 1991; see above). It is likely one of the kind of experiences incorporating exploratory computer and visual activities considered useful and advocated by some of the researchers reviewed above (e.g. Tall, 1991; Thurston, 1994; Cuoco & Goldenberg, 1992), and which provides elements of proof as "explanatory" (Hanna, 1995).

This example (from a case-study of a pair of high-school students) is taken from a larger research that investigated the mediating role of a Logo microworld designed for the exploration and study of infinite sequences and series, in students' conceptions of infinity and infinite processes. That study involved detailed case studies of 4 pairs of students working and interacting with the microworld. (Students worked in pairs to facilitate the sharing and discussion of ideas — simultaneously providing the researcher with insights into their thinking processes — and give them independence from the instructor). Each pair of students, previously instructed in Logo programming, worked with one computer for five 3-hour sessions. To facilitate the analysis of students' experiences, we worked with only one pair of students at a time, using a clinical interview style. The role of the researcher was that of a participant observer, suggesting the field of work (the initial procedures and activities), as well as new ideas for exploration when needed, yet allowing students to be in control of the explorations, giving them freedom to explore and express their ideas. Students were informally interviewed throughout the sessions but formal interviews were conducted at the beginning and end of the study.

As part of the microworld activities, students explored sequences such as \{1/2^n\}, \{1/3^n\}, \{(2/3)^n\}, \{2^n\}, and \{1/n\}, \{1/n^{1.1}\} and \{1/n^2\}, and the sequences of their corresponding partial sums. They wrote Logo procedures to construct visual models of those sequences, using Logo's turtle geometry: spirals (Fig.1) (where each successive "piece" of the spiral
represents a term of the sequence, so that the total length of the spiral corresponds to that of the sum of the terms, i.e. the corresponding series), bar graphs (Fig.2), staircases, and straight lines (where again, the total length represents the corresponding series or partial sum of the terms of the sequence).

![Fig.1: Spiral model for the sequence \(\{\frac{1}{2^n}\}\)](image)

![Fig.2: Bar graph model for the sequence \(\{\frac{1}{2^n}\}\) with numeric output](image)

For example, one of the initial Logo procedures used in these activities was of the form:

```logo
TO DRAWING :L
  IF :L < 1 [STOP]
  MODEL
  DRAWING (FUNCTION :L)
END
```

Where `MODEL` described the steps for building a model such as a spiral (FD :L RT 90) or a bar graph (FD :L JUMP), and `FUNCTION` described the operation on :L at each step (e.g. :L/2).

Thus, the different visual models for the same sequence provided different perspectives of the same process. As the explorations progressed students added Logo commands to their procedures that would allow them to carry out a complementary analysis of the numerical values (to further analyse their behaviour, and the apparent limits, if any existed or appeared to exist). Through the observation of the visual (and numeric) behaviour of the models, students were able to explore the convergence, and the type of convergence, or divergence, of a sequence and its corresponding series.

The microworld was designed to simultaneously provide its users with insights into a range of infinity-related ideas, and offer the researcher a window (cf Noss & Hoyles, 1996) into the users' thinking processes. The microworld provided a means for students to actively construct and explore different types of representations (symbolic, visual and numeric) of infinite sequences via programming activities. In general, the computer setting provided an opportunity to analyse and discuss in conceptual (and concrete) terms the meaning of a mathematical situation. For example, drawing a geometric figure using the computer necessitated an analysis of the geometric structure under study and an analysis of the relationship between the visual and symbolic representations.

What is relevant for us here, is that the exploratory setting of the microworld activities allowed students to engage in an active process of discovery of the properties and characteristics of the processes under study. That is, the environment seems to have
provided a language for asking questions, as well as tools for exploring these questions. In many cases students found what seemed like patterns and properties, which led them to formulate and test conjectures, as well as articulate relationships and build generalizations.

There were several levels in which the microworld activities functioned as stepping-stones towards a proof. At a first level, students made observations and discoveries situated within the medium of the microworld. We have described elsewhere (e.g. Sacristán, 1997) how students were able to discover patterns related to the processes under study but situated within the context of the microworld environment. By playing in, interacting with, and working within the microworld, they could express themselves through the tools, activities and forms of symbolism built into the environment. At a second level, some students were able to abstract and articulate their findings in a way that could be taken beyond the medium in which the findings were constructed; consciously exploiting the tools of the microworld for discovery, exploration, and "pragmatic proof" (Balacheff, op.cit.) of mathematical relationships or "theorems".

**Pragmatic proofs: discovery, generalization and validation in the microworld**

Through the sample data below, taken from one of the case-studies (a pair of 16-17 year-old boys: Manuel and Jesús), we aim to illustrate, in particular, how students made predictions and then tested their validity by using all the available tools in the microworld.

During the second worksession of explorations, as described above, of sequences of the type \( \{(1/k)^n\} \), these students discovered that the series of the type \( \sum_{n=1}^{\infty} \frac{1}{k^n} \), where the integer \( k > 1 \), converge to \( \frac{1}{k-1} \). These students had been exploring and comparing the sequences \( \{1/2^n\}, \{1/3^n\} \) and began to discover a pattern in the behaviour of the corresponding series: Manuel observed that as they increased the denominator value \( k \) in the sequences of the type \( \left\{ \frac{1}{k^n} \right\}_n \), then the limit of the corresponding series was smaller and in fact seemed to have as value \( \frac{1}{k-1} \). They explicitly constructed a generalization for this mathematical result (which later they would call proudly "their theorem") and used it to predict the probable behaviour of other sequences and series of the same type:

Manuel: Look, if you subtract 1 from the number that is the base in the denominator, and you divide 1 by that number, then that is the number to which it will approach. If we do it with 3: 3 minus 1 is 2, and it tends to a half...

So if it was 1/2000\( ^N \), the sum must approach 1/1999...

Jesús: Yes, the bigger the base in the denominator, the smaller the limit.

---

1 Manuel and Jesús seemed to consider \( k \) implicitly as a positive integer larger than 1, although they did not make this condition explicit.
Manuel: But now we have a method for knowing to where it approaches.... We saw that $1/2^N$ became small very quickly, but the case of $1/3^N$ decreases much much more quickly. And we saw that its series didn't tend to 1 like the previous one, that it approached a half, so we noticed a more or less regular behaviour, so if we wanted to know to how much the series of $1/2000^N$ would be we would only have to reduce it by a number, and it would tend to $1/1999$.

Manuel and Jesús then employed the medium and its tools to test out their predictions, looking for a proof of their conjecture. They began by changing the sequence generating function to $1/4^N$, predicting that the corresponding series would tend to $1/3$. They used all the resources available to explore this sequence and its series, looking at all the available visual models (the Spiral, Stairs, Bar Graph and Line models). They were amazed at how quickly the values of the sequence decreased. From the rapidly decreasing behaviour of this sequence they deduced that the corresponding series converged, which they visually verified, using the Line model. Although the visual explorations were enough to convince the students of the validity of their conjecture, they complemented these with a numeric exploration of the partial sums (they built a procedure which computed the value of a partial sum). They observed that the 20th partial sum printed out to be 0.3333333333, confirming further their hypothesis. A final test of their conjecture was carried out by exploring the sequence $\{1/13^n\}$, through visual and numeric representations — which showed the much more rapid decrease of this sequence — and again verified that the corresponding series tended to the predicted value of $1/12$.

For Manuel and Jesús there was now no doubt that the conjecture was true, but Manuel did worry that this mathematical generalization would not hold if the value of $k$ was infinite (what Balacheff, 1987, 1999, has described as a crucial experience), and he looked for favourable arguments:

Manuel: Listen... there might be a contradiction in our assumption: if we did one over infinity... Ah! but infinity minus any number is still infinity..., so we are right! It tends to zero. If one over infinity tends to zero, then also one over infinity-minus-one, because infinity minus one is infinity, then it also tends to zero. And here we have that the bigger the base of the denominator gets, the smaller the series.

It is worth noting that most students, including a pair of younger students (two 14 year-old girls, one of them called Consuelo) discovered the rule for the behaviour of the series of the type $\sum \frac{1}{k^n}$, which they tested and then generalized. Manuel and Jesús were more experienced mathematically which was reflected in the way they expressed the rule, but the younger students also constructed the generalization within the context of the activity — what Noss & Hoyles (1996) have called a situated abstraction — expressing it relative to the inputs used by the procedure (e.g. the scale):

Consuelo: So the sum of the bars for $1/3$ it's one half [the scale], and for $1/4$ it would be $1/3$ [of the scale], and for a fifth: $1/4$ [of the scale], and so on.
DISCUSSION AND CONCLUDING REMARKS

The possibility of working with many cases (different sequences of the same type), and use diverse resources (different visual models and complementary types of representations: visual and numeric), provided students with a means to (i) infer their own generalization through the discovery of a pattern, and (ii) to validate and confirm their predictions and generalization (becoming convinced of the general validity of their conjecture). In this sense, the microworld became a mathematical laboratory. The results were not formally proven, and the students were aware of this, but the process of repeatedly observing different variations, cases, and situations, was enough to convince the students of the validity (or in other cases falseness) of their conjectures, constituting pragmatic proofs. Elsewhere, we called these experiences “situated proofs” (Moreno & Sacristán, 1995; Sacristán, 1997). These are pragmatic proofs that result from the combined use of all the elements available in the microworld in an attempt to confirm conjectures. Situated proofs are experiences that lead students to discover and make sense of a mathematical relationship, convincing them of its validity. In the same way as situated abstractions, these experiences are dependent on the tools of the medium (hence the term “situated”). They are therefore not yet detached enough from the representations of the objects and the actions to constitute an intellectual proof.

Nevertheless, progress is shown for all three components. The fact that students spontaneously tested their conjectures (adjusting them as a result of the explorations), in order to convince themselves (and others) of their validity, shows progress on the level of the validation component. On the level of the knowledge component, the formulation of predictions or conjectures involved a process of reflection and analysis on the part of the students, as they had to, for instance, evaluate the role and relationship of the variables involved. Also, the Logo-based activities allow students to construct certain forms of symbolism to express and interact within the medium (situated abstractions); this is progress on the level of the language component. Thus, these experiences were often powerful enough to act, at least, as explanatory proofs (Hanna, 1995). They are pragmatic proofs that can be thought of as the collection of activities that build meaning for a theorem before a formal proof is presented.

Thus, the use of technological tools can provide a field of exploration and mathematical experimentation in which it is possible to deal with mathematical content through the representations provided by the medium. Proofs on the pragmatic level can become more powerful and enrich students' mathematical experiences by allowing them to discover results and formulate probable conjectures. In this sense, we consider that this type of

---

2 Exploration through visual and numeric representations, observation of the behaviour of the process under study, and the structure of the code, are all elements that students used to convince themselves of the convergence or divergence of a process, and/or of the existence of a limit.

3 This contrasts with findings in another of our studies using Cabri-Geomètre, where geometrical objects are manipulated, and there is a development of geometric visualisation, but the use of the symbolic geometric language is very limited.
microworld activities can strengthen the foundations for the passage to intellectual proofs. However, more research is needed to find activities that follow or are based upon computational activities, which will lead to the transition towards intellectual and formal proofs; in agreement with Hanna (1995), the role of the teacher is likely to be crucial.

REFERENCES

This study is a part of an ongoing research that attempts to characterise the relationship between mathematics teachers’ knowledge and practice. Here we are focusing on the identification of the domains that are integrated in distinct moments of teachers’ practice, in particular in the introduction of Thales theorem. Data were obtained through audiotapes of several semi-structured interviews, observations and videotapes. Although the teachers of our study had a similar background and experience, the analysis of data showed differences in the way of introducing the theorem, in the characteristics of the domains integrated in the previous decisions and in the changes related with the initial planning. The study contributes to highlight the complexity of the teachers' professional practice.

INTRODUCTION

Over the last decades, the relation between mathematics teachers’ knowledge and practice has been studied from different perspectives. Within the cognitive perspective, Leinhardt and her colleagues have shown that teachers have a background that provides them resources for confronting the different teaching situations (Leinhardt et al., 1991). Other researchers have pointed out several ways in which teachers’ knowledge and conceptions influence what the teachers are able to do in their classrooms (Lloyd and Wilson, 1998, Sherin, 2000). Furthermore, analytical models have been created to characterise ‘the decisions and actions of teachers as they teach’ (Schoenfeld, 2000, p.243), or to examine teachers’ instructional practice with respect their underlying cognitions (Artzt and Armour-Thomas, 1999). The latter have tried to understand the role of the cognitions in the instructional practice by examining knowledge, beliefs and goals in different stages of teaching. For them, these components form a network of overarching cognition that controls the instructional behaviour of teachers in the classroom, assuming that differential instructional practice is related to differences in teacher cognitions.

FRAMEWORK AND AIMS

Our work draws upon the literature described just above and is situated in the line of researches that attempt to characterise the relationship between mathematics teachers’ knowledge with different moments of their practice. In this study, we consider teachers’ professional knowledge as ‘a personal construction generated through the professional activity in which several domains of knowledge are integrated’ (Garcia,
1997). This knowledge is developed over a long time and in different context, being a 'situated knowledge' (Brown et al, 1989). We assume that cognitive integration of the different domains of knowledge (pedagogical content knowledge, subject-matter knowledge) takes place in the different situations of professional practice.

In addition, we consider professional practice as 'the set of activities that the teacher generates when he carries out the tasks that define the teaching of mathematics, and the justifications that he provides about these activities' (Llinares, 1999, p. 110). Following this author, we consider that the professional practice is not limited to classroom events. It is conceptualised from a wide perspective that includes the relationships between peers, work in groups, etc., and the articulation, justification and communication of the decisions and actions. Therefore, although our study is built on cognitive perspectives, we try taking into account socio-cultural aspects.

Although we assume that teachers' practice is 'a conglomerate that cannot be understood by looking at parts split off from the whole' (Simon & Tzur, p.254.), in our research project, we have focused on the teaching/learning process management of two secondary mathematics teachers' in a set of lessons to describe and characterise the professional practice. These lessons were related to the unit 'Thales theorem and similarity'. On other occasions within the above mentioned research project, we have studied what happens in mathematical classes when mathematical content appears different to that scheduled by the teacher (Escudero y Sánchez, 1999). The present study is focused on the identification of the domains that are integrated in distinct moments of the practice, (in particular in the introduction of Thales theorem). We are trying to characterise these domains, studying their role in the changes in relation to the initial planning.

Since we investigated the teachers' knowledge and practice in relation to Thales Theorem and similarity in our study, it is important to make explicit the framework that guide this inquiry. Our framework incorporates the consideration of the similarity in a 'intrafigural' way based on the properties of similar figures or as a geometrical transformation. We also consider the different modes of representation used (real world situations, manipulative, figurative, natural language, symbolic representations), and the type of tasks and the demanded activity in these tasks (calculation, construction or demonstration).

METHODOLOGY

Participants and Site

The research participants were two experienced Secondary teachers, Ismael and Juan (the names are pseudonymous). There was not a specific preparation as regards the design or implementation of the unit. Both prepared their units independently. The pupils belonged to two classes without any special characteristics (3rd and 4th years of Compulsory Secondary Education, 14-15 and 15-16 years of age, respectively). The schools were situated in the outskirts of the city.
The unit

The development of a new curriculum for Secondary level (12-16 years) in Spain commenced in the early 1990s. This reform has emphasised the teaching of Geometry. Objectives in this section include 'knowledge and use of basic geometrical properties: Pythagorean theorem, Thales configurations, similar figures and elementary notions about trigonometry (Junta de Andalucía, 1993, p.133). Supporting documents encourage teachers to include these objectives in their planning.

Instruments

Data were obtained through audiotapes of several semi-structured interviews, observations and videotapes. We videotaped each of the teachers teaching the whole unit of their own design (eight lessons and nine lessons respectively). During the initial interview, the teachers were asked to explain their lesson plans and to describe how they meant to develop the lessons. Previous and post lesson interviews were carried out. The field notes taken down during the observation provided information about classroom events that might not show on the videotape. Transcriptions were made of the audio part of the videotapes for analysis.

Data analysis

We analysed the previous interviews in terms of their goals, lesson plans, selected problems, etc. Thus, we obtained the teachers’ agenda. The observation notes and the videotapes were used to categorise the teachers’ instructional practice. Firstly, we identified ‘segments’ in the lessons (presentation segments, monitored practice, homework check, etc), considered as parts of a lesson with an objective, and perfectly differentiated by teacher and students (Leinhardt, 1989).

In the different segments, we characterised the actions developed by the teacher to reach the objectives, taking into account the grade of intervention of the teacher with respect the pupils and the type of data used. We identified different actions in the presentation segments: utilisation of an example/problem for reaching a definition, a property, a theorem, with the constant intervention of the teacher and pupils; explanation for reaching a definition or property, with minimum or nil intervention from the pupils, among others. In these cases, the data were whole numbers. The whole set of actions provided us with the structure of the segments. By integrating the data of the different instruments it was possible to know the reasons and justifications that made the teachers adopted a specific structure. This allowed us to identify and characterise the underlying domains of knowledge in the structure.

Through our analysis we were able to discern differences in teachers’ instructional practice. We used the integration of domains as a way of better understanding these differences. In particular, within the segments identified in the unit, here we are going to focus on a presentation segment identified in the two teachers, whose objective was to introduce the Thales theorem. Firstly, we are going to present the structure we have identified. Afterwards, we will characterise the domains of knowledge that have
influenced the adoption of this structure, and the aspects of these domains that were responsible for the changes.

RESULTS

The two teachers in our study had a similar background and experience. Nevertheless, we were able to observe differences in the structure of the presentation segments of Thales theorem and in the characteristics of the domains related with the previous decision of adopting these structures.

For Ismael, the unit of ‘Thales theorem and similarity’ was important because ‘it helps to give sense and to understand the concept of numerical proportionality’. In particular, the theorem is considered as a context to visualise the numerical proportion in order to be able to connect ‘the abstract numerical view with graphical images’. This unit was developed throughout 9 consecutive fifty-minute lessons. In these lessons, we identified 7 presentation segments; 3 monitored practice and 1 homework check, which were used alternately. In particular, the presentation segment of Thales theorem occupied the first place and was developed in 80 minutes (almost two lessons).

This segment belonged to a group of three segments, which structure was composed by the following actions: utilisation of an example or problem / explanation for reaching the definition or formula / definition / explanation for completing. This structure was identified in those cases in which the introduction of the definition or property was based in contents previously introduced by the teacher in other units. In the introduction of Thales theorem, former contents were numerical proportion and parallel lines cut off intersect lines. The teacher wanted the pupils to identify these contents in some proposed problems.

In the first action, utilisation of an example, Ismael proposed three problems previously selected in his planning. Through these problems, Ismael wanted ‘to collect pupils’ previous ideas that are related to the theorem’ (initial interviews). The three problems were real world situations that included figural representations, pointing out the aspects of projection and homothety. They were proposed together to small groups of pupils. The teacher had justified the importance of this way of working by saying that ‘the pupils work together sharing meanings and communicating their ideas’ (initial interview).

In the following action, explanation for reaching the definition, the teacher pointed out the ideas that he had collected through the interaction with the groups of pupils, which he considered important for the introduction of the theorem. Ismael had mentioned that: ‘after the work in groups, I am going to collect the important theoretical ideas, clarifying the difficulties’ (initial interview). Ismael conducted a whole-class discussion, writing these ideas on the blackboard. He ended with the definition of the Thales theorem. Finally, through the explanation for completing, the teacher introduced other aspects that allowed him to connect with the monitored practice. He justified the introduction of this contents by saying: ‘I would try to show several Thales
configurations in relation to the position of data and unknown', adding 'the consequence of Thales theorem diminishes the difficulty that the pupils may have with a specific type of configurations' (initial interviews).

Globally considered the characteristics of the domains of knowledge that were decisive as regards the previous decisions of adopting this structure were related with his pedagogical content knowledge. In particular, the importance of establishing relationships between the earlier knowledge and the new concept by means of several problems previously selected, and working in small groups as a way of communicating and sharing ideas, followed by his intervention as 'organiser'. His knowledge of specific difficulties about the content played a more specific role, influencing his decision of including an explanation after the definition of the theorem.

Nevertheless, regarding the structure identified in the classroom, we appreciated variations in relation to the agenda. The teacher had indicated that his way of working 'was working in small groups/ setting out common grounds/ recollecting the important ideas and clarifying the difficulties to reach the formal definition' (initial interviews). Why did the setting out common grounds disappear? It was related to the difficulties that pupils had with the content. The teacher justified this omission by saying: ‘I meant to start the explanation when the pupils had advanced more, but I had to intervene because of their difficulties’ (Post-lesson interview). We want to point out two ideas. Firstly, the way in which Ismael understood the ‘setting out common grounds’, focused on his own intervention of collecting and clarifying the pupils’ ideas that he considered important. This was coherent with the action ‘explanation for reaching the definition’ identified in our analysis.

Secondly, the important role of the difficulties in the change of action. Ismael related these difficulties to specific characteristics of the content. In particular, in the post-interview he pointed out two aspects, which were important for him. The first aspect refers to the difficulties related to the contents he wanted the pupils to identify in the proposed problems: ‘with the first two problems, the pupils had difficulties with the proportion they had to identify’ (post-lesson interview). The second aspect refers to the characteristics of the real world situation proposed in the problems. Initially, Ismael emphasised the use of real world situations and the importance of recognising the proportion in different figural representations, therefore, all three problems were real world situations with different geometric configurations. The problems showed both aspects projection and homothety. Two of the problems established a relationship between two data and the other was a missing value problem.

Nevertheless, the pupils’ understanding of the enunciate of the problems was complicated by the real situations. Ismael concluded that this was a cause of difficulties: ‘I realised that the enunciate of the problems was too long compared to what these pupils were habituated to’ (post-lesson interview). This allowed him to think about changing the real world situations for other easier ones (even though these situations were no-real world situations) in the future. For Ismael, the role of real world situations was motivation. Nevertheless, he did not doubt of maintaining the use
of several problems with variations in geometrical configurations. This aspect, and the importance that Ismael gave to the role of Thales theorem in the unit, was closely related to his subject matter knowledge.

All of this shows the role played by the perception in the classroom of the difficulties with the syntax of the real situations and the specific aspects of the content. Why did he have included these problems? As we have mentioned before, his decisions were related with his subject matter knowledge, but they were also influenced by his knowledge of other students. The teacher justified his election by saying: ‘I had proposed these problems to older pupils. I think I overvaluated their capacity of abstraction’ (post-lesson interview). The knowledge of students of Ismael was situated in other pupils.

For Juan, the inclusion of the Thales theorem in the unit was justified because it is used later on to establish the criteria of similar triangles, and also because of his previous experience ‘I have done it like this for years’ (initial interviews). This unit was developed in 8 fifty-minute lessons. We identified 11 presentation, 7 monitored practice and 4 homework check segments. The presentation segment of Thales theorem took about 20 minutes and was the second of the unit. It belonged to a group of 4 presentation segments with the following structure: utilisation of an example or problem/ definition/ explanation for completing. This structure was linked to the teacher’s introduction of contents whenever he supposed the pupils had obtained some knowledge of the matter in previous courses (‘the pupils have learned about numerical proportionality of previous courses’ (initial interviews)). On this basis, Juan thought to introduce the concepts of ratio and proportion of segments, which he considered previous to approach the theorem, in the same unit.

In the first action, utilisation of an example, Juan developed the content in sequential steps by means of instructions to the whole group, intercalating questions and asking for the results. Juan was indicating to the pupils that made a verification of properties of parallel lines cut off intersect lines to equal and distinct distances by means of measurements carried out with drawing tools. The examples to be used, though previously selected by the teacher, were not known to the pupils at the beginning.

Juan justified this way of introducing the theorem because he considered that the pupils knew the geometrical elements that intervene in the examples to be used (parallel lines, intersect lines, segments) so that they will be able to follow his instructions. Furthermore, by assigning a numerical value to the segment pupils could connect with the arithmetic proportion (‘already known’). During the initial interview Juan explained that the pupils ‘more easily believed things’ after having carried out the verification by them.

The enunciate of the theorem (by means of a transparency) collected all mathematical aspects that were sequentially emphasised in the performed verifications, showing a ‘typical’ configuration of the theorem, and emphasising the projection aspect. Finally, in the explanation for completing, the teacher stressed the generality of the lines in the
drawing and placed emphasis on the general character of the theorem by specifically mentioned to the pupils that ‘the things that we have done with these specific cases are going to be always true’ (video transcriptions).

Globally considered, the domains of knowledge that intervened in the adoption of this structure were related to his knowledge of school mathematics as a teaching/learning object and the knowledge about learning processes, considered as a part of pedagogical content knowledge. Especially, as regards the use of a verification as a procedure of validation and the use of sequential steps that the pupils were carried out ‘because they learn more’ (post lesson interview). However, Juan specifically mentioned the low level and lack of motivation of these pupils in the initial interview. We think that this aspect was also integrated in the previous decision of using verification. Juan mentioned the characteristics of the general case only in the content of explanation.

This teacher only presented few variations as regards of his way of working compared to his agenda. In the case of Juan, difficulties played a different role in comparison to the case of Ismael. By dividing the content into sequential steps and giving a certain type of instructions to the pupils, few difficulties came up in the classroom that the teacher considered worth while to take into account with respect to his objective of introducing the theorem. Pupils' difficulties with the lack of precision at measuring the segments, which had an effect in the results of the verifications, were not relevant aspects from the perspective of his subject matter knowledge in relation with the introduction of the theorem. The algorithmic view, which was appreciated in the sequential steps, underlined the decision of including the theorem, in the sense that it was considered as a previous step towards the later introduction of the concept of similar triangles. Along with this, it was made evident the influence of the school culture, which traditionally assigns an important role to theorem.

**CONCLUSIONS**

This study is a part of an ongoing research into the relationships between teacher's knowledge and practice. The main objective of this paper was the identification and characterisation of domains of knowledge that intervened in this relationship. The objective of the presentation segments of both teachers was the introduction of the Thales theorem. Pedagogical content knowledge and subject matter knowledge were integrated in their decisions. Nevertheless, our study has shown that these teachers adopted different structures, being the initial decisions of adopting these structures linked to different characteristics of the domains of knowledge, which were integrated in a very different way.

Both teachers realised the importance of the pupils’ difficulties in the adopted decisions. But, whereas Ismael was very sensitive to the difficulties, which came up during the interaction, Juan minimised the importance of these difficulties. He tried to avoid the difficulties globally in his previous decisions about his planning, admitting the verification as an easier procedure for the introduction of the content. The
characteristics of the subject matter knowledge related to Thales theorem made that Ismael gave a great importance to the establishment of numerical/geometrical connections by means of the selected problems. Juan's algorithm approach of the contents was associated to a more general view of school mathematics.

There are many issues in our research that require further investigation. A better characterisation of domains of knowledge and its role in the different moments of professional practice can help to improve our knowledge about the complexities of mathematics teaching.

REFERENCES

Beliefs, attitudes, emotions and values are the categories of affect used in mathematics education research. All these categories are founded on mental background systems which control thinking, learning and acting. To gain a deeper insight in the mechanisms of the mental systems and their forecasting character, results of neuroscience are used. By distinguishing between an explicit conscious memory system, which stores experiences about emotions, and an implicit emotional memory system, which operates unconsciously, it is possible to understand some emotional reactions in a better way.

1. Research in Mathematics Education on Affect

For a long time mathematics learning has been mainly seen as a problem of cognition. Researchers investigated the specificity of mathematical terms and concepts, steps of concept building, the influence of representations on the learning process, and so on. Consequences of research were theoretical models describing the learning process. The consideration of the social conditions in classroom learning led to an important extension. Mathematics learning was seen as a social process which controls the cognitive processes of the individual learners.

During the last decades there has been an increasing interest in affect and its influence on mathematics learning. The first step was to use the psychological "attitude concept" to explain differences in the students' mathematics performance. "Attitudes toward mathematics" (seen as a (learned) predisposition to respond in a consistent way with respect to a special object) was identified as a factor influencing the learning process and, as a consequence, the mathematics outcome. The most influential measure to investigate attitudes toward mathematics was the Fennema-Sherman Mathematics Attitude Scale (Hart, 1989; McLeod, 1994).

One consequence of this concept was the development of a "generic model for relating affect and outcome" (Fennema, 1989). In this model affect is a consequence of external influences like gender, social class etc. which influence learning activities and the mathematical test results. (For a further development of this model, see Evans, 2000).

A second very important concept in research on affect is the "belief concept" which stresses students' knowledge about mathematics in a very broad sense. The belief concept includes beliefs about mathematics, about the self, about mathematics teaching and about the social context (McLeod, 1992, 1994).
Furinghetti and Pehkonen (2000) describe the function of beliefs in the following way:

(a) beliefs form a background system regulating our perception, thinking and actions; and therefore, (b) beliefs act as indicators for teaching and learning. Moreover, (c) beliefs can be seen as an inertial force that may work against change, and as a consequence, (d) beliefs have a forecasting character. (p. 8 - 9)

Research on attitudes and beliefs is based on questionnaires as instruments and statistical methods for evaluation. Qualitative methods especially in connection with research on nonroutine problem solving processes and higher-order thinking skills led to the interest in more intense affective reactions called “emotions”. Goldin (2000) describes a model of affective states on different steps of a nonroutine problem solving process. These affective states can evoke special heuristic problem solving strategies.

The categories beliefs - attitudes - emotions are used by McLeod (1992) to reconstruct the research on the affective domain in mathematics education. To better distinguish these categories, McLeod (1989) uses the dimensions intensity - direction - stability. Longitudinal studies on mathematics learning processes and affect motivate DeBellis and Goldin (1997) to introduce a fourth affective category “values/morals/ethics”. This new category emphasizes the appraisal aspect of affect.

A summary of the discussion of affect in research of mathematics education is provided by a quotation from Goldin (2001) which describes the categories of affective representations:

(1) emotions (rapidly changing states of feeling, mild to very intense, that are usually local or embedded in context),

(2) attitudes (moderately stable predispositions toward ways of feeling in classes of situations, involving a balance of affect and cognition),

(3) beliefs (internal representations to which the holder attributes truth, validity, or applicability, usually stable and highly cognitive, may be highly structured).

(4) values, ethics, and morals (deeply-held preferences), possibly characterized as “personal truth,” stable, highly affective as well as cognitive, may also be highly structured). (p. 3)

The categories of affect in research on mathematics are on the one hand a consequence of research methods and on the other hand motivated by observed phenomena. The concepts don’t describe the interaction between affect and cognition in a sufficient way to understand some affective reactions; especially, the relationship between conscious and unconscious is not really discussed.
2 Affect and Cognition -- Some Results of Neuroscience

First some remarks:

1) The use of terms “affect” and “emotion” is not uniform in neurosciences (Ciompi, 1999; Roth, 2001). Often they are used synonymously as generic terms for affective-emotional basic conditions.

2) The brain is the organ in which is represented all the knowledge about the world outside but also about inside of the body.

3) All systems of the brain are the result of evolution with the aim of helping the individual to survive. Emotion and cognition are also part of the brain system and therefore a result of evolution (Ciompi/Wimmer, 1996; Damasio, 1999; LeDoux, 1998; Roth, 2001).

4) A special brain system of an individual is a consequence of the evolution as well as of the ontogenetic development of the individual (Ciompi, 1999).

5) First of all we have to note that all processes on the neuronal level are unconscious. But some of these processes lead to conscious results. We are aware only of these conscious parts of the processes.

Emotion and cognition are both subsystems of the brain system. They are located in different parts of the brain (Damasio 1999; LeDoux 1998; Roth 2001) but there are connections between both systems which allow interactions. A very important consequence of these two different systems of concepts is the fact that we have to distinguish between “feeling” and “knowing that we have a “feeling” (Damasio, 1999; 26) or “emotional reactions” and “conscious emotional experience” (LeDoux, 1998; 296).

The emotion system has also connections to the arousal systems, therefore emotional reactions are often combined with “body reactions” (LeDoux, 1998). For this paper the interaction between affect and cognition are of particular interest:

* The emotion system influences memory processes. On the one hand, the emotion system is involved in the storage process. The system works like an appraisal filter. On the other hand, the results of the retrieval process are emotionally related (Roth, 2001).

* The emotions and consciousness interact: “While conscious control over emotions is weak, emotions can flood consciousness” (LeDoux, 1998; 19). That means that emotions have more influence on the cognition than the cognition has on emotions.

* LeDoux (1998) uses the concept of working memory to represent “the here and the now in the brain.” In the working memory inputs from a sensory system meet inputs from the emotional and arousal system and information from the long-term memory.
3. Reconstructing the Theme by Results of Neuroscience

The most important research concepts of affect are beliefs and attitudes. Both are seen as the stable mental background which regulates perceptions, thinking and actions of a person (Furinghetti & Pekhonen, 2000). This stable mental background system is a consequence of all the processes of an individual to a special object, person or idea. Törner and Grigutsch (1994) speak therefore of a “mathematical world view” of a person; Ciompi (1999) of “one’s own truth”.

Research methods for investigating beliefs and attitudes are in the most cases questionnaires; in some cases interviews. Both methods rely on the memory of the interviewees.

If we look at the results of neuroscience in relation to the memory, we have to distinguish between two memory systems with repect to emotions: the implicit emotional memory and the explicit memory about emotions (LeDoux, 1998). The implicit emotional memory operates unconsciously, is strongly connected to arousal systems and may often lead to bodily reactions.

The explicit memory about emotional situations contains all the conscious knowledge about emotional situations, emotional reactions to objects, persons and ideas etc.. The most important consequence is the fact that this memory system is part of the cognitive memory and there is no distinction between a remembrance of an emotion and a remembrance of a cognitive content (LeDoux, 1998).

The fact that the memory about emotions is a cognitive memory has some important consequences:

1) We have knowledge about our feelings and their origin. This knowledge is stored in memory systems as cognitive knowledge. Therefore we have the possibility of investigating knowledge about affect using cognition. Research methods used in cognition research (questionnaires and interviews) can help us to explore affect.

2) The memory about emotions is open for “rational” manipulations. That means we are able to think about our emotional remembrances. But we have to note all verbal statements are controlled by the cognition.

3) A very important control authority to all verbal statements is the “feeling of one’s own worth”. Therefore we try to give our emotional remembrances a meaning which doesn’t destroy the feeling of one’s own worth. In this sense persons have in interviews a tendency to trivialize their own weaknesses. This trivialization can, for instance, take place by the expression of opinions that particular mathematical contents are unimportant if the person is unable to cope with these kinds of problems (Wagneder, 1998).

4) Research on emotion and memory suggests that humans “construct” their memories in a way that they are able to live with this memory. A part of this
process is that we forget unpleasant facts more easily than pleasant ones. And our memory has suppression mechanisms to handle unpleasant remembrances (Roth, 2001).

5) Group processes have an important influence on verbal statements concerning contents which are emotionally coloured. Humans are able to “learn” emotions in group processes (Ciompi, 1999; Damasio, 1999). These processes can lead to common shared emotions concerning special contents. Especially, shared value systems can influence the contents of the memory. In this sense we have to see the habitus concept (Gates, 2001) or the socially constructed “feeling rules” (Ulich & Kapfhammer, 1991) (Feeling rules mean that the group says what a member of the group has to feel in a particular situation).

These reflections on the two memory systems give us a better insight into the meaning of the belief and attitude concepts. Both concepts are based in the outcomes of the cognitive memory system. This system contains not only our knowledge of cognitive contents but also the conscious knowledge of emotions. Therefore we are able by questionnaires and interviews to get information on cognitive as well as on emotional facts. The difference between the both concepts lies more in the kind of questions than in the quality of the memory. The restrictions of the remembrance of emotional situations and the handling of emotions by the memory also restricts the meaningfulness of the concepts. Belief and attitudes as a mental background system do not completely regulate our perception, thinking and actions, because the conscious controls on our emotions are only weak (LeDoux, 1998). Therefore we have learning situations, which are not ascertainable by the belief – attitude concept. In this sense it is not surprising that qualitative research methods led to a new affective category.

Studies on the problem solving process, especially with nonroutine problems, suggest that there exist emotional outbreaks during the problem solving process. These emotional reactions could be from mild to very intense, and are local and embedded in a special contextual situation. Goldin (2000) developed a model which describes states of the problem solving processes and the possible affective-cognitive reactions to the demands of this state. All these reactions are situational, caused by the demands of the problem solving process. The model describes two possible results, dependent on whether the problem solving process leads to success or not.

Interpreting these results by the concepts of neuroscience we have to note that there is a second memory in connection with emotions. This memory (LeDoux calls it emotional memory) operates unconsciously. Its evolutionary function is to help an individual to survive. Therefore it often works in dangerous situations, is strongly connected with arousal and bodily systems, and leads to reactions which are not controlled by cognition (LeDoux, 1998). This
emotional system is always activated if the appraisal of a situation leads to the result an activation is necessary. This appraisal of a situation is not conscious.

If we analyze the model of Goldin (2000) there are states in the problem solving process which can activate the emotional memory system. This activation can be observed by the researcher. The most well-known signs of an activation of the system are bodily reactions. To interpret bodily reactions is a qualification which is evolutionarily rooted in humans and therefore a valuable research method to evaluate emotional situations. As discussed above, these emotional reactions underlie only a weak control by the cognition (LeDoux, 1998) and are therefore especially valuable. Goldin describes the feelings by words which we can connect with the concerning expressions of the face, shaking of the hand, quavering of the voice, and so on. These signs of the body also allow us to recognize all changes of the emotional state.

It is important to note that emotional situations are not only stored in the memory which contains the knowledge about feelings they are also stored in the emotional memory and influence therefore further reactions to a special situation.

Activation of the emotional memory can lead in some cases to very intense emotional reactions. Reports on learning situations in adult education in mathematics tell from “learning blockades” (Lindenskov, 1996; Schloglmann, 1999; Wedege, 1998). To elucidate these problems I will give an example which was reported on the internet discussion group “adult numeracy” by Bonnie Fortini:

Has anyone run in to a case like the student I have had who seems unable to do any math that has unknowns or variables in it? She is mid 40s, very bright, English major going on to a Masters program. She can do all sorts of computations including fractions, percentages, ratios, and word problems are some of her favorite things to do. But as soon as you give her something like \(4 + 2x - 6 + 5x = 95\), she is totally frozen. She can't get past go when trying to combine like terms, and reacts physically (anxiety, tears, etc.).

Such an emotional reaction is not understandable within the conceptual frame which is used by research in mathematics education. This reaction is a traumatic reaction. The distinction between emotions used in mathematics education research is the stability. This is not a short sign of frustration described in papers to emotional reactions in problem solving processes. The mental system which caused this intense emotional reaction is stable, operating always if the relevant content is recognized.

LeDoux (1998) writes about such reactions:
In traumatic situations, implicit and explicit systems function in parallel. Later, if you are exposed to stimuli, that where present during the trauma, both systems will most likely be reactivated. (p. 202)

The specificity of such emotional reactions is that there is no chance to help on the cognitive level. Such problems are not solvable in classroom situations. The emotion flood the cognition and the whole cognitive system is blocked and not able to be reached by “rational” arguments.

During the last year there has been an increasing interest in teachers’ values and beliefs and the consequences for the classroom practice. Some researchers see a strong connection between teachers’ values and beliefs and the classroom situation. But classroom observations and case studies suggest that there are differences between beliefs and values expressed in interviews and the real classroom practice (Skott, 2000). Bishop, FitzSimons, Seah, and Clarkson (2001) describe the situation in the following way:

It is also recognized that there are differences between the values that are officially planned and those espoused by teachers, as well as between teachers’ espoused beliefs and their actual classroom practices – due in part to differential positionings as interview subjects and as teachers. (p. 170)

We note that beliefs as well as values expressed in interviews are products of cognition. Both use the explicit memory as background. In the classroom reality implicit unconscious systems are also activated and these systems influence all actions in complex situations. We have in the classroom situation on the one side the cognitively controlled values and beliefs and on the other side the unconscious from the implicit emotional memory system influenced actions. It depends on the local situation which system dominates the concrete action. Especially in critical situations, the implicit system is more active because the implicit system leads to actions which allow survival independently of which values and beliefs are formulated in interviews.

Summarizing the results of this paper: Neuroscientifical results helps to prove the adequacy of the theoretical concepts used in research of mathematics education. Furthermore they can help us to understand these concepts in a better way. However, it is not the idea of this paper to say that research questions of mathematics education can only be solved by neuroscience.

4. References

Advocates of testing often maintain that tests can provoke teachers to adopt new instructional practices. The purpose of this paper is to share results from a large-scale study designed to investigate the teaching practices of a group of fourth grade teachers who are all involved in state-mandated testing programs. We found that while teachers are aware of the test and have made some instructional changes in terms of specific teaching strategies, the changes that have been made tend to focus mostly on strategies and techniques such as the use of small group instruction or manipulatives rather than changes in, for example, the nature of the discourse that takes place in the classroom.

Introduction and Framework: In the last two decades, more and more states within the United States have either introduced or extended their testing of children (Editorial Projects in Education, 2001). This trend, however, is not limited to the United States (Niss, 1996; Keitel, and Kilpatrick, 1998 as cited in Abrantes, 2001; Firestone and Mayrowetz, 2000; Abrantes, 2001). Some advocates of tests consider them to be part of a broader effort to raise educational standards and make educators accountable for reaching them. They see testing as a way to use the authority of the state to improve teaching and learning and enhance equity by holding all children accountable to the same high standards (O'Day & Smith, 1993). Some maintain that a test that is well designed can prompt teachers to revise their practices because teachers will inevitably “teach to the test”, and that can be good if the test is well designed. Others maintain that content that is emphasized on tests gets emphasized in class, and that untested content either falls out of the curriculum or gets put off until the end of the year (Corbett & Wilson, 1991; McNeil, 2000). The types of items that are placed on the test are also claimed to influence the types of problems teachers use in class. The argument is that by including items that require students to solve more complex types of problems, teachers will be more likely to provide students with the opportunity to do the same in class. One reason given for the great interest in various forms of performance assessment and portfolios in the 1990s was the hope that tasks requiring students to show their work and explain their answers would promote inquiry-oriented instructional approaches (Resnick & Resnick, 1992; Rothman, 1995). Currently many tests combine conventional, multiple-choice formats with other formats intended to measure higher order thinking and problem solving abilities. However, even when tests employ formats where students construct responses, some of the same risks that are typical of the more traditional tests have been found to occur (Smith, 1996; Stecher & Barron, 1999).
Some opponents believe that extensive testing will encourage measurement of less relevant skills, and reinforce traditional approaches to teaching (McNeil, 2000). There are also those who believe that the effects of state tests have been overstated and that any modest changes in teaching exist alongside what has been conventional practice (Wilson & Floden, 2001). Regardless of the format, the evidence that testing promotes instructional change remains unconvincing or inconclusive at best (Newmann, Bryk, & Nagaoka, 2001; Smith, 1996).

In this research, we were interested in learning more about teachers' reactions to a standardized state test designed to encourage them to implement more student-centered instructional practices that reflect state and national standards (c.f. NCTM, 2000), and what kinds of practices they were actually implementing in their classrooms. Would the teachers, for instance, adopt practices that are associated with reforms and found to be more likely to help students to develop a deeper understanding of mathematics (Davis, 1984; Cobb, Wood, Yackel & McNeal, 1993; NCTM, 2000; Klein and Tirosh, 2000; Schorr, 2000)? Would they adopt specific strategies, like using more manipulatives? Would they simply ignore the test and not make any changes? Most importantly, we were also interested in how the changes that they might report actually manifested themselves in the context of their actual classroom instruction. More specifically, in this research, we were interested in gaining a deeper understanding of how teachers feel that the fourth grade test is impacting their teaching, and also in learning more about their actual mathematics teaching. This paper presents data regarding the actual practices of a group of teachers and their perceptions of how the test has influenced their teaching. We looked for evidence that teachers were incorporating approaches that would provide opportunities for students to learn mathematics as they were engaged in meaningful mathematical activity. Our approach in this research was to observe a sample of 4th grade mathematics teachers from across the state, and interview them about their practice and their reactions to the test (The test that we focus on is New Jersey's fourth grade Elementary School Performance Assessment (ESPA) that has been in place since 1999.) which include any changes that the test has prompted in their teaching. This paper describes the results. The particular codes and methods of analysis will be further described below. Our data suggest that the teachers we interviewed and observed are adopting new procedures as part of their instructional practice but not changing their basic approach to teaching mathematics. For example, they tend to continue to assign tasks that reinforce a procedural view of

1 A portion of this paper was presented, in a preliminary format, at the annual meeting of the American Educational Research Association, April 2001 and at PME NA, October 2001. Neither presentation focused on both the test data and the observation data. The work on this paper was supported by two grants from the National Science Foundation. The opinions presented here are those of the authors and are not necessarily shared by NSF, Rutgers University or Rider University.
mathematics, and classroom discourse does not tend to encourage students to defend and justify solutions.

Methods and Procedures: This paper focuses on observational and interview data from the first two years of a three-year multi-method study of testing and teaching in New Jersey that combines a statewide survey with a more intensive observation and interview study of a smaller sample of teachers.

Sample: The observation study focuses on 63 teachers. The sample was chosen to be representative in terms of both district wealth and geographic spread—i.e., north-south, east-west (Firestone et al., 2001). Almost all teachers taught fourth grade. That grade was chosen because it is the elementary grade tested in New Jersey.

Actual Observations: Fifty-eight teachers were observed for two math lessons and five teachers were observed once for a total of 121 classroom observations. The classroom researcher kept a running record of the events in the classroom, focusing on the activities of the teacher as well as capturing the activities of students, all problem activities and explorations, the materials used, the questions that were posed, the responses that were given—whether by students or teachers, the overall atmosphere of the classroom environment, and any other aspects of the class that they were able to gather. (For further information on sample selection, see Schorr and Firestone, 2001; Firestone, et.al. 2001)

Interviews: At the conclusion of each lesson, the teachers were asked to respond to a series of open-ended questions about the observed lesson. For example, they were asked: What were you trying to accomplish for today’s lesson? What concept or ideas were you focusing on? What, if anything, would you change about today’s lesson, and why? Why did you do this, or how did you feel about that (referring to a particular instance where for example, students explained mathematical ideas to each other or to the teacher, or with regard to a particular event or activity).

Teachers were also asked how state testing affected their teaching. Sample questions included: What kinds of things do you generally do to help your student get ready for the Elementary School Performance Assessment (ESPA)? Considering either the ESPA or the Content Standards, how, if at all, has that affected the topics you teach? How have you changed the teaching strategies you use in response to the ESPA and/or the Content Standards?

Coding: While observations were underway, researchers conducted detailed analyses of records of classroom observations, and adapted several pre-existing coding schemes to be used for coding the classroom data. These were based on the works of Stein, Smith, Henningsen, and Silver (2000); (Stigler & Hiebert, 1997, 1999); and Davis, Wagner, and Shafer, 1997). These codes were selected because they reflected ideas about effective mathematics instruction as indicated in national and state
standards. They included attention to the mathematical discourse that emerged, the opportunity for conceptual understanding to take place, the nature of student conjectures, the opportunities students had to share ideas and defend and justify solutions, etc. They were also chosen because we felt that they would supply information on the nature and use of reported strategies (i.e. manipulatives, small group instruction, use of different types of problems and activities, questioning strategies, etc.).

A preliminary coding scheme was tried out on approximately six observations before being agreed upon. A sheet of code definitions was created and a training session was held for coders involved in the activity. Ultimately, a coding instrument was developed which incorporated 18 dimensions, along with detailed descriptors of each coding category.

Two individuals independently coded each observation—at least one coder was an experienced mathematics education researcher. The other coder also had extensive experience in elementary education. After independent coding, raters sought to reconcile their differences and were successful in all but 2 of the 108 cases. In those two cases, another mathematics education researcher discussed differences with the raters and helped them to reach agreement.

Interview data were transcribed and entered into a qualitative data analysis software package. Interviews were sorted by question. Responses were analyzed in clusters, as there was considerable overlap in responses given to individual questions. Within each cluster, responses to specific questions on test preparation practices were reviewed and coded according to emergent themes. Responses were counted within each code. Interviews from 58 of the 63 teachers were available for analysis.

Results and Discussion: Some teachers reported that they liked the changes they had to make in response to ESPA. Nine made general comments to the effect that the test is forcing teachers “to evaluate their teaching style”. Several made more specific comments that the presence of ESPA was encouraging them to use alternative teaching methodologies like manipulatives or have children respond to more open-ended questions. Many teachers reported that ESPA is encouraging them to implement more inquiry-oriented instructional practice. One teacher explained, “It’s become my philosophy to teach them the concepts before, just, you know, ramming these rote facts down their throats.”

In the interviews, teachers mentioned four general changes: having students explain their thought processes, using manipulatives, problem solving and working on students’ writing. Forty three percent talked about trying to get students to explain their thinking in more detail. According to one teacher, the part “that I guess I really didn't do a lot of before is really get the students to start to learn how to
explain their thinking, to explain what they were doing. Sometimes they do it in writing; sometimes they do it to a partner; sometimes they do it to me.” One strategy to encourage student explanation is the use of more open-ended questions on tests and in class, and was mentioned by 33%. Fourteen percent talked about using more “how” and “why” questions in their whole-group teaching. One described this as working on “critical thinking skills” instead of “feeding them the answer”. Several also talked about using small-group instruction so students would explain their work to each other.

Another theme involved using manipulatives, and was mentioned by 45%. The ESPA has questions that involve at least written or pictorial descriptions of manipulatives. Many teachers felt that students who are more familiar with some of the current manipulatives could therefore better respond to those questions.

A third theme was a greater emphasis on problem solving (mentioned by 38%), though the actual meaning of “problem solving” was not always clear. For example, some teachers noted that they actually give students a set of strategies (i.e. draw a picture, think of a simpler problem, work backwards). Another teacher said, “We do a lot of work with problem-solving skills, just the basic skills of how you read a problem, how do you find the question, how do you find the information that you need, how do you check to see whether your solution is logical and can solve it a couple of different ways.” This emphasis on word problems reflects in part the use of open-ended problems on the ESPA.

Finally, 40% said that they emphasize “writing” to prepare their students for the ESPA. One teacher said that she now had her students “write all the time for all subjects.” Some teachers used “writing” to have their students explain their line of thinking in mathematics. In fact 12 teachers said they had students keep journals in math as well as other subjects.

The observations confirm that teachers are making some changes. Manipulatives were used in about 60% of all observed lessons. Similarly, students worked in groups for at least a portion of the time, in almost 65% of all observed lessons and in almost half of all cases, teachers made an effort to connect the lessons to the students’ real life experiences.

The adoption of specific strategies was not necessarily accompanied by a change in overall approach to teaching mathematics, however. For example, while manipulatives were used extensively, they were used in a non-algorithmic manner in less than 19% of all observed lessons. This essentially means that the manipulatives were used in ways that did not foster the development of conceptual understanding. In fact, in almost two thirds of the lessons where manipulatives were used, they were used in a very procedural manner, where the teacher generally told the students exactly what to do with the materials, and the students did it as best they could.
Other times, teachers used manipulatives to demonstrate a particular procedure to the class. In many of the lessons—while many teachers had students physically touch concrete manipulatives, there often was little or no opportunity for the students to develop their own solutions to the problem or consider the relationship between the problem activity and the concrete (or alternative) representations.

Beyond looking at the use of specific practices and materials, we also examined the mathematical tasks students were asked to perform. We categorized tasks as memorization only, doing procedures where the focus was on producing correct answers rather than developing mathematical understanding, doing procedures to develop a deeper understanding of mathematical concepts or ideas, or doing a mathematical task that requires complex and non-algorithmic thinking (Stein and Smith, 1998). Only 3% of all observed lessons involved situations where students were required to do non-algorithmic thinking.

We also examined whether tasks involved practice or non-practice activities. With practice tasks, the teacher demonstrates or develops a procedure, such as long division, and then assigns a number of similar problems on which students are to repeat the same procedure (Stigler, 1999). Alternatively, in a non-practice task the student may be required to invent a new solution method, analyze a mathematical situation, or generate a proof. Practice tasks predominated, constituting almost 80% of the observed lessons.

We also found that classroom discourse did not foster substantive conversations amongst students. Many teachers reported that they were interested in having students explain their reasoning. They also said they were interested in having students find and understand multiple strategies for solving problems, however, they rarely insisted on such activity. For instance, one code documented whether or not the teacher encouraged students to reflect on the reasonableness of their responses. In almost 80% of all cases the teacher rarely asked students whether their answers were reasonable. If a student gave an incorrect response, another student provided, or was asked to provide, a correct answer, but there was little discussion of an appropriate strategy to solve the problem. In an additional 15% of all cases, the teacher may have asked students if they checked whether their answers were reasonable, but did not promote discussion that emphasized conceptual understanding.

When students were provided with opportunities to talk about their answers or strategies, they usually simply stated answers to problems, and did not elaborate on their solutions. When a student was asked to share his solution, often he would respond with a numerical answer such as “5” or a procedure such as “you should add”. Students were rarely asked to explain how they got their answer, or how they arrived at their particular strategy. In fact, students only explained their responses or
solution strategies in a way that went beyond the execution of procedures in six percent of the observed classes. Sometimes teachers would ask for an explanation for using a particular operation but would not encourage students to expand upon their answers, or move beyond simplistic responses.

Conclusions: The teachers involved in this research have indicated that they have been motivated to change their styles of teaching as a result of the ESPA test. Indeed, our observations confirm that they do incorporate many of the strategies and techniques that they reported in our interviews (such as small group instruction and the use of manipulatives). This research does not and cannot document just when these strategies first became part of their practice; we can only note that the teachers attribute the implementation of many of them to the test. This study provides evidence that the teaching practices that we noted in our observations, however, are not focused on the more conceptually oriented aspects of instruction. Perhaps with appropriate support, teachers who are ready and willing to make changes in their teaching will be able to incorporate practices that will enable children to have access to mathematical instruction that fosters the growth of mathematical thinking.

The current study focuses on students’ conceptions of a mathematical definition. The research instrument consisted of written questionnaires and group activities. These activities aimed at eliciting considerations and argumentation surrounding students’ decision-making process related to the acceptance of a statement as a definition of a well-known mathematical concept. The focal concept for this study was a square, because of students’ familiarity with it. Data was collected from students’ responses to written questionnaires and videotaped observations of their group activities. The findings suggest three main perspectives underlying students’ conceptions of an acceptable mathematical definition.

PROLOGUE

We invite the reader to consider the following statements:

1. A square is a rectangle with four equal sides;
2. A square is a parallelogram with diagonals that are equal and perpendicular;
3. A square is a polygon with four sides, in which all sides are equal, and all angles are equal.

Which of the statements would you accept as a definition of a square? Which of the statements that you accept, do you prefer the most? Why?

The following three excerpts of 4 outstanding 12th-grade students debating over these questions convey the spirit of our study, which we report hereafter.

Excerpt 1:

Erez: [refers to statement 3] It’s correct, but it is not a definition.
Yoav: It’s correct, and it is a definition.
Erez: It has too many details.
Yoav: Too many details, but it is still a definition.
Omer: What does “too many details” have to do with that?

Excerpt 2:

Erez: I don’t accept statements (a) and (b) [refers to statement 1 above, in which a square is described as a special rectangle, and to another statement where a square is described as a special rhombus].
Yoav: I don’t either.
Omer: Why?
Erez: Because you need to know what a rhombus is, and you need to know what a rectangle is.
Omer: So what?
Erez: It is not acceptable to base a definition on other concepts.
Yoav: In fact a square is a special rectangle or a special rhombus, so you can define it using these concepts.
Erez: There is no doubt that it is correct, it is correct. But a definition, according to its nature, should be based on the lowest base.

Excerpt 3:
Omer: Yoav, draw a square.
Yoav: [sketches a square] o.k.
Omer: Erez, draw a square.
Erez: [looking at Yoav’s square] You mean he didn’t draw it with the diagonals?
Omer: Exactly.
Erez: What’s the connection?
... Mike: When you draw a square you see this [draws a square with his finger on the table], like he [Omer] told you, you see sides, you don’t see diagonals that are perpendicular. A square is first of all 4 sides. You don’t refer to the diagonals. The diagonals are a property of the square.
Erez: So are equal sides and right angles, they are also properties.
Omer: No, they are a definition.
Mike: Right, sides are sides. They build the square. Sides and angles build the square. Diagonals don’t build the square.

The current study is part of a larger one. A different portion of it, sharing some aspects of the theoretical background, appears in Shir & Zaslavsky (2001).

CONCEPTUAL FRAMEWORK

Definitions play a central role in mathematics and mathematics education. Recent studies on the notion of definition (e.g., Winicki-Landman & Leikin, 2000; Furinghetti & Paola, 2000; de Villiers, 1998; Borasi, 1992, 1987; Linchevsky, Vinner & Karsenty, 1992;) differ mainly with respect to the population under investigation (students vs. in-service or pre-service teachers) and the features of a definition that are focal to the study. The vast majority of these studies investigate how the participants view the minimal aspect of a definition. Others look into the arbitrariness aspect that is associated with the freedom to choose a definition among equivalent statements as well of the advantages of certain choices over others. In addition, Borasi (1992) studied gradual refinement processes directed towards reaching a valid definition. Our study looks into students’ ways of thinking about mathematical definitions and their processes of reaching an agreement on the necessity of a broad range of features of mathematical definitions.

Features of mathematical definitions

There are various features of a definition that characterize a mathematical definition (Vinner, 1991; Borasi, 1992; van Dormolen & Zaslavsky, 1999). For some of these
features there is a consensus regarding whether they are strictly necessary or just preferable, while for others there is no such consensus. The following three features of a definition are commonly accepted as crucial, thus, a mathematical definition must be: non-contradicting (i.e., all the conditions of a definition should co-exist), unambiguous (i.e., having only one interpretation), and logically equivalent to any other definition of the same concept. In addition, there are some features of mathematical definitions that are necessary only when applicable: A mathematical definition must be invariant under change of representation. In addition, when possible and appropriate, definitions should be hierarchical (i.e., based on basic or previously defined concepts, in a non-circular manner).

As mentioned above, a possible feature of a definition is hierarchy. We find it reasonable and useful, when applicable, to consider the level of hierarchy of a definition for concepts that are hierarchical in nature. For example, the 3 statements in the prologue are all hierarchical, yet they differ with respect to what we call level of hierarchy. Accordingly, statement 1 is based on a rectangle (thus we consider it the 1st and highest level of hierarchy), statement 2 is based on a parallelogram (thus we consider it the 2nd level), statement 3 is based on a polygon (which we consider the 4th level). Note that a definition of a square based on a quadrangle would constitute the 3rd level. We may continue in this way to even higher levels of hierarchy. The hierarchy of polygons to which we relate is rather common and concurs with the hierarchical classification of quadrangles opposed to the partition classification that de Villiers (1994, 1998) discusses.

Unlike the features described above, there are features of definitions upon which there is no consensus regarding their ultimate need. For example, it is not unanimously agreed upon whether a mathematical definition must be minimal (i.e., economical, with no superfluous conditions or information). While Hershkowitz (1990), Winicki-Landman and Leikin (2000), Vinner (1991) and Borasi (1987) claim that minimality is an ultimate requirement of a definition; others (e.g., de Villiers, 1998; Pimm, 1993) recognize the role of context with respect to the minimality requirement.

Another kind of distinction can be made between different types of definitions. A definition can be either procedural – by genesis, or structural - by a common property (Leron, 1988; Pimm, 1993)*. When geometric concepts are involved, we distinguish between a structural definition that relies on a property of certain parts of the object, and a property that is common to all, and only to, the points that constitute the object (i.e., definitions that are stated in terms of loci).

In our study we focus on definitions of a square that differ along the following dimensions: minimality, type (structural vs. procedural), and levels of hierarchy.

* Definitions can also be recursive (e.g., \( n! = n(n-1)! \)), or axiomatical (e.g., the definition of the Natural Numbers), however, our study does not address these types of definitions.
THE STUDY

The aim of the current study was to investigate students’ conceptions of a mathematical definition. Thus, we decided to focus on alternative definitions of a familiar and well-known concept—a square.

Four 12th-grade top-level students participated in the study. The participants took part in three consecutive meetings dealing with alternative ways for defining a square. At the first meeting each student received a written questionnaire that contained eight equivalent statements (see Table 1), and was asked to reply to it individually. In the second meeting the four students were grouped together and were requested to relate to the same task and to try to reach an agreement. In the third and last meeting, the students were asked to reply again to the original written questionnaire individually. Table 1 presents the eight statements in the questionnaire, and their characterizing features.

Table 1: The Statements in the Questionnaire and their Characterizing Features

In constructing the different statements for the research instrument, we attention was given to several features. As mentioned earlier, the statements differ from each other with respect to three main constructs: minimality, type (procedural vs. structural), and...
hierarchy. The hierarchical statements differed from one another with respect to the level of hierarchy of the defining concept.

**FINDINGS**

Students’ written responses to the questionnaire included 152 arguments: 108 arguments justifying the acceptance and 44 arguments justifying the rejection of a statement as a possible definition. The written arguments, as well as the arguments that were raised during the group discussion, were classified according to what seemed to be their underlying perspective: *mathematics, receptiveness, or figurative*.

Table 2 presents the distribution of types of arguments that the students used to support their decisions.

Table 2: Arguments for Accepting or Rejecting a Statement as Definition of a Square

By a *mathematics perspective* we refer mainly to arguments in which logical considerations were involved (e.g., evaluating a statement on the grounds of its
correctness, namely, on whether it is both a necessary and sufficient condition for a square). Other considerations related to the extent to which the statement is useful in mathematics (e.g., for proving or for classifying examples and non-examples) or to the legitimacy of using definitions that are not in the form of a conditional statement (e.g., procedural). Excerpt 1 in the Prologue is an example of students' employing mathematical considerations in their discussion.

By a receptiveness perspective we refer to arguments that focus on the communicative nature of a definition. According to this perspective a statement was evaluated based mainly on its clarity and whether it is comprehensible, within reach to those who deal with it, captures the essence of the concept, and based on accessible concepts (see Excerpt 2).

The last category of arguments, which we call a figurative perspective, has to do with the way the participants perceive a geometric object and its different components. According to this perspective, there is a distinction between the parts that seem integral to a geometrical object (such as the sides and angles of a polygon) and those that are often hidden (such as the diagonals of a polygon). In accordance with the figurative perspective, the latent parts are not equally considered integral parts of the object. Arguments of this category focused on the issue of whether it is legitimate to define a figural concept by properties of its latent parts (e.g., congruence of its diagonals). Thus, this perspective is characterized by the reluctance to accept statements that are based on properties of latent parts of a square (see Excerpt 3).

Note that about half the arguments (45%) for accepting a statement were based on mathematical arguments, while there was less mathematical support (25%) for rejecting a statement. On the other hand, receptiveness considerations played a major role both in accepting (54%) as well as in rejecting a statement (70%).

The group discussion (in the second meeting) yielded more insight to students' conceptions regarding what a (good) mathematical definition is. During this discussion the students found out that they don’t agree on what conditions a mathematical definition should satisfy. One of the questions that they raised dealt with the correctness of the statement, as in the following two excerpts:

Mike: All the statements can serve as definitions.
Erez: All the statements are correct, there is no doubt about that.
Omer: No, (h) can’t, because a definition should be more abstract and (h) is... a...
Erez: (h) is an instruction how to construct a square.
Mike: No way, (h) is too long.
Yoav: (h) constitutes construction instructions, it’s not...
Erez: [interrupts] It’s a description of how to build a square.
Omer: So, our question is whether we agree to accept it as a definition, [writes while speaking: w-e do-n’t ac-ce-pt...] we don’t accept statement (h) as definition, because?
Erez: because it’s not a definition, it’s an instruction regarding how to build.
The next excerpt occurred after reaching a consensus regarding Statement (h). In this part the students are discussing Statement (c):

Yoav: [refers to Statement (c)] We don’t accept it. It doesn’t mean that it is not correct. We just don’t accept it.

Erez: It is obviously correct, all the statements are correct, so should we accept them all as a definition?!

Omer: If it is correct, why can’t it be a definition?

Erez: [turns to Omer] Is statement (h) correct? Is it correct? Is statement (h) correct or isn’t it?

Mike: Statement (h) is correct.

Erez: [turns to Omer] So why didn’t you accept statement (h) as a definition?

Mike: [turns to Omer] Yes, why didn’t you?

Erez: [turns to Omer] Give yourself an answer for that.

Omer: Because it isn’t abstract.

Erez: This statement [refers to Statement (c) (see Excerpt 3 in the Prologue);] is also correct, but I am not willing to accept it, in the same way that statement (h) is correct and I was not willing to accept it.

Eventually, Erez succeeded to convince all the others that correctness of a statement is not a sufficient condition for a mathematical definition, and that there are many other considerations that should be involved in the decision process.

Other interesting questions, which were raised and discussed by the group of four included: Is it legitimate to define a concept based on properties of its latent parts (e.g., equal diagonals)? (as in Excerpt 3 in the Prologue); On what kind of concepts can a definition be based? (as in Excerpt 2 in the Prologue); Must a definition be minimal? (as in Excerpt 1 in the Prologue); Should the term (i.e., the concept name) indicate the meaning of the concept?

There were only 2 statements on which there was a unanimous agreement between all four students in their pre and post written responses, as well as in their final group decision. For Statement (d) they all agreed that it is acceptable as a definition, while for Statement (h), they agreed that it was unacceptable. Interestingly, in the latter case they expressed no doubts at all, while in the former case they had a stage in the second session in which they reconsidered their views.

The group discussions proved particularly influential with respect to the views held by the participants regarding the remaining 6 statements. Thus, for each of these statements at least one student changed his standpoint as a result of the interaction with his peers. Interestingly, students continued to think about the issues they had discussed together even after the second session was completed. Consequently, there were 3 occurrences of a student changing the standpoint that he held at the end of the group discussion, and responding differently in the third session (i.e., in the second time the written questionnaire was administered).
CONCLUDING REMARKS

Our findings suggest that the kind of task that was designed and implemented within the study has the potential of creating a rich and stimulating learning environment, in which the learners are motivated to interact meaningfully on their own, taking an active part in genuine mathematical inquiry surrounding different features of a mathematical definition, and engaging in argumentation and justification, in the sense that Yackel (2000) discusses and in the spirit of NCTM (2000). This activity also proved valuable as a research tool aimed at identifying students’ conceptions of a mathematical definition and its roles, and tracing the changes in their thoughts as a result of interactions with each other. Presumably, such activity may enable students to develop a view of mathematics as a humanistic discipline in which there is room for various opinions (e.g., Borasi, 1992). In fact, at the beginning of the study the students were convinced that a textbook definition is unquestionable, while at the end they became aware of the arbitrariness of the choice of definition and of their right to question a given definition and suggest alternative ones that are supported by valid considerations.

REFERENCE

BELIEF RESEARCH AND THE ACTUAL AND VIRTUAL COMMUNITIES OF A NOVICE TEACHER’S PRACTICE

Jeppe Skott, The Danish University of Education

So far, few attempts have been made to develop socially oriented understandings of the relationship between teacher beliefs and classroom practices. Two such attempts are outlined and a third presented, which is based on an empirical study of a novice teacher. This study suggests understanding the belief-practice relationship from the perspective of the multiple actual and virtual communities of a teacher's practice.

Research in mathematics education has recently moved towards a greater focus on the social contexts of the teaching-learning processes (Lerman 2001; Bishop, 2001). This social turn in mathematics education (Lerman, 2001) is apparent for instance from the increasing emphasis on the communicative and interactive aspects of learning and from the inclusion of situated perspectives on knowing.

There are, however, fields in which the social emphases are still conspicuously absent. One of them is research on the relationship between teachers’ beliefs and the classroom practices. Belief enactment, then, is still considered a highly individual endeavour, and beliefs are often considered an explanatory principle in relation to the classroom interactions (cf. Skott, in press). More specifically, if - from an observer’s perspective - there is apparent compatibility between the beliefs espoused in research interviews and the classroom practices, there is little more to explain. If no such compatibility is found, an argument for the lack of impact is made, for instance using highly individualistic and condemning explanations of teacher inconsistency, or capitalising on the methodological and conceptual problems of beliefs, deeming the classroom practices dependent on beliefs residing at other levels of consciousness, than those espoused in research interviews or questionnaires. In this understanding, beliefs are seen as a main determinant and the teacher as the sole agent of the mathematics classroom. It is indeed the teacher’s practice.

One socially oriented reaction to this is Hoyles’ (1992) and Lerman’s (2001) claim that beliefs are contextualised. Drawing on the work of Lave and Wenger (1991), Hoyles introduces the notion of situated beliefs. In this understanding, situations are co-producers of beliefs, and mismatch between beliefs espoused outside the classroom and the practices within it is only to be expected. Slightly modifying this argument, Lerman claims that although there may be ‘family resemblance’ between the views of school mathematics expressed in research interviews and those held in the mathematics classroom, they are qualitatively different entities (2001, p. 36). Another socially oriented reaction to the individual emphasis in the larger part of belief research, is to adopt an interactionistic perspective. Skott (2001) points to the classroom interactions as a source of changes in the objects and motives of the teacher’s activity. When the intention of facilitating mathematical learning is submerged other motives of the teacher’s activity (managing the classroom, building students’ self confidence, taking their family backgrounds into consideration, etc.),
there may not be compatibility between the teacher’s explicit priorities and his/her contributions to the classroom interactions. However, this is neither to be seen as teacher inconsistency (as traditional belief research claims), nor as belief change within the situation at hand (as Hoyles suggests). It is to be perceived as a situation in which the teacher becomes involved in activities not immediately related to mathematics teaching: (s)he is ‘playing another game than that of teaching mathematics’ (ibid. p. 24).

This paper is based on the premise that the extremely individual perspective often adopted in research on the belief-practice relationship is too limited, and that a social turn is needed also in this field. However, the above attempts to include a social perspective appear to need an elaboration. Hoyles’ use of the notion of situatedness does not indicate specific ways in which different situations structure beliefs, and the notion seems to be conceived merely in terms of time and setting. Consequently, it becomes an explanatory principle for otherwise inexplicable differences between beliefs and classroom practices, ironically somewhat in the same sense as teacher beliefs have become an explanatory principle in more traditional belief research. Skott, on the other hand, includes activity as a constituting element of situatedness, but does not account for how the objects of the teacher’s activity relates to contexts broader than the immediate interaction. More specifically, it is beyond the approach taken how for instance a set of dominant educational priorities in a certain school is brought to the classroom by the pupils and the teacher, and how they become part of the set of mutual expectations that frame the interactions.

The intention of this paper is to suggest an approach to research on belief-practice relationships that takes it seriously that a social perspective on teachers’ beliefs is needed, while maintaining that beliefs are significant. I shall refer to a study initially framed within traditional belief research to make the point.

**THE STUDY**

The study described in this section aimed to contribute to an understanding of the relationship between novice teachers’ beliefs and the classroom practices. Larry, a 29-year-old teacher from Copenhagen, was one of 4 teachers for primary and lower secondary school (1-10) selected for the study upon their graduation from college.

Larry had responded to a questionnaire sent to those Danish student teachers in their fourth and final year of pre-service education, who specialised in mathematics. The questionnaire included open and closed items on the students’ views of teaching-learning processes in mathematics and their priorities of different aspects of mathematics as a school subject. Also, it asked questions about the students’ own educational experiences with mathematics, their reasons for specialising in it at college, and their confidence as beginning mathematics teachers.

11 student teachers were selected for interviews out of 115 respondents to the questionnaire. Larry was interviewed immediately after the holidays following his graduation, i.e. within the first week of his teaching career. A semi-structured,
qualitative approach was used (Kvale, 1996) in which he was invited to elaborate on his priorities in relation to school mathematics and to describe significant educational experiences with the subject. Also, he was asked to comment on three sets of written materials: (a) a grade 5 student, Mathias, proudly presenting a false conjecture about the area and perimeter of rectangles; (b) an experienced teacher describing the different roles of investigative activities for high and low ability students; (c) five 12-17 line transcripts from imaginary interviews with teachers presenting different visions of school mathematics. (I shall return to (a) later).

Larry’s mathematics classes were videotaped for 2½ weeks six months after his graduation. The videotapes and transcripts were analysed from the perspective of congruence and conflict with the value judgements and educational priorities Larry expressed in the questionnaire and the interview. How, for instance, do the interactions look, when viewed from the perspective of his proclaimed view of student learning? A special focus was on how he organised and orchestrated classroom communication both in whole class and small group settings. In a final interview, Larry was asked to comment on 5 video clips selected as exemplary for the interactions when viewed from this perspective.

**Larry at the time of his graduation**

Larry was selected for the study because he seemed strongly committed to teaching, and because his views - as presented in the questionnaire and the interview - reflected significant aspects of current reform initiatives in mathematics education (e.g. NCTM, 2000). These views, he claimed, were mainly the outcome of his pre-service education. He described learning as individual knowledge construction especially related to investigative activities with manipulatives, and he saw teaching as facilitating learning in a variety of ways, not merely as explicating concepts and procedures. However, Larry also emphasised more traditional elements of school mathematics, especially student command over basic skills. This lead to a perceived conflict between the amounts of time needed for investigations and the pressure to cover the traditional syllabus. Further, he considered these two objectives irreconcilable: at any one time you have to do one or the other. These priorities - including the perceived conflict between them - was apparent in his response to the questionnaire, but even more so in the first interview. As a teacher, you have

"to see how your individual students understand - of course you can’t see that - but you can see how the individual student works and see how they try to move on and see what works for them. [...] Actually, I’d like to allow the students to have more time. Maybe if I can inspire them in different ways, they find out on their own [...], but I also know that we don’t always have the time to do that [...] Sometimes you just have to lecture ... all the other stuff isn’t possible all the time. [...] maybe 70% of the time they have to work traditionally, and then they may experiment in the last 30%". (The first interview)

Larry was concerned with how to differentiate his teaching according to the students’ ability levels, an issue that was important in his pre-service education. His view of the issue was apparent from his reaction to the transcript on Mathias, cf. the previous
section. In the transcript, Mathias works with three other students to find the area and perimeter of rooms they have measured and to present their findings to the rest of the class. At the end Mathias exclaims with some excitement: ‘Wow, look at this, the longer the perimeter, the larger the area!’ Larry was informed that as he did not know Mathias and the class, he was expected only to provide an immediate reaction to the situation. He said he would praise Mathias for the observation, but challenge him to find counter examples. Asked if other students would be involved he said:

“No, this is Mathias’ observation, so it’s OK that he continues with it ... it’s also a way to differentiate between the students, because he is ready for it, but maybe the others would find it boring [...] If some of the others see what he is doing and are caught by it, then they can continue working on it, but I wouldn't impose it on them”. (The first interview)

In summary, Larry claims that student investigations are required but isolates them from the bulk of his instruction dominated by more traditional tasks. This ‘island’-approach is combined with a view of differentiated teaching, which individualises student activity and misses significant opportunities for communal learning.

**Larry meeting the school**

Larry works at Mellemvanga, a conservative private school 30 km from the city. To exemplify the school’s traditional educational priorities, he mentions that marks are given from grade 1; standardised tests are used frequently, and the results published within the school, so that marks may be compared between students, classes, and teachers; and students are streamed according to ability in grades 8, 9, and 10. These practices, alien to those of most Danish schools, are the result of decisions made by the management. However, they are endorsed by the parents, who are interested in their children’s education, but focussed on traditional values like good behaviour and skill acquisition. At times, their interest does become a trying experience.

Already in the first interview, Larry is worried about the extent to which his own educational priorities would clash with those of the school:

“... somehow it [the management] doesn’t fit very well with the ways I think, [...] I have to strike a balance between the expectations of the parents and the school management and the ways I want to work [...]” (The first interview).

Also, Larry considers his colleagues an obstacle to change. He explains that they used the management as an excuse for not taking any initiatives themselves:

“...several of my colleagues have said, if we’ve discussed doing things differently: ‘Good idea, but you have to remember that at any time you’ll be held responsible by the parents and the management, and it’s important that you can [...] show that you’ve been through all that is in the curriculum’.” (The first visit to Mellemvanga)

Larry is very much aware that he is deemed responsible for the students’ learning. At Mellemvanga, teaching is a highly individual endeavour:

“It is the individual teacher who makes all the decisions. There is no teamwork. This means that the experiences I am to gain from older colleagues have to be collected in a hurry during the break, while I’m eating my lunch, and doing a whole lot of other stuff...
that needs to be taken care of - so obviously: It isn’t much. [...] And I miss that a lot. [...] It would be easier if some of my colleagues would ask ‘I’m going to try this out, do you want to join in’. I would say yes immediately. But nobody asks” (The first visit to Mellemvång)

It is apparent from the initial interviews that Larry considered himself in opposition to the dominant priorities of the school. He soon developed an ‘I-they’ relationship, not an ‘I-we’ relationship, to the colleagues, the management, and the parents.

**Larry meeting the classroom**

Larry teaches mathematics in grade 5. He calls it ‘my little luxury’, as there are only 15 students, there are very few disciplinary and social problems, and most of the students do well in mathematics. The only major difficulty is that the school’s competitive assessment practices have lead two girls to attach a self-imposed stigma on their mathematical activity, due to their relatively poor performances.

On the day when the class begins on the new chapter on integers, Larry starts off by correcting the students’ homework in a fast and insistent manner in a whole class setting. He then introduces the notion of perfect squares by writing ‘$2^2 = 2\times2 = 4$’ on the board, and asks what $3^2$ may mean. A student suggests that the result is 6. Larry, turns it down, saying “Now you have multiplied by 2”. He writes ‘$3^2 = 3\times3 = 9$’, and another student suggests that the two numbers be the same. Larry confirms this and writes the students’ homework - a number routine tasks from the textbook - on the board. The students start working on these tasks individually, Larry giving fairly direct instructions to the ones who find it difficult. By the end of the lesson, Larry writes the perfect squares from 1 to 196 on the board and asks for a connection between the numbers. After a few seconds, a boy exclaims: ‘Between each number there is an increase of two’. Larry praises him for the observation, and asks, if they think this pattern continues. They claim that it does. Larry agrees and gives an explanation, but one that few students understand. Immediately afterwards, a student interrupts and claims to have found another pattern: ‘If you multiply something/two numbers with 5s in the end [as the last digit] the result is always something with a 5’. All of a sudden, other students present other conjectures in a very spontaneous fashion. Larry chooses to close the issue and not pursue the questions any further.

This first lesson on integers is exemplary for the atmosphere in Larry’s classroom. First, Larry often dominates whole class discussions in the sense that he uses the textbook to delineate a narrow focus for the students’ activity. Second, he is fairly explicit in his support to the students. Third, the students often present conjectures on patterns or relationships, either spontaneously or after being prompted. To sum up, Larry uses fairly traditional modes of interaction with the students in large parts of the lessons, but an atmosphere has evolved that encourages and values student contributions. Larry’s response to these contributions is generally to take over the conjecture or observation, both when it concerns a standard result and when this is not the case. The following episode exemplifies the latter situation.
In the next lesson Larry brings in a box of centicubes, i.e. plastic cubes of 1\times 1\times 1 centimetres that may be put together and used for instance when teaching place value. The students are to make squares and cubes out of centicubes in order to relate integer concepts of perfect squares and cubes with their geometric representations. Larry suggests that the students build just a skeleton of a corner and its adjacent sides to illustrate a cube (cf. fig. 1). The students begin and soon this happens:

**Kasper:** I came to think ... I found that when you make one of these, you don't use 27 centicubes [shows a skeleton of a 9\times 9\times 9 cube].

**Larry:** Well how many do you use?

**Kasper:** You only use 25.

**Larry:** Because //

**Kasper:** //even though 3 by 9 is 27 ... because you make like this [takes off two rods of 8 centicubes each]. Now there are 9 centicubes.

**Larry:** Yes.

**Kasper:** And then these two, they are 8 each [shows the two rods of 8]. And together ... that is 25.

**Larry:** And that is 25, yes, and that is simply because //

**Kasper:** [Is trying to remain in control of his proposal] //but Max he thought that the 8\times 8\times 8-cube would be 24...

**Larry:** Yes, well that is because this one [picks up Kasper's cube, and points to the centicube in the corner] //

**Kasper:** //it counts as three.

**Larry:** It belongs to - take good care now - it belongs to this side, to this side, and to this one [Larry takes over and continues his explanation].

In this episode, Kasper presents his observation that fewer cubes are needed than expected. Larry praises him for it, but takes over the conjecture, preventing Kasper to remain in control. Commenting on the episode in the interview, Larry explained that he wanted to give other students access to Kasper's observation, but that few of them did understand. He did not consider this a problem and referred to need to differentiate his teaching. Also he did not pursue the observation any further, because he was uncertain where it would take him, and because

"there are certain things we have to cover in the course of the year, and that's why we spend a lot of time doing textbook tasks. We also have to do stuff like this, but it is obvious that I have to limit it and consider, how much they are to do of one and the other. Obviously I could return to this later, but I am not sure I'd do it. I don't think I would."

(The final interview)

The above episodes from Larry's classroom significantly resemble his school mathematical priorities as espoused in the initial interviews and in the questionnaire. The atmosphere invites student conjectures, which may be pursued by the originator, but never by the whole class, cf. Larry's concern for differentiation. In most cases,
Larry takes over the students' observations and conjectures and closes the investigative opportunities without involving the students. This latter characteristic of his classroom is a result of his initial intention of ensuring enough time for more traditional activities, but is fuelled by the pressure he is under at Mellemvang to ensure that the students perform well in next test.

DISCUSSION AND CONCLUSIONS

As mentioned earlier, two attempts have been made to describe belief-practice relationships socially. One emphasises how the energising element of the teacher's activity emerges from the interactions with specific groups of students and directs her further contributions to the discourse; the other uses situatedness - in terms of time and setting - as an explanatory principle for discrepancies between beliefs and practice. The study of Larry suggests combining these attempts by using the notion of communities of practice (Wenger 1998).

Wenger claims that developing a practice requires

"the formation of a community whose members can engage with one another and thus acknowledge each other as participants. As a consequence, practice entails the negotiation of ways of being a person in that context. [...] In this sense, the formation of a community of practice is also the negotiation of identities” (1998, p. 149).

From this perspective, there is no community of teaching practice at Mellemvang. The teachers' do not jointly relate to the same children, do not discuss ways of handling classrooms in general, do not to challenge the educational priorities of the management, and do not participate in joint efforts to develop or make different use of teaching-learning materials. In short, they do not mutually engage in practices related to facilitating student learning. However, this delineation of the teachers' engagement signifies important aspects of a community of teachers' practice, albeit in negative terms. Other aspects of this practice are how to behave in the staff room, how to prepare for the school festival, how to put a request to the management or how to prepare for the next PTA-meeting. These negatively and positively defined fields of practice are those in which the teachers 'acknowledge each other as participants', in which they jointly engage, and which constitute their identities at Mellemvang. At times Larry struggles hard to become part of this community.

However, the community of teachers' practice is not a source of Larry's identity as a facilitator of learning. Repeatedly, he referred to his experiences with mathematics and mathematics teaching and learning at college, both when he was satisfied with his own teaching and when he was not. In spite of the physical and temporal distance between Larry's pre-service education and his teaching activity, the former does constitute a context for the formation of his identity as pertaining to the latter, not only while he was still at college, but also at the beginning of his teaching career. In other terms, when Larry's classroom activity is primarily directed at facilitating learning his participatory framework, the social aspect of his professional identity, is linked to his pre-service education. Specifically, what matters most for the ways in
which he invites student contributions, for his use of manipulatives to support their learning and for the ways he deals with problems of student differentiation, is his participation in the educational discourse of his pre-service training. Upon his graduation, then, Larry is related to the virtual and probably fading community of teaching practice established and defined in the course of his pre-service education, the main source of his beliefs.

The moral of this story concerns how the role of teachers’ beliefs in relation to practice may be conceived. The need for a contextualisation of beliefs, i.e. for a social turn in research on belief-practice relationships, neither requires one to refrain from dealing with beliefs as a set of relatively stable school mathematical priorities, nor does it force one to rely on vague descriptions of a ‘family resemblance’ between beliefs and practice. I suggest - in line with Lave and Wenger (1992, p. 32 ff.) - to include activity as a constituting element of situatedness, and to acknowledge the simultaneous existence of multiple, possibly conflicting, actual and virtual communities of a teacher’s practice. Each of these may play a role when different objects of the teachers’ activity emerge in the course of the classroom interaction. From this perspective, the focus of classroom research on teachers’ beliefs is not to state congruence or conflict between beliefs and practice, but to disentangle the ways in which - from the teachers’ perspective - the multiple communities interact and frame the emergence of different objects of his or her activity.

DESIGNING TASKS TO EXPLORE DRAGGING WITHIN SOFT CONSTRUCTIONS USING CABRI-GEOMETRE.

Cathy Smith
Faculty of Education, Cambridge University, UK

Tasks were designed to study the relationship between students' actions and reasoning in Cabri geometry problems. In task-based interviews with two UK students of differing geometric experience, I recorded the simultaneous words, actions and visual results whose interrelation expressed their problem solving approach. This data was analysed using Arzarello's (1998) classification of dragging modes, and relationship with transitions between inductive and deductive reasoning. This indicated that these students spontaneously used dragging modes related to soft construction and inductive reasoning, sometimes also finding deductive explanations. Implications of these results for future task design include the importance of promoting construction as a means of gaining control of a figure for future enquiry.

AIMS

In this study I design and evaluate tasks that exploit and promote distinctive heuristics identified in the research concerning learning with Cabri-geômetre. Cabri is a dynamic geometry environment characterised by: direct manipulation of screen geometric “drawings”, construction tools based on Euclidean geometry, and - its key design feature - the invariance of geometric dependencies under dynamic variation of their initial objects (dragging). Any software medium changes not only the accessibility of mathematical objects of study, but also their nature, the way that they are acted upon and how meaning is made of them. We can therefore distinguish between the geometry of the curriculum, and the meanings constructed through Cabri.

A review of case studies of children's work with Cabri illustrates the variation in children's geometric knowledge and in the foci of researchers' interest across different countries (Hölzl, 1996; Arzarello, 1998b; Jahn, 2000 Healy, 2000). The background to my study is the UK curriculum, which traditionally has little in the way of extended problem solving or explicit teaching in deductive geometric reasoning. Given appropriately designed tasks, could such students find that dragging heuristics supported deductive geometric learning?

DRAGGING AS MEDIATOR BETWEEN CONCRETE AND ABSTRACT

The functional uses made of Cabri – the actual sequences of drags and clicks – are of interest in pedagogic research because they are both indicative of the learner's understanding, and formative in making meaning. The computer provides a window that enables reconstruction of the learner's conceptions from her actions in a context that is both exploratory and expressive (Noss et al., 1997). Cabri users recursively...
exploit the dual exploratory/expressive dialectic by developing heuristics of dragging in which geometrical conceptions, already reorganised by the Cabri medium, are made accessible at a perceptual level to permit further reorganisation (Arzarello, 2000).

Noss et al. (1997) identify a situated abstraction: a reorganised mental concept which does not replace a concrete visual representation but simultaneously derives from it and gives meaning to it through actions. Hancock (1995) finds a similar two-way interaction in his notion of transparency: a computer modelling tool embodies mathematics in a way that makes it easier to “see” its subjects; but equally the subjects are a background against which the mathematics can be seen. He traces a phenomenological-epistemological progression from naïve transparency, as learners use Cabri to express what they already know, to opacity as they struggle with the tool and with their geometric understanding, to co-ordinated transparency as the two are reconciled. The progression from opacity is the hardest, and of most interest to teaching.

Different modes of dragging

Recent literature has distinguished modes of dragging according to how they are used and their mathematical nature. This emergent classification has been summarised and extended by Arzarello (1998b), who focuses on the interplay of perception, movement and thought, and the distinction between what is taken as given and what is sought.

Wandering dragging: describes the often random dragging that is used when exploring a construction, seeing the dynamic relationships and searching for an interesting feature. In this mode there is only one direction of progress: from visual/physical to conceptual; and successful use puts a high premium on what students perceive and how they interpret it.

The dragging test: dragging part of a construction to verify that a desired regularity is maintained. This powerful and direct Cabri representation of the mathematical idea of generality is the most clearly related to inductive and deductive geometric reasoning: affording both empirical justification and a sequence of actions that expresses relationships between the initial objects and the conclusion. However, the necessary co-ordination of a set of figures with an appropriate independent variable and a construction sequence leading to an interpretable phenomenon is often a complex task.

Lieu muet dragging. Whereas the dragging test starts with a set of conditions on which to verify a hypothesis, lieu muet dragging seeks to establish a locus for which the hypothesis is satisfied. Arzarello (1998a) relates this mode of dragging to logical abduction: seeing what rule you have the case of. This mode of dragging is popular when students learn with Cabri (Jahn, 2000): it is a heuristic that is suggested by the medium rather than a representation of a traditional geometry heuristic.

Bounded dragging: dragging a point along a perceived trajectory to explore what happens to a feature of interest. The difference from the dragging test is that the
trajectory is not actually constructed, so the domain of the draggable point remains implicit and is independent of the history of construction.

**Use of dragging within constructions**

The dragging test has a natural mathematical status in verifying a conjecture formed as an if-then statement. Students, however, are found to prefer the other forms of dragging, and may rarely perform a drag test without the mediation of other modes. Hölzl (1996) first describes the common heuristic of dropping a construction constraint then varying by dragging until a visual solution is found. Working on a task without simultaneously concentrating on all conditions allows the user to construct representations of the constraints in the most natural way without considering the order of dependence necessary for a linked construction. Healy (2000) identifies similar heuristics in what she calls soft constructions. Both Hölzl and Healy show how students’ soft methods could have led to complete geometric solutions, but raise the question of how to support students in this final stage of reasoning. The starting point for this study is Healy’s finding that students had difficulty in making connections between deductive reasoning and apparently equivalent Cabri construction sequences, and her recommendation for more consideration of soft construction methods in task design.

Such research has been started by Arzarello (1998a, 2000) in the context of students who have had explicit instruction in modes of dragging. He traces their shifts from exploration to explanation, or from ascending to descending control, and finds that dragging, especially lieu muet dragging is a crucial mediator. The actions of clicking and dragging taken as non-verbal language have both a deictic and a generative action function in triggering and supporting the students’ transition to abstract generalisation. Students’ verbal reasoning changes from broken oral narrative associated with exploration using wandering dragging, through abductions describing lieu muet dragging, to the more sequential linear sentences of canonical mathematical proof, which may still use the vocabulary of Cabri actions. One crucial transition appears to be between seeing a lieu muet locus as a dynamic trajectory resulting from dragging to a geometric object that could be constructed in its own right (Jahn, 2000).

In summary, distinctions between the geometry of the curriculum and Cabri geometry become evident in differing approaches to the activities and logic of problem solving. Difficulties such as functional dependence, and the co-ordination of several constraints arise in both geometries, but Cabri can offer modes of action and of expressing meaning that are intermediary in finding a solution. Tasks have been most successful when learners have a clear idea of the type of endpoint required, either in Cabri or in geometrical terms, and have explicitly been taught some Cabri heuristics. The focus of study should be the interplay between the actions and words accompanying a task, which characterises the modes of dragging, and then between these modes and developing control of the problem solving and proving strategies.
METHODOLOGY

The study includes task-based interviews with two contrasting subjects: a six-year old, Daisy, with no experience of either Cabri or Euclidean geometry, and a nineteen year old, Helen, working on a task developed during a mathematical reasoning course using Cabri. Daisy’s 45 minute interview was interactive; in Helen’s case I took the role of non-participant observer for most of the hour interview, asking her to type responses into comment boxes onscreen, but finally asked her to talk through her progress and intentions. The data collected were recordings of what was said or written annotated with the simultaneous Cabri actions and gestures, and the screen’s appearance. This data was analysed using the classifications of dragging and reasoning modes as described above.

Daisy’s task – Circles and Rectangles

The aim of this interview was to investigate designing a Cabri task involving only elementary properties of shape but accessible to different modes of dragging and reasoning. Daisy played with Cabri circles and triangles, and I then gave her a previously constructed rectangle, which she dragged, from tall/thin to short/fat, then aligned horizontally with traditional proportions.

Cathy: If you have a rectangle, can you make a circle that touches all four of its sides?

Daisy constructs a circle, placing the centre near the centre point of the rectangle and pulling out the radius. “No – it would have to be an oval,” stops dragging and draws an ellipse in the air. Changes the rectangle to look square, “Now you can...” and fits her circle to it.

“And if I pull it now, it won't be touching ”: she extends the square horizontally into a rectangle.

“If we were trying to move it across we would have to move it up too because if we didn't move up it would change into an oval. Say we had a square the sides of the square are all the same size. If we had a rectangle they are not all the same size. If we have to pull it across ... to be a circle it has to be the same length everywhere ... and those were against the edge so if we move it up it's going to go off the top.”

Daisy’s initial response is visual – she imagines a curved shape inside a rectangle and recognises that it would be an oval i.e. not a circle. Her focus on the special case of a square appears to be motivated by getting some solution on screen. She then starts to reason about continuity from a square via one-way enlargement, a mode of reasoning afforded by my prior construction of the dragable rectangle. She makes her argument verbal, firstly in transformational terms, describing the effects of hypothetically dragging the circle (“if we were trying to move it ..”), and finally by relating the geometric properties of a rectangle, square and circle (“it has to have the same length
everywhere”). Her use of “Say we had… If we had…” indicates that this is an abstract
generalisation, although still phrased in concrete dynamic terms (“go off the top”).

Cathy: Can you make a circle that touches all four corners?

Daisy: “No, only if it's a square”. She drags back to a square and pulls the circle out to
touch all four corners. “It’s on the outside now”.

She drags out a rectangle and starts to make the
circle bigger. Pauses. She moves the centre of the
circle fairly haphazardly and reattaches the two
right hand corners. She increases the radius again,
and again moves the centre to attach the corners.
Eventually: “Yes I think you can ... its got to be in
the middle.”

She drags the centre of the circle onto the middle of the rectangle, adjusts the radius,
points and checks: “One, two, three, four corners, yes you can.”

Daisy initially intended to use her previous heuristic of arguing from a square to a
rectangle to demonstrate impossibility, but the perceptual results of dragging intervene
to change her reasoning. She realises that she no longer has to keep the circle inside
the horizontal and vertical dimensions of the rectangle. Hancock's description of
opacity seems apt as Daisy struggles for another way to relate the two shapes. She has
lost the naive transparency of her earlier interactions with the geometric objects, and
no longer uses any of her knowledge of horizontal and vertical symmetry. Eventually
by repeating the actions of varying the centre she establishes a horizontal locus for the
centre of the circle - lieu muet dragging to meet relaxed constraints - and this suggests
the centre of the rectangle. Finally she notices as a geometric phenomenon that it is
equidistant from all four corners.

**Helen’s task - Perpendicular bisectors**

Draw a quadrilateral ABCD. Construct the perpendicular bisectors of each side. Label
the four points (M, N, P, Q, say) at the intersection of the perpendicular bisectors from
adjacent sides. If you move ABCD, what happens to the inner quadrilateral MNPQ?

1. Investigate the relationship between the
   internal angle at A and the internal angle at M.

2. For what types of external quadrilateral is
   MNPQ a parallelogram?

3. Find a quadrilateral ABCD that is similar to
   its inner quadrilateral MNPQ (i.e. an
   enlargement/reduction).
This construction is also described in Arzarello (2000) with students exploring the degenerate case, but this version starts with angle relationships which are familiar to UK students, and has structured goals that leave open further enquiry. Helen started the task by wandering dragging, noticing that one inner point was invariant when she dragged A. She used the causal metaphor of dragging to describe this geometrical relationship: changing A changes only two outer sides, which changes only two inner sides, so only three of the inner points. She stated that the inner angles at A and M add to 180.

Helen’s next step was intuitive (and she couldn’t later explain it)- she constructed the diagonals of the inner and outer quadrilaterals, and it helped her see a way to make MNPQ a parallelogram: “It would be a parallelogram on the outside because the intersections of the diagonals must be at the same point. That’s the only way; if I move A away, the centres don’t coincide.” Her reasoning accompanying this lieu muet dragging seems to be purely inductive; arising from the observation that as she dragged ABCD to move the intersections of each pair of diagonals together, both MNPQ and ABCD became parallelograms.

Helen again moved on without explanation to the third question. Like many of the students she did not use the geometric meaning of “similar”, but also tried to give ABCD and MNPQ the same orientation: “Can’t find exactly similar – must be a rotation, because to get the same angles ... need a square or a rectangle .. and then it disappears.” She spent some time explaining to herself why this degeneracy happened. In doing so she went back to the relationship of the angles at A and M, and wrote a justification of this invoking the two right angles in the quadrilateral with diagonal AM. Although the degenerate case was a deviation from the set questions, considering the role of the perpendicular bisectors helped to give insight into the whole task. Helen then wrote a deductive explanation of her second result: “For MNPQ to be a parallelogram, its opposite sides must be parallel. The sides of MNPQ are the perpendicular bisectors of the sides of ABCD so for them to be parallel, the sides of ABCD must be parallel”. Helen then tried to manipulate the quadrilateral ABCD while keeping it a parallelogram, an example of bounded dragging, but she had great difficulty co-ordinating this and finally gave up. While her perceptual aim was clear in this episode, she was less clear in her purpose within the task: “I’m looking for it to be the same ... similar”.

Helen’s task gives an example of progress towards a deductive argument in a more challenging geometric context. Although the task was structured to build up a sequence of reasoning, she actually synthesised all her reasoning at the end of the sequence of exploratory tasks. Unlike Daisy, Helen's developing reasoning was not immediately associated with her concurrent screen actions, which led her simply to visual answers, and so it is less clear whether dragging played a specific mediating
role or that she simply had inspiration. However it was noticeable that she built up a body of empirical knowledge through the soft dragging modes before attempting any explanations at all. The construction of the diagonals, for example, was a temporary stage of her reasoning and after making her explanation she later deleted them. It was nevertheless important because it gave her *wandering dragging* a clear visual endpoint, and allowed her to progress to finding the *lieu muet* that achieved this condition.

**CONCLUSIONS**

My aim was to design tasks that asked for elements of deductive geometric reasoning but were accessible to students with little experience of such problems. I followed the suggestions of Healy (2000) that task design in this context should give equal consideration to soft construction methods, and of Arzarello (2000) that the focus of observation should be the interplay between the physical/visual aspects of different modes of dragging and the language of argument. Both Daisy and Helen spontaneously made purposeful use of the *wandering, lieu muet, and bounded* dragging modes that are characteristic of soft constructions. These modes were always associated with the purpose of exploring the next situation, finding the next answer and making progress with the task. Equally it is clear that they accompanied inductive reasoning and making abductions, i.e. establishing and expressing necessary conditions for a solution. In Daisy's case these lead to a contradiction and she finds a deductive argument, but Helen's explanation remains at the stage of finding what is necessary. This is what Arzarello characterises as gaining *ascending* control of the problem. Helen does start to move towards *descending* control, trying to express the reverse argument by varying a general parallelogram ABCD to see what happens. This suggests that her reasoning at the end of her investigation is still closely related to her perception and expression in Cabri – she does not look to see that the logical connectives are all equivalences, but starts another dynamic experiment.

In the final stages of their task both subjects carry out painfully slow dragging as they try to co-ordinate their physical actions with a number of perceptual constraints, and the experience is frustrating. Much of this could be avoided by using construction e.g. fixing the radial point as a rectangle vertex, or ABCD as a parallelogram, but Helen and Daisy did not attempt to do so. It seems that the most important heuristic is finding the methods that allow us to control the variation that we want to perceive. The soft dragging methods above have the benefit of being very accessible, allowing the user at the same time to explore the task and start to make sense of it, but they also have their limitations when the user has more sophisticated experiments in mind. It is perhaps at this stage that Arzarello's students benefited from their teaching in Cabri techniques, and were ready to start again with a fresh construction that would enable them to vary what was now of interest. *Lieu muet* dragging was found to phenomenalise a locus of conditions, thereby mediating the transition from ascending
to descending control, but the next stage would be to make explicit this locus as the starting point for experiments and the given for deductive reasoning. This study suggests that it may be helpful not just to exploit the potential of soft dragging methods in making sense of and establishing a context for a theorem, but also to include support for reorganising the problem and expressing the context as a construction which can be dragged in the desired way.

TEACHERS' BELIEFS ABOUT GENDER DIFFERENCES IN MATHEMATICS: 'GIRLS OR BOYS?' SCALE

Riitta Soro
University of Turku, FINLAND

The focus of the paper is to examine teachers' beliefs about the differences of boys and girls (aged 13-15 years) as learners of mathematics. For this purpose a rating scale was developed with a new type of response format: 'Girls or Boys?'. A sample of teachers of mathematics (N=204) were asked to classify a list of characteristics as being more frequent among girls or among boys in their mathematics classes. Factor analysis revealed six main dimensions indicating beliefs in gender differences and one secondary factor suggesting a core belief dimension 'Mathematics as a gendered domain'. The teachers' scores on the six belief dimensions revealed the following highly believed gender differences: girls avoid using intelligence and boys attain most of the teacher attention.

INTRODUCTION

Since the early 1970's there has been an increasing research activity in the field of gender and mathematics education especially in the English-speaking Western nations (Leder, 1992; Leder, Forgasz & Solar, 1996; Lubienski & Bowen, 2000). Research on affect and mathematics has focused on the affective responses of students rather than those of teachers (McLeod, 1994). Identifying classroom behaviours that influence gender differences in learning, and patterns in how students choose to study mathematics has been difficult (Fennema, 1995). Teachers' knowledge of, and beliefs about, mathematics have been studied from the perspective of cognitive science, but this perspective is less used in studies concerned with gender (Fennema & Hart, 1994). Studies that deal with the mental processes of teachers might give insight into why teachers interact with boys and girls the way they do. The body of literature available regarding gender issues related to teachers' beliefs does not give conclusive evidence that teachers believe that mathematics is more appropriate for males than females (Fennema, 1990; Li, 1999). The acquisition of beliefs or their modification is a major issue in the activity of teaching. As Green (1971, p.42) further points out, beliefs are always gathered as parts of a belief system. Therefore it is more important to explore the nature of sets of beliefs or belief systems than to examine the nature of a belief alone.

The problem is, that in the educational literature and among researchers, there is no common definition for the concept "belief", nor a clear distinction between beliefs, conceptions and knowledge (Pajares, 1992; Pehkonen & Furinghetti, 2001). Thompson (1992) distinguishes knowledge from belief systems on the basis of the possibility of objective evaluation of validity.
The distinction between the terms “belief” and “attitude” is also problematic. The instruments to assess or measure beliefs are those used in the research of attitudes. Whereas attitude refers to a person's favorable or unfavorable evaluation of an object, beliefs represent the information he has about the object. One distinction that has been repeatedly proposed is the theory of three components of attitudes; affect, cognition, and conation, and beliefs belonging to the category of cognition. Fishbein and Ajzen (1975) reserved the term “attitude” for one of the categories, namely affect. Beliefs are on the border between cognition and affect. The latter, affect, is often more or less emphasised in a teacher's belief concerning gender and especially gender and mathematics.

METHOD

The aim of the study was to examine teachers' beliefs about the differences of boys and girls as learners of mathematics. A new scale was developed for this study. There are two research questions:

Do Finnish mathematics teachers believe in gender differences in mathematics?

What are the components of teachers' beliefs about gender differences in pupil's behaviours in mathematics learning situations?

Instrument

The study was a survey, a belief inventory, and quantitative methods of analysis were employed. The instrument of the study was a belief questionnaire with 55 structured items and some open questions, in which the teachers were asked to characterize, in their own words, boys and girls as mathematics learners. In this paper I approach the belief components, which I call belief dimensions, by factor analysing the answers to the structured items. It was anticipated that starting with a large number of items would be necessary in order to find the most relevant ones. The 55 statements of student characteristics were grouped under the following headings: A) Girls and boys in math-class, B) Girls' and boys' attitudes, C) Girls' and boys' abilities and cognitive skills, D) Upper secondary mathematics choices and career choices, and E) The situation of gender equity in school. This grouping of the statements was only intended to support the teacher in answering.

The topics of the items were mostly found in the literature about gender issues. Some of the items were adopted and modified from earlier studies (e.g. Maccoby & Jacklin, 1974; Leder, 1992; Brusselmans-Dehairs & Henry, 1994). Some items arouse from my experience as a mathematics teacher and reflections upon my beliefs and gender dependent teaching practices. The topics were discussed with a couple of experienced in-service mathematics teachers. The instrument was examined by some ten mathematics teacher educators and researchers. The first version of the questionnaire was tested with a group of fifteen pre-service secondary mathematics teachers. All the groups mentioned above gave valuable feedback and helped in developing the items.
The Girls or Boys? scale

According to Fishbein and Ajzen (1975, p.12) with respect any object–attribute association, people may differ in their belief strength, in terms of the perceived likelihood that the object has the attribute in question:

we recommend that “belief strength,” or more simply, “belief,” be measured by a procedure which places the subject along a dimension of subjective probability involving an object and some related attribute. (Fishbein & Ajzen 1975, p.12)

The three commonly mentioned rating scales for verbalized attitudes are Thurstone, Likert and Osgood scales (see e.g. Nunnally 1967; Henerson, Morris & Fitz-Gibbon 1978 p. 82; Keats 1997). The Likert method of constructing and applying attitude scales is by far the most common. The items have alternatives e.g. “strongly agree, agree, undecided, disagree, strongly disagree”, which are scored 2,1,0,-1, and -2, respectively. The alternative “undecided” has been shown to lead to anomalous results and should possibly not be used (Keats 1997).

Forgasz, Leder, and Gardner (1996) have reexamined the widely used Fennema-Sherman Mathematics as a male domain scale and they found evidence that several items in the scale may no longer be valid. For example it is nowadays not obvious what can be referred from disagreement with the item: "Girls can do just as well as boys in mathematics." Are girls doing better or are girls doing worse?

In this study it was aimed to develop a new scale, and to take into account the remarks mentioned above. A Likert-type rating scale with a response format suitable for comparisons and measurements of differences was constructed. The statements in the questionnaire were of the type: "X finds mathematics difficult." For each statement, the respondent had to select the subject X out of the following five alternatives:

G usually a girl

g a girl more often than a boy

± a girl as often as a boy

b a boy more often than a girl

B usually a boy

The principle of this Girls or Boys? scale is that each item counts for two Likert-type items a) and b) which are opposite to each other and in sum-scales either of them is reversed (Table 1). The scores for the Girls or Boys? items are counted as the average of the two scores a and b* of the corresponding Likert items (score b* is a reversed one): G = -2, g = -1, ± = 0, b = 1, and B = 2.

When a Girls or Boys? item needs to be reversed for sum-scales, it means that the Likert item to be reversed is item a) instead of item b). For certain this Girls or Boys? scale does make only an ordered scale, but like Likert scales it will be used in this study as an interval scale.

*reversed score

The scale of this study meets the requirements of summative models. In the summative scaling of people respect to psychological traits it is assumed only that individual items are monotonically related to underlying traits and that a summation of item scores is approximately linearly related to the trait (Nunnally 1967, p. 604).

The response format was based on probabilistic interpretations: it was assumed that e.g. the answer ‘usually a girl’ means that the respondent assigns a probability of about 90 % (i.e. from 80 % to 100 %) to X being a girl and respectively, a probability about 10 % to X being a boy. The percentages in Table 2 are only hypothethical and used in order to justify reversing and summing up the item scores. The scores (from -2 to 2) are linearly related to the middle of the probability intervals (10 %, 30, % ...).

Participants and design of the study

The study was a survey. The test participants were Finnish mathematics teachers from a sample of 150 randomly chosen schools for grades 7-9 (13-15 year olds). In each school one female and one male mathematics teacher, if available, were asked
to answer to a questionnaire. This was carried out in February 2000. The response rate was approximately 69%. One year later, in May 2001, ten of the respondents were interviewed.

Implementation

The goal of the factor analysis was to detect structure in teachers' beliefs about gender differences in mathematics. In the choice of the analysis method, principal component analysis vs. classical factor analysis was considered. In the former it is assumed that all variability in an item variable should be used in the analysis. In the latter only the variability in an item that it has in common with the other items is used, and it is assumed that the remaining variance of an item is its unique variance (Harman 1976, p.15). Furthermore, the theoretical background of gender beliefs did not suggest the latent factors to be uncorrelated, which directed the choice to an oblique rather than to an orthogonal reference system.

I started with the principal component analysis and then compared it to a classical factor analysis in which I extracted the results by the principal axis method with oblique rotation. Further I factor-analyzed the data with hierarchical principal axis method to divide the variability in the items orthogonally into that due from shared or common variance (secondary factors) and unique variance due to the clusters of similar item variables.

It was not aimed to use all the items of the questionnaire but to choose the most relevant ones for the belief structure. The amount of items was reduced based on low communality (<0,35) in principal components and classical factor analysis (both methods yielded similar results). After three reiterations 31 items were left for the final analysis. Cattell's scree test and Kaiser criterion (Harman 1976, p.163) were used to determine the number of factors that best describe the data. The former supported five to seven factors and the latter nine factors. The six factor solution was chosen since it appeared to be very interpretable. Moreover the seven and eight factor models would not have raised markedly the accountability except on only one of the item variables. The six factors accounted for 47 % of the total variance.

RESULTS AND DISCUSSION

Both the principal components model and the hierarchical principal axis model with oblique factors represented similar "clusters" of item variables. Each of the obtained six factors determined a sum-scale of the items that loaded highest on that factor. These new variables, called belief dimensions, each representing one component in the belief structure, were taken to measure the direction and intensity of the beliefs about gender differences.

A positive value on a belief dimension indicated that the teacher associated the characteristics of the dimension to a boy more often than to a girl. A negative value indicated that a girl more often was mentioned having the characteristics. Value 0 was the score for no difference between boys and girls. A value 0 or near 0 was also
obtained if the respondent gave contradictory answers e.g. “a girl more often” to X are capable of higher mathematical thinking” and “a boy more often” to There are more mathematically talented among X.

The mean score was negative for Avoid using intelligence -0.59 (sd 0.37) indicating a belief in a trait typical for girls. A positive mean score, indicating a feature addressed more often to a boy than to a girl, was found for Teacher attention 0.53 (sd 0.49), Expectations of success 0.44 (sd 0.37), and Talent 0.22 (sd 0.37). Smaller average differences were found on the dimensions Lack of equity 0.09 (sd 0.37) and Work-orientation -0.12 (sd 0.41). All these means differed statistically from the ‘no difference’ value zero.

The hierarchical principal axis analysis gave one secondary factor. All item variables of the primary factors Avoid using intelligence and Talent and one variable of the factor Expectations of success loaded on this secondary factor. Of these the item "X is innately mathematically more talented" had the highest loading. These results can be interpreted to reflect a core belief dimension "Mathematics as a gendered domain". These three central belief dimensions are represented in Table 3.

The validity of the scales refer to the validity of reported verbalized beliefs, which may not correlate highly with the behaviour pertaining to the belief. The validity is limited to what individuals know about their beliefs and are willing to relate. After a
year had passed the reliability of the empirical data was examined by interviewing ten of the respondent. The persistence of the item responses was about 95\%. Also the interpretations of the item contents were confirmed in the interviews.

The instrument developed, the questionnaire with a new answering scale, seemed to be feasible and practical in measuring beliefs about gender differences. According to the interviews it was answered without much effort and maybe frankly as well. It still remains open how sufficient the verbal expressions alone are as evidence of beliefs.

The responding rate (69\%) supported representativeness. The results and findings discussed in this paper can be generalized to include the wider population of all mathematics teachers in lower secondary schools in Finland.

The most emergent result of this study was the teachers' belief in girls employing inferior cognitive skills. The results of the factor analysis did not show any general belief factor that would affect all kinds of beliefs measured by the items. Nevertheless the results suggested a core belief dimension "Mathematics as a gendered domain". Is this a "primary belief" as Green (1971, p.44) defines i.e. a belief for which a person can give no further reason?

The results of this study are alarming if these beliefs of mathematics teachers - boys use their brain and girls are just hard workers - reinforce and sustain these differences.

REFERENCES

We employed eye-tracking technology and individual interviews to investigate the differences among prospective elementary school teachers, practicing teachers, and mathematics educators as they observed and analyzed a videotape of a mathematics teaching episode involving a researcher and a fifth-grade student thinking about fractions. Results indicate that, relatively speaking, mathematics educators attend more closely to the student, teachers attend more closely to the interviewer, and prospective teachers attend more to the mathematical content than do the mathematics educators and teachers. We discuss these differences in terms of an expert-novice continuum and conclude by discussing implications for video use in teacher development and enhancement.

Videotapes are widely used in the preparation of prospective elementary school teachers and in the professional development of practicing teachers because they can provide rich contexts for considering issues of learning and teaching. Although widely used, there is little research to guide mathematics educators as they determine effective ways to incorporate the use of videotapes in teacher development and enhancement. At a more basic level, we know little about that to which people attend while viewing videotapes, or how one’s background and training affect the sophistication with which one interprets videotapes. The purpose of this study was to address these issues by investigating differences among three groups; prospective elementary school teachers, practicing teachers, and mathematics educators, as they viewed a mathematics teaching episode involving a researcher and a fifth-grade student. We employed a methodology whereby reactions of participants were gauged though analysis of point-of-gaze and level of attention, measured and recorded with sophisticated eye-tracking technology. Additional data was collected through interviews of the participants. The study was part of a larger project aimed at helping prospective elementary teachers better understand the depth of knowledge necessary for teaching elementary school mathematics, and was intended to inform the development of early field experiences that would meet this goal.

Early studies contrasting expert and novice reasoning (e.g., Larkin, McDermott, P. Simon, & A. Simon, 1980) have indicated that experts are more likely than novices to focus on relevant problem features that lead them to qualitatively better conclusions. Experts have access to a large body of organized knowledge that can be quickly accessed and used to guide problem interpretation and solution. In a major study of the qualities exhibited by experts, Dreyfus and Dreyfus (1986) outlined five stages of development of expertise: Novices are relatively inflexible in their reasoning, advanced beginners have experiences that allow them to build cases that complement their book knowledge; the competent performer can articulate goals and
find means to achieve them; the proficient performer recognizes similarities between
derifferent situations and are more holistic in their approach to finding solutions; and
experts share this holistic approach by responding effortlessly and appropriately to
the situation encountered. Livingston and Borko (1990) noted that teaching
mathematics has characteristics of expertise found in other domains, that is, expert
and novice mathematics teachers differ in their perceptions, information processing,
knowledge structures, and decision making. Indeed, in their own comparison of
review lessons of expert and novice teachers, they found that explanations of expert
teachers were conceptually linked and less procedural whereas teachers spent time
coming to understand the content themselves.

The eye-tracking technology used in our study was developed by Marshall (1998).
The information on eye movement is coupled with documentation of effortful
cognitive activity that accompanies enlargement or dilation of the pupil. A large
body of research has shown that "the pupil dilates on presentation of cognitive or
affective stimuli; pupil dilation occurs with effortful information processing in many
areas;...(and) the degree of dilation varies by individual and task (p. 2)".

METHOD

Four prospective elementary teachers, four experienced elementary teachers,
and two mathematics educators (with doctorates) participated in the study. Each
viewed a videotape of a fifth-grader being interviewed by one of our project
researchers (R). While watching, each was fitted with equipment used to track point
of gaze and level of cognitive activity. Each individual then was taken to another
room where she viewed the video again, this time with the white dot tracking her eye
movements. During this second viewing, a researcher from our project, pausing
frequently, interviewed the participant regarding her reactions to the videotape.

The videotape selected for this experiment was a 22-minute interview of a fifth grade
girl who was said to be of "average mathematical ability." The girl was poised,
pleasant, and cooperative, and appeared to be quite comfortable with the videotaping
process. The interview was taped in a studio that allowed a double screen to be
shown on the final version of the video. The top of the screen showed the interviewer
on the left, the girl on the right; the bottom half of the screen, called the "work area",
allowed simultaneous viewing of all paper work and manipulative use. The interview
had three distinct parts. In the first part, Terry’s fraction knowledge was assessed.
She was asked to circle the larger of pairs of fractions or to place an equal sign
between two fractions if they were equal. Her knowledge of fractions was very weak.
In the second part of the interview, R gave an explicit, procedurally oriented lesson
on changing mixed numbers to improper fractions and back again. Terry learned the
procedure but could not apply it later in the interview. The third part of the interview
was a conceptually based lesson during which R used Pattern Blocks\(^1\) to begin to develop Terry's understanding of fractions.

**Data collected.** In addition to a videotape showing point-of-gaze for each participant, the eye-tracking staff provided us with (a) gaze traces of each individual during a 2-minute interval; (b) graphs indicating the percentage of time spent by each of the three groups looking at the interviewer, at the child being interviewed, and at the work area; and (c) estimates of the cognitive activity over 30-second intervals of each individual as she watched the video. To make sense of this data, we then divided the entire video into 30 second intervals, documented what was happening in the interview during each interval, and charted the level of cognitive functioning for each individual during that 30 second interval. We of course also had the transcribed interviews from the second viewing of the video.

**RESULTS OF INTERVIEWS**

During interviews we asked the same set of questions of each participant and they were encouraged to say anything about the video at any time.

**Initial Reactions to the Videotape.** The two mathematics educators both made initial comments on the structure of the interview, on expectations, and on technological aspects of the videotape. The teachers were very aware of the conceptual problems children have with fractions. They tried to understand Terry’s thinking, but sometimes found it difficult to do so. All teachers commented on Terry’s confidence and poise. T2 thought it was frightening that she was so confident in her misconceptions, “She spoke like a very confident child and she’s obviously had much success in her schooling. You could just tell by the way she articulated her responses to R’s requests.” The prospective teachers had few comments to make before reviewing the video tape.

**Reactions to Assessment Section.** The mathematics educators were not surprised with Terry’s poor performance, but they realized that her knowledge of fractions was very weak for a fifth grader. From their own experience, they thought that their own students (preservice teachers) would find some of the questions unfair. “(My preservice teachers) often pick up on the nuances of the interviewer’s questions, and say, “That was a trick question” or “She didn’t understand” and “It’s not the student’s fault”. For the most part, teachers were not surprised by Terry’s responses to the assessment questions. They thought Terry should know more about fractions than she did, but thought the errors she made were typical. The prospective teachers appeared to be at least somewhat surprised at how weak Terry’s knowledge of fractions was, but they were careful not to fault her. One said that “It looked like she had not learned it yet, but considering if she had not learned that, she was doing pretty good” (although she was not doing well at all).
Reactions to Procedural Lesson. ME2 thought that the interview demonstrated the chasm between what teachers think they are teaching and what is actually being learned. ME1 found value in the fact that the interview showed how easily Terry picked up on the procedures without a clue as to what they meant, and that she held on to her misconceptions. Teachers reflected on the kind of teaching Terry had probably experienced. All commented on her lack of sense-making. One said “That it’s probably the kind of teaching that she’s had, what she’s comfortable with.” The teachers realized that Terry needed something concrete to help her understand fractions as quantities. Interviews of the prospective teachers indicated that they had particular ways of doing things that made it harder for them to understand Terry’s thinking. For example, PT3 said, “I’m trying to figure out why she would choose one-half because I’m so used to, well, I was converting it to decimals, like three-tenths was point three and one-half was point five.” There was also a tendency on the part of these four to excuse Terry for her weak knowledge base.

Reactions to Conceptual Lesson. ME2 recognized that Terry’s knowledge was still very fragile at the end of the lesson, and thought Terry was beginning to feel some conflict. “In fact, she called it I’m pretending whether I know fractions or whether I don’t. That is how she handles the conflict. Obviously she’s recognizing that her old way failed her.” ME1 did not think this lesson helped Terry see any connection between the blocks here and the procedures from the earlier lesson. Both educators also made comments about the use of manipulatives. “When I think about using the Pattern Blocks like that, I’m also aware of the ... I’m not convinced about what she really understands about fractions in terms of relating them to a whole other than a hexagon.” Teachers were dismayed that even after her work with pattern blocks, Terry still responded that 1/2 plus 1/2 was less than one. “She wasn’t convinced even though they had done all that work (with blocks). Then when prompted to push forward, to visualize the pieces, she’s got something to grab onto but that one experience wasn’t enough to undo the damage.” They could see that she was struggling to accommodate the new and contradictory information she was being exposed to. T2 said “She has all her misconceptions now and she’s really struggling because R’s really shifted her paradigm a little bit but she’s still not there yet. She’s really in disequilibrium.” The teachers picked up on small things as telling. For example, T4 noticed that Terry never used the word ‘equal’ even though R did, and even though equality was a key concept in understanding fractions.

When asked for comments on the second lesson, the prospective teachers had little to say. One said “I think the blocks helped her to visualize and really understand.” She later said that “I think it was good that you allowed her to see things first and you didn’t contradict her and tell her ‘No that was wrong’ and let her see it for herself.”

Would it be helpful to show this video to preservice teachers? Both mathematics educators thought it would be valuable for preservice teachers, but they were cautious in talking about how it could be used. ME1 said “It is long. It’s something
that might be done over two weeks. . . For me, it raises some issues. It would allow me to talk about the whole variety of issues as well as the questioning.” The four teachers also felt that the videotape should be shared with prospective elementary teachers of mathematics. From T1 we heard, “Absolutely. I think it would be a great way to help them come to believe that there is a reason to explore concepts deeply before procedures,” and from T3: “They can have an idea as to how concept development happens and why that concrete part is so important.” Interestingly, T2 would show it to prospective teachers, but not to teachers in her own district because they would simply blame the teachers Terry had had. All four thought that the most important segment to show was the teaching with manipulatives. Prospective teachers who had been exposed to the use of manipulatives in their content class for teachers thought that the video should be shown to their peers. PT4’s statement was similar to those of PT2 and PT3: “I think it is a different approach to fractions and I happen to like it. I think it’s very cool. I would show the last part definitely.

Comparing the two lessons. Both mathematics educators found value in both the procedural and the conceptually oriented lesson. ME1 found it interesting that “She doesn’t seem uncomfortable or threatened by either lesson. That was a pretty mature kid, really. It was pretty evident that she was punting, but it seemed to me that she was able to keep a presence of mind, like ‘Am I going to be able to pull this one over on him? Maybe he won’t notice.’” Teachers were well aware of the difference in the manner in which Terry responded in the two lessons. “In the second segment (the procedural lesson), she didn’t seem to connect the numbers to any conceptual knowledge. She was able to see R’s procedure and use it. But I don’t think that she connected it to anything at all. In the third segment, again, she’s a bright girl; she caught on quickly. But she would need a lot of time with the manipulatives to really cement her knowledge and to realize that some of the things she had thought before weren’t true.” When the prospective teachers were asked about the differences in the two teaching sequences, their answers showed that they saw differences, but in a very vague ways. PT3 said “(The last lesson) was more conceptual, I guess, visual. The other one was more math, as long as you knew how to do your math.” They were asked which parts should be shown to prospective teachers. “I would show the last part definitely. I think the last part took a different approach because most everyone knows how to find the improper fractions.”

WHAT WE LEARNED FROM THE EYETRACKING DATA

The point-of-gaze information we have on a selected 2 minute segment confirms that the prospective teachers spent up to 75% of their time looking at the work area where the work was being shown. All four PTs looked at the work area (and sometimes at R or Terry) during almost every 5-second interval of this time period. These prospective teachers appeared to spend a good deal of their time mentally figuring out the answers to the problems given to Terry so that they would know if she was doing them correctly. “I think during this time I was probably trying to answer the questions in my head . . . and trying to see if it would match hers” (PT3). We
conjecture that part of the reason for this focus on the work area was that these individuals needed to first work out each problem given to Terry for themselves, and that they were not always able to do this quickly. The mathematics educators, on the other hand, spent about half the time looking at the work area, and practically no time looking at R. They were most interested in Terry and what she was doing. Teachers spent about 60% of their time looking at the work area and less time looking at R than did the prospective teachers.

The three groups had significantly different levels of cognitive functioning ($F(2,43) = 106.05$), and each group was significantly different from the other two. We were surprised to find that the mathematics educators had the lowest cognitive workload, followed by the prospective teachers, with the teachers registering the highest of the three groups. Upon reflection, and after analysing interview protocols, we speculate that the mathematics educators had the lowest cognitive workload because they found very little of surprise in the interview. Both had undertaken many such interviews themselves and viewed many interviews similar to this one. The teachers, on the other hand, have little opportunity to see one-on-one interviews with children. Also, they had developed expectations built on their own experiences. Each of the teachers has a strong interest in mathematics learning, and thus found this video interview interesting, causing them to reflect on what they were seeing at the same time they were viewing the interview. The prospective teachers lacked knowledge needed to interpret what was going on in the interview. They did, however, appear to attend to the problems being given to Terry, working them out, sometimes too late, so that they could try to make sense of her responses.

**SUMMARY AND DISCUSSION**

The university mathematics educators acted in ways one would expect experts to act. They responded effortlessly to the interview situation, as was evident in the cognitive workload graphs of each individual and in the composite graphs of the two individuals. Their level of cognitive functioning remained in the low range throughout. They agreed that the procedural lesson should confirm, for any viewer, the ineffectiveness of this type of instruction. Both were aware of the limitations of the Pattern Blocks as an instructional aid. Both commented on the interviewer’s skill at questioning. Both were cautious about using the videotape with prospective teachers, commenting on the need to show pieces over a period of time and plan for appropriate discussion. In our discussions of this data, we realized that having the interviewer on the screen may have been an unnecessary distraction to others, who spent considerably more time looking at R.

The cognitive workload for the teachers was in the moderate to high range for the most part; higher than that of the professional mathematics educators. The teachers knew what an average fifth-grader should know about fractions, and this knowledge played out in the interviews. They recognized Terry’s answers as typical of a student with poor understanding of fractions, and tried to understand the underlying
misconceptions Terry had, knowing that those misconceptions would need to be overcome for Terry to progress. But they expected the work with the Pattern Blocks to be more effective than it was, not realizing that the lesson was too brief to have lasting effects. We considered the teachers to be experts, but at a less advanced level than the professional mathematics educators. The teachers’ access to their own knowledge of the mathematics involved in R’s questions, their interest in Terry’s responses (as compared to the greater interest of the prospective teachers in the problems posed rather than in responses), and their ability to understand and interpret the various parts of the interview were qualitatively different from those of the prospective teachers.

The prospective teachers did express some surprise at Terry’s lack of understanding of fractions, but thought she had probably not learned about fractions yet. They had their own ways of solving the problems posed to Terry, and consequently found her answers hard to follow. The reactions of the prospective teachers were, in most respects, quite different from those of the teachers. They could accurately be classified as novices. As in the Livingstone and Borko study (1990), the prospective teachers had different knowledge structures and processed information differently. They spent a high percentage of the time looking at the work area, trying to understand the mathematical content of the questions rather than focusing on the verbal and nonverbal behavior of Terry.

What lessons did we learn from this study? We recognize that the teachers reactions to the video interview were heavily influenced by their many years of experience in the classroom, working with students like Terry. They had knowledge of the mathematics appropriate for this grade level, and they had expectations that helped them evaluate Terry’s mathematical knowledge. However, the data from this study led us to believe that there are experiences we can provide for prospective teachers that can help to refine their knowledge of what children know, change their expectations of what children should be able to do, and offer them new ways to observe and make sense of the children’s responses to problems posed to them. This belief has guided our design of experiences that can have these effects. For example, we have prospective teachers who have just completed a highly-structured early field experience during which they, in pairs, interview individual elementary school students, then discuss, as a class, what they have learned. With another set of prospective teachers, we offered a seminar during which the prospective teachers viewed and discussed a carefully selected and sequenced set of videos of interviews with students. We believe that such experiences can change the knowledge structures of prospective teachers, the manner in which they process and interpret student answers, and make decisions about what next steps should be taken. They can move, in the words of Saber et al. (1991), from being novices to being advanced beginners, and thus will be more likely to succeed in teaching, and to take less time becoming experts. The major implication of what we learned from this study for our work with prospective elementary school teachers was that careful attention must be paid to how videos are used with prospective teachers. For them to benefit from
viewing a video in the manner intended, particular care must be given to the selection of the video and to the preparation for the viewing. But simply solving the mathematics problems beforehand may not be sufficient preparation for viewing a videotape if the children’s solutions in the video do not model their thinking; prospective teachers need to anticipate the kinds of solutions children may provide. We also must pay attention to the tools used in a video, so that, for example, before showing a video of a child using a hundreds chart, it is necessary to acquaint them with the hundreds chart and even help them consider ways the chart might be used.

Observing a video twice is often helpful; the first time watching all the way through without considering any guiding questions and the second time watching with particular questions in mind. A purpose for watching videos needs to be understood, especially when if videos are assigned for homework. For example, in preparation for conducting an interview with a child, we often gave as an assignment watching a video of a child solving the same problem that they was posed to the child during the interview. In this case, we ask the prospective teachers to pay attention to particular aspects of the video such as the interviewer’s prompts or wait-time or the children’s use of language. Another advantage of observing video for homework is that the prospective teachers can rewatch a video as they need, which some do. Thus, the eye-tracking study has guided us in further project activities aimed at helping prospective teachers gain more expertise about children’s thinking.

A CASE STUDY OF A UNIVERSITY STUDENT’S WORK ANALYSED AT THREE DIFFERENT LEVELS

Nada Stehlíková
Charles University in Prague, Faculty of Education

An on-going study of a long-term one-to-one work with a future mathematics teacher will be presented. The framework for a threefold analysis of data is suggested. The first level of the analysis of data yielded several settings which will be described by some variables (e.g. didactic contract), the second level of analysis concentrates on different situations within the settings and the third level of analysis investigates communication patterns. The first results of our analyses are briefly given. Finally, further research is proposed.

In 1998, we started a research project focused on the building of internal mathematical structures [1]. A series of semi-structured interviews was conducted with several future mathematics teachers who volunteered to be part of the research. One of them, Molly, who was in her first year of study then, was very excited about the mathematical topic she was working on – so called restricted arithmetic RA [2]. She studied it at home and often came back to the experimenter (the author of this paper) with new suggestions. Very soon the previously formal interviews transformed into a qualitatively different setting in which the research purposes grew less and less important, while the teaching-learning purposes became prominent. Molly continued investigating RA with growing autonomy, formulated hypotheses, definitions, tentative theorems, meeting regularly with the experimenter to discuss her work. Her ‘co-operation’ with the experimenter spanned all five years of her study and culminated in her writing a two-hundred-page diploma thesis on the topic.

What contributed to Molly’s enthusiasm and endurance? Why did she do so much additional work in her free time? Why did she feel such a need to explore RA as much as possible? Why did she go on with the work while the other students were content with several interviews and stopped? What teaching-learning settings did she go through during her interaction with the experimenter and how can they be characterised? We do not know the answers to these questions yet but we have tried to find a methodology of how they might be found. This will be the focus of this paper.

THEORETICAL BACKGROUND

At the university level, many types of teaching-learning situations can be determined, some similar to those in elementary or secondary schools, others specific to university teaching: tutorials, lectures, seminars, individual instruction, demonstration, class discussion, home study, office hours, etc., among non-standard teaching-learning situations we have, for instance, scientific debate (Alibert, Thomas, 1991), and using constructive, interactive methods involving computers and co-operative learning (Leron, Dubinsky, 1995). Some attention has been paid to individual types of
situations, e.g. tutorials (Nardi, 1996, Jaworski, 2001), lectures (Boero, Dapueto, Parenti, 1996), however, the author does not know of any research which focuses specifically on situations at the university level and determine their invariants and specifics.

We will use a qualitative research paradigm and our considerations will be grounded in the theory of constructivism and its basic tenets that knowledge cannot be transmitted but must be constructed by the learner (von Glasersfeld, ed., 1996) and that it is necessary to create contexts which stimulate creativity (Hejný, Kurina, 2001).

METHODOLOGY

As stated above, the object of our research will be our work with Molly. For the present purposes, we will focus mainly on interactional and emotional matters, neglecting the cognitive point of view (i.e. what knowledge is being learned) which will be the topic of subsequent studies.

The data consist of tape recordings of interviews, protocols, Molly’s work from the interviews, the experimenter’s field notes, Molly’s solutions to mathematical problems, subsequent versions of Molly’s ‘mathematical’ text (mathematical description of RA), her concept map of RA and the protocol of her description of it, the protocol and recording of Molly’s teaching experiment and subsequent versions of her analysis of the experiment, and finally subsequent versions of her diploma thesis. The framework for the interpretation of data we want to propose here is based on a threefold analysis.

First level of analysis

First, seven settings S1-S7 [3] will be distinguished in the course of our work with Molly and characterised by variables. For our considerations at this level of analysis, we will borrow a general term of the definition of situation from interactionism and a more specific term of didactic contract (Brousseau, 1997).

Every situation can be viewed as a communication situation in which its participants play some role. Each participant defines the situation on the basis of his/her prior experience with similar situations. Their definitions of situation come to the fore when they are not compatible and when, for instance, some participants' expectations are violated. When defining a situation, a person assesses (McHugh, 1968) the theme and its elaboration during the interaction, how individual parts of the interaction fit the theme, if the instance in the interaction is typical or likely, if it is given by some previous event, etc.

It is not easy to describe briefly the term didactic contract introduced by Brousseau. Bodin and Capponi (1996) give a concise explanation: Didactic contract "refers to the system of reciprocal expectations held by teachers and students, in other words all the rules, mostly implicit, which determine the part for which each of them, teacher and students respectively, is responsible for handling in the teacher-student relationship".
Similarly to the definition of situation, the didactic contract is being constantly redefined by the participants on the basis of their interaction.

**Second level of analysis**

Next, within these settings different situations will be identified. Here, we will draw on the theory of didactic situations (Brousseau, 1997): situations of action (students first attempt to solve a problem), situations of communication (students communicate the results of their work), situations of validation (the results are justified), and situations of institutionalisation (results are summarised, the ‘official’ terminology is used).

**Third level of analysis**

Last, the analysis of interaction will be made with the aim to identify communication patterns in individual situations. For the analysis of interactions between a student and the experimenter, we will use the framework presented in Dreyfus, Hershkowitz, Schwarz (in press) and used for the analysis of pair interactions. They distinguish six types of statements which establish and maintain the flow of the conversation: control statements (proposals, plans), elaborations (what is done to continue or develop an idea), explanations (comments on the results of actions), queries (which put in question previous utterance(s)), agreement (or concession) and attention. The last type of utterances only show that the person pays attention to the actions of others.

In the interactionist research, several patterns of interaction in the classroom have been identified, e.g. recitation pattern, funnel pattern and focusing pattern (Wood, 1998), repetition pattern (Cestari, 1998), various thematic patterns of interaction (Voigt, 1995, cited in Sierpinska, Lerman, 1996, p. 854). Dreyfus, Hershkowitz and Schwarz, (in press) identified four patterns of interaction which can lead to abstraction: guidance/self-explanation, symmetric argumentation, asynchronic collaboration and collaboration in parallel. Brousseau's Topaze effect and Jourdain effect (Sierpinska,' Lerman, 1996) can also be seen as interactional patterns. It is important to note that the various forms of interaction "are not always consciously recognised by students, or even by teachers" (Ellerton, Clarkson, 1996).

**ANALYSES AND THEIR FIRST RESULTS**

The paper presents an on-going study. In this section, the process of analysing the data will be briefly presented and some preliminary results discussed.

The settings presented below can be defined by the didactical variables, and also by the psychological and sociological variables (Sierpinska, 2000), i.e. the personal characteristic of the teacher/experimenter, and those of the student. Molly has always been a diligent student. Her mathematical ability is above average (in comparison with her fellow students), her attitude towards mathematics (and German language which is the second subject she will be teaching) has always been positive. She is a conscientious worker. She often underestimates her abilities. She is communicative and willing to speak about her thoughts and feelings.
First level of analysis – identification and description of settings

So far seven settings S1–S7 which we feel are different in at least some characteristics have been identified in the course of our work with Molly. Using the comparative analysis of the settings, the following variables have been determined so far for the description of the seven settings: MR – Molly’s role, MG – Molly’s overall goal, ER – experimenter’s role, EG – experimenter’s goal, MDS – Molly’s definition of situation (part of didactic contract), EDS – experimenter’s definition of situation, E – emotions.

One setting will be described in more detail, the others only listed and briefly characterised. The names of the settings are only tentative. In S1-S3 and S7 there are two participants – Molly and experimenter, in the others Molly alone.

S1 – semi-structured interview

MR: pupil
MG: to try her best to solve the tasks
ER: expert
EG: to get data for the research on structuring mathematical knowledge; to motivate Molly for independent work; not to teach anything
MDS: expects to be told what to do; to be presented with some mathematical problems; maybe to be taught something
EDS: expects Molly to be a problem solver; expects Molly to communicate about her ideas and thinking; expects to be an observer
E: Molly is a bit apprehensive about the non-standard situation (being recorded), she thinks of the situation as similar to an oral examination; gradually she is more and more relaxed. Her worries whether she will be able to solve the problems diminish when the experimenter keeps encouraging her and saying that the situation is non-standard and nobody is expected to understand it straight away. Molly is more and more attracted by the mathematical tasks.

Notes: The expectations of both participants are to a certain extent violated. Molly expects more help from the experimenter. During the first session, Molly redefines the situation and starts to behave in a more independent way.

The other settings are: S2 – teaching interview (unlike in S1, the experimenter has didactic intentions and behave more like a teacher, rather than an observer), S3 – discussion (Molly continues investigating RA, the experimenter is a discussion partner, sometimes a teacher), S4 – home study (Molly is engaged in studying on her own), S5 – writing a mathematical text (Molly acts as a ‘mathematician’, she was asked to write in a concise way everything she had learnt so far about RA for a journal), S6 – Molly's teaching experiment (Molly acts in the role of a teacher and researcher, she prepares, carries out and analyses her own teaching experiment), S7 – spontaneous discussions (while S3 are sessions planned in advance and Molly knows that she will be expected to speak and explain work she has done at home, S7 is more like impromptu ‘office hours’ with Molly coming to ask a question or make an observation).
Setting S4 does not exist by itself. It is combined with S1, S2, S3, similarly S5 is combined with S3 and S7. The complex situation is best illuminated by the following figure which shows the time sequence of our work with Molly.

Molly’s role has changed during the course of our co-operation. From the role of a pupil (expected to be taught) she got into the role of an independent problem-solver, autonomous learner, ‘mathematician’ at times, teacher and teacher researcher. We consider the process of change between the individual roles an important aspect of the whole process and will analyse it in more detail in the future.

**Second level of analysis - situations**

Every effort was made to suggest the "natural order" of the growth of scientific knowledge (Sierpinska, 2000) from action, formulation and validation to institutionalisation during our work with Molly. Moreover, whenever Molly validated anything it was her own conjecture or the conjecture conceived in co-operation with the experimenter, not given as a ready-made product.

Sierpinska (2000) also claims that at the university level, the last type of situation is the most frequent while the others do not appear at all or only in a degenerate form. She gives an example of proofs of theorems which are not students' own conjectures as a degenerate situation of validation; an example of a degenerate form of a situation of formulation when a teacher punishes an incorrect formulation of a definition; a degenerate form of a situation of action when a teacher gives students hints and suggestions before they tackle the problem. The first analyses of our data showed that despite the experimenter’s effort on the contrary, some degenerate actions can be identified especially during the first interviews with Molly. They will be the subject of further analyses.

**Third level of analysis – communication patterns**

In this section, we will restrict ourselves on S1 – semi-structured interview [4]. The communication patterns can be briefly characterised as follows (E stands for the experimenter, M for Molly):
- a lot of *encouragement* from E ("Well done");
- virtually no *rhetorical questions* (i.e. utterances which only pretend to be questions);
- E’s queries (the result of her need for clarification) have often the form of *repetition* of M’s utterances;
- a good deal of M’s *thinking aloud* (we do not classify it as explanation because it does not explain the results of action but rather M speaks as she thinks);
- there were some instances of E’s utterances which we classified as *pointers* which were specific to the experimental situation (e.g. E repeats what M is writing in order to record it on the tape recording and thus make the analysis of the data later easier; or utterances like “Write the solution to a new problem on a different sheet”, “Write in a different pen”, “Say aloud what you are doing on the calculator”; some of them can be classified as control statements);
- E’s *prompting* (e.g. “So...?”); a lot of E’s *control statements* (E sets the agenda most of the time) – often it has the form of: E’s control statement, E’s question (“Do you understand?”), M’s consent or M’s *reformulation* of the task in her own words;
- E’s *admittance* that she herself does not know the answer or that M found something which E did not see before (e.g. “I do not know if there is a pattern.”, “Well done! I did not see this before.”);
- demonstrations of *rapport* between E and M (e.g. jokes, laughs);
- M’s *questions* are of a technical nature (“Shall I do it here or at home?”, “Shall I finish the problem?”), she never asks for strategies; towards S2, the typical pattern is: E’s question, M’s explanation, E’s brief consent (often non-verbal), M’s explanation, E’s consent, etc.

**PEDAGOGICAL IMPLICATIONS**

On the one hand there are indisputable advantages of the long term individual work with a student (it has a very strong and long-term influence on the individual, a student experiences ‘doing’ mathematics and constructivist learning and thus it is one of the ways how to get constructivist teaching to schools [5]). On the other hand, we cannot omit the fact that there was no co-operation with other students and that it is time consuming for both participants. Moreover, it is very difficult, if not impossible to reproduce a didactic situation (see obsolescence of didactic situations, Brousseau, 1997), "the practices observed are the products of multiple interactions whose elements are not always the same, even for any one teacher " (Bodin, Capponi, 1996).

**PROPOSED FURTHER RESEARCH**

Within the given framework of analysis, we have so far completely omitted at least three aspects which strongly contributed to the success of our work with Molly. First, the *mathematics* Molly was working on – RA, which is a rich context suitable for a student’s independent investigation. Second, the *personality* of the experimenter and
her motivation. Mathematics, no matter how interesting, does not work by itself in the above way. And third, the experimenter previously investigated RA herself and was herself very excited about it. We hypothesise that if a teacher works on the same topic as his/her students, it is an important source of a positive motivational climate. All three aspects will be the focus of our analysis in the future.

It was stated at the beginning that the present study is an on-going one. Next, the analysis outlined above will be consolidated and applied to data, the cognitive aspect will be put under scrutiny and last but not least, Molly’s long-term progress as a practising teacher will be followed. We hypothesise that Molly's experience with her long-term work will influence her teaching strategies towards the constructivist approaches.

In order to answer the questions stated at the beginning of the paper, a comparative analysis of interviews with other students must be made, too. Why did Molly go on with her work? We are sure that the reason must be a combination of several factors.

NOTES
1. First results were given in Stehlíková, Jirotkóva, 2001.
2. For its description see Stehlíková, Jirotkóva, 2001.
3. We will need a more convenient term 'situation' for other purposes.
4. We presume that further analysis will show that the communication patterns differ in individual settings. However, only S1 and S2 were tape recorded, in S3 and S7 our considerations can only be based on written materials, the experimenter's memory and Molly’s self-reflection.
5. In view with Becker and Selter (1996), we strongly believe that simply hearing or reading about new teaching approaches is not enough. The student – future mathematics teacher – has to experience the new approaches in a way we want him/her to use at school.

TEACHERS DIFFER IN THEIR EFFECTIVENESS

Peter Sullivan
La Trobe University

Andrea McDonough
Australian Catholic University

This article reports an unanticipated result from a large scale project that sought to examine ways of improving numeracy learning. We found that there were marked differences in achievement between classes, irrespective of geographic or socioeconomic variables, and we argue here that these differences are attributable to the teachers. In other words, teachers influence the learning of their students and there are marked differences between teachers in their effectiveness.

INTRODUCTION

One sometimes gets a sense that the community at large, and even some education bureaucrats, believe that anyone can teach, or that teachers are born, or that new teachers can learn to teach just by watching others. The assumptions behind those beliefs seem to be that effective learning is the result of curriculum policy statements, resource provision, school leadership, or other factors amenable to central policy decisions. We argue the opposite: children from similar backgrounds have markedly different experiences at school, and these differences are attributable to their teachers.

Of course teachers have responsibility for more than the learning of the students, but this learning is clearly fundamental to the teacher's role, and the following argument is based on an assumption that a measure of the effectiveness of teachers is the growth in learning of their students.

There is a tradition that connects learning to teaching effectiveness. For example, Darling-Hammond (1997), in proposing a case for teacher education, summarised research on data from 900 school districts in Texas that found that 40% of the measured variance in student achievement across grades 1 to 11 was due to teacher expertise. She argued that, even after controlling for socio-economic status, the large differences in achievement between "black and white were almost entirely accounted for by differences in the qualifications of their teachers" p 8.

Such research can be unconvincing because of the way that achievement is sometimes measured using multiple choice items on tests of low level skills. The following argument draws on results from a large scale numeracy project to examine this issue using carefully collected, ample and representative data, based on a research informed view of a particular domain of mathematics, measurement of length. We conclude that teachers make a difference to the learning of the children in this domain, and we suggest that such differences may be evident in other domains as well.
THE ROLE OF THE TEACHER IN IMPROVING LEARNING

The object of educational reform is improved learning of the children. Clearly the instruments of any improvement in learning are teachers. Yet we suspect that there is an assumption that teachers are more or less equally skilled, or that reforms are to some extent independent of the teacher. Certainly the structure of terms and conditions of employment, and of professional development programs themselves, do not seem to make assumptions about differences between teachers.

One possible explanation for this lack of acknowledgement of the importance of the teacher is connected to the way that learning is conceptualised. It is common for reforms to be informed by a social constructivist perspective that was summarised by Ernest (1994) as recognising that knowing is active, “individual and personal, and that it is based on previously constructed knowledge” (p. 2), and that the knowledge is not fixed, rather it is socially negotiated, and is sought and expressed through language. It is possible to infer that learning is independent of the teaching. Yet Ernest saw the teacher as central listing among the pedagogical implications that teachers need to be sensitive to learners’ previous constructions, to seek to identify errors and misconceptions, to foster metacognitive techniques, and to acknowledge social contexts of learners and content. Likewise, Cobb and McClain (1999) argued that teachers should have a clear impression of the direction that the learning of the individuals and the class will take. They proposed that the teacher should form for the class an “instructional sequence (that) takes the form of a conjectured learning trajectory that culminates with the mathematical ideas that constitute our overall instructional intent” (p. 24).

Another possible explanation for the underemphasis of the teachers’ role might be a belief that the primary determinant of students’ learning is their family or cultural background. Tschannen-Moran, Hoy and Hoy (1998) reviewed research on teacher efficacy that contradicted this. Teacher efficacy refers to the extent that teachers believe that they can influence how well students learn, independent of their motivation, their background, their prior learning or other factors. Tschannen-Moran et al. cite a range of studies that connect high scores of efficacy by the teachers with higher achievement of their students.

In other words, teachers have an active role in promoting learning, and this is connected to their beliefs about the nature of learning and the nature of learners, but this active role is not necessarily acknowledged in educational policy and practice.

SEEKING A MEASURE OF THE EFFECTIVENESS OF TEACHERS: SOME RESULTS FROM THE ENRP

To explore the impact of teachers on student learning, we draw on results from the Early Numeracy Research Project\(^1\) (ENRP) that investigated mathematics teaching and learning in the first three years of schooling, involving teachers and children in
35 project ("trial") schools and 35 control ("reference") schools (for details see Clarke, 2000; Sullivan, Clarke, Cheeseman, & Mulligan, 2001). One source of data was a one-to-one interview over a 30 to 40 minute period with every student at the beginning and end of the school year (Feb/March and November respectively). Interviews were conducted by the classroom teachers, who were trained in all aspects of interviewing and recording. The processes for assuring reliability of scoring and coding are outlined in Rowley and Horne (2000). The data reported in this paper were collected in the year 2000, the second year of the project.

The data from this project arise from intensive interviews with large numbers of children, with trained interviewers, and experienced coders, with double data entry, and using a framework for learning based on interpretation of research. We argue that these data provide a reliable measure of learning, and a further perspective on previous research on the ways that teachers influence student learning.

Learning of Length Measurement

The data, on which the argument proposed below relies, is based on growth in students’ learning of aspects of length, one of nine domains on which data were sought within the ENRP. Growth points for the key aspects of learning length were proposed, and assessment tasks administered individually were developed, after consideration of some common findings in length research.

Much research on learning of measurement is influenced by work of Piaget and his colleagues, who identified stages of development in coming to understand measurement concepts such as conservation, the idea of a unit, transitivity, and iteration, with focus on development of cognitive abilities within individuals. Nunes, Light, and Mason (1993) present an alternative Vygotskian perspective in which competence is not fixed within individuals but cultural representations play a mediating role in development of understandings. In measurement, such cultural representations are often conventional rather than conceptual. In developing the assessment framework, we were concerned that Piagetian stages did not lead to clear teaching and assessment guidelines (see Carpenter, 1976; Kamii & Clarke, 1997).

Through the framework and interview for the domains of Length, the ENRP gives emphasis first to whether children show awareness of length through tasks that facilitate use of language. Measurement by direct comparison is then considered. We intended that both the growth point and the task prompting direct comparison be inclusive and suggestive of conservation as well.

The next growth point requires the use of a non standard but consistent unit to quantify a length measurement, including some of the requirements for iteration. The final two points relate to the use of standard units and their application. We did not include transitivity directly in the framework.
The six proposed growth points for length are as follows:

- No apparent awareness of the attribute of length and its descriptive language. (Not apparent)
- Awareness of the attribute of length and use of descriptive language (Awareness of the attribute)
- Compares, orders, & matches objects by length (Comparing lengths)
- Uses uniform units appropriately, assigning number and unit to the measure (Quantifying lengths)
- Uses standard units for estimating and measuring length, with accuracy (Using standard units)
- Can solve a range of problems involving key concepts of length (Applying).

These were developed as a conjectured sequence. It was assumed that students will follow different pathways in their learning, but nevertheless the intention was to describe the learning trajectory of the majority of students. To illustrate the style of the assessment, the following were the first two tasks posed (with italics indicating what to do, and the normal text indicating what to say):

**The string and the stick**

*Drop the string and the skewer onto the table.*

A) by just looking *(without touching)*, which is longer: the string or the stick?
B) how could you check? *(touching is fine now)*
C) so, . . . , which is longer?

**The straw and the paper clips**

*Get the straw and show the child the eight (5 cm) paper clips.*

Here are some paper clips. Here is a straw.

A) measure how long the straw is with the paper clips. . . . *(if child hesitates)* use the paper clips to measure the straw.
B) what did you find? *(no prompting)*

*If correct number is given (e.g., 4), but no units, ask “4 what?”*

The interviewers proceeded through the interview in order, but moved directly to the next domain (e.g., Mass) if the student answered a question incorrectly. A coding rubric was used to score the students’ responses.

**Entry Level Students and the Length Growth Points**

The issues of interest here are how the students responded to the tasks, and how they improved over the year. Table 1 presents the percentage of entry level students (commencing at age 5) in project schools rated at each growth point in both March and November, near the start and end of the school year respectively.

<table>
<thead>
<tr>
<th></th>
<th>March (n=1488)</th>

</tr>
</tbody>
</table>

The students are spread over the growth points, even at the start of their schooling. It is suspected that these differences are due to home or other specific experiences prior to school, recognising that language would be a contributing factor in some cases.
Given the low number of students who have reached the growth point, *Awareness of the Attribute*, the first two points are combined for the subsequent discussion, and termed *Not yet comparing*. To examine further the improvement over the year, individual responses in March are compared with those in November. Table 2 presents these as numbers of students.

**Table 2: Comparisons of Student Growth from Respective Growth Points (n=1369)**

</tbody>
</table>

Under 4% of the students went backwards, 47% stayed at the same growth point and 50% improved. The argument here is about growth, and to explore this further, we examine the largest set of students whose rating did not improve over the year.

The 453 students who were at *Comparing lengths* in March who were still at that point in November represent 33% of this group. These "Comparing length" students have not had whatever experiences may have been necessary to grow to *Quantifying length*. To explore further the nature of the development and potential of such students, some other aspects of their learning of mathematics were explored. Table 3, for example, compares their responses on the *Counting* domain in November to those of the group overall (n=1369).

**Table 3: The Comparing length students (%) on Counting in November**

<table>
<thead>
<tr>
<th>Growth point descriptor</th>

<td>13</td>
<td>17</td>
</tr>
<tr>
<td>Can count from x by 2, 5, 10</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

The *Comparing length* students have a similar profile on the *Counting* domain to the group overall. This suggests that there is little direct connection between *Counting* and *Comparing length*, at least at this level. For example, over one quarter of these *Comparing length* students were able to count forward and backwards from various starting points. Only 11% were not able to count a collection of 20 teddies. That these students could not progress to *Quantifying length* over the year is not due to inability to count.

Similarly, in the other domains of *Place Value, Addition and Subtraction, Multiplication and Division*, and *Time*, the profile of these *Comparing length* students was similar to the group overall. This suggests that to develop to the next growth point the students need particular experiences associated with the learning of
length, rather than general mathematical development. In other words, the mathematics experiences that these students have had has not resulted in across the board changes but rather that improvements are a result of domain specific experiences.

To explore this further, we examined the improvement by classroom on the Length domain for Entry level students. As Table 4 shows, there are marked differences between the classrooms. Note that the table presents results for Entry level students who are in the 54 classrooms with only entry level students, and the results of students who are in multi-age classes are not included in the analysis.

To be more specific, there was a class in which 24 out of 27 children improved, another where 21 out of 24 improved, whereas there was a class where 2 out of 25 improved, and others where 3 out of 24, 5 out of 28, and 2 out of 21 improved respectively. These are very noticeable differences and are unlikely to have occurred due to chance factors. An examination of the schools and other factors indicated that neither being effective nor being less effective teachers in terms of promoting improvement was dependent on school size, socio-economic community, student language background, or years of experience of the teacher.

This suggests it is possible for students at this level to move through the growth points but it is teacher dependent. A similar analysis of results of Grade 2 teachers on Length showed similar although less striking differences. This result is also similar to that reported by Sullivan, Clarke, Cheeseman and Mulligan (2001) with respect to differences in effectiveness in the teaching of multiplication and division at Grade 2.

Characteristics of teachers who made a difference

To explore the nature of these differences between the results of the classrooms, six teachers who had higher proportions of students improving on length in each of the first two years of the project were interviewed. Among other items, each of the teachers was asked to describe an example of an activity they used in their teaching of Length. A particular feature of the teachers was that they seemed able to describe rich experiences for the students and the purpose of those experiences. For example, the following is an extract from the response of one of the effective teachers:

Well my favourite one ... "The Long Red Scarf" and I based the series of lessons on that covering the different growth points ... I had a whole lot of teddies that the children made scarves for and we compared lengths and then we actually taught them how to measure...
using blocks and bears and things and we measured our scarves and ... language because a lot of our children do not have the language so even simple things like longer and shorter ...  

I started with reading the book and we talked about scarves, then I brought in scarves and we put them on the floor in the middle of the big circle and I spread them out haphazardly and I said well “which scarf here is the longest?” and the children said “have a guess at anything sort of thing” and I have got a very bright boy who said “no you can’t do it like that, you have to line them up” and he lined them up and then someone else said “no but you’ve got to match them at the end” so they matched them at the end ... so we got lots of language.  

The second lesson ... we actually said we were going to make scarves so I gave them paper. ... they had to make a scarf long enough to go around their teddy ... they proceeded to make their scarves and some of them even decorated them and then we actually compared lengths again so that was all one lesson, they came back and they put their scarves down and we talked about who had the longest and some of them had very long scarves because they had bigger teddies and some had short scarves.  

It seems that this teacher had a clear vision of the experiences that were needed, was able to engage the students, and was not deterred from such a rich experience by the unfamiliarity of some of her students with the language demands. Other effective teachers gave similarly rich examples. Another common theme, was that these teachers were prepared to probe the thinking and understanding of the children. For example, in response to the same prompt another teacher said:  

I always try and make sure that there’s a sharing of findings at the end of each session ... and I always ask the kids “how did you obtain such a result?” or “how did you get your answer?”. So there’s that constant reflection ... “if you measured your foot and you found out that it was 22” ... also I try and challenge the kids by asking them “if we’ve all measured our feet and we’ve all measured the length of a basketball court and we’ve all got a different response, why is this?” so I’m actually getting them to think a little bit beyond just obtaining a result.  

In other words, the teachers seemed to be aware of characteristics of rich experiences and how to use those experiences to extend the students’ thinking.  

CONCLUSION  

In a detailed study of a small aspect of a large project, an unanticipated result emerged. Teachers who were given extensive professional development including teaching advice some of which focussed on teaching of measurement, participated in structured planning teams, and released from teaching to interview all of their students, differed substantially in the extent to which their students improved in defined growth points in Length. That teachers make a difference is supported by other studies. The data presented here suggested that the differences between the most effective and least effective teachers are substantial. Effective teachers seemed able to articulate focused, developmentally appropriate and engaging activities for their students, and engage them actively in interrogating those experiences.
Before substantial policy decisions are taken more research is required. If further research confirms these results then there may be some important and somewhat challenging implications. If there are teachers who are substantially more effective than others, presumably steps could be taken to find out who those teachers are and acknowledge their effectiveness in some way. If there are teachers who are substantially less effective than others, we could seek to find out who those teachers are, and find ways to assist them to understand the impact of their teaching, and to examine strategies that might assist them to become more effective. We fully recognise the dangers of simplistic solutions to such issues, but suspect that it is possible to devise strategies that avoid undesirable side effects.

The Early Numeracy Research Project (ENRP) is a collaborative venture between Australian Catholic University, Monash University, the Victorian Department of Employment, Education and Training, the Catholic Education Office (Melbourne), and the Association of Independent Schools Victoria, and is directed by Doug Clarke, and the team includes Barbara Clarke, Jill Cheeseman, Ann Gervasoni, Donna Gronn, Marj Horne, Andrea McDonough, Pam Montgomery, Anne Roche, Glenn Rowley and Peter Sullivan (who was at Australian Catholic University for most of the project).
Despite a history of teachers' resistance to change, researchers in mathematics education have learned that mathematics teachers can change. The process of change, however, is usually long-term and difficult. This paper discusses the issue of change from the teachers' perspective. How do teachers perceive their own, professional changes? What are factors that teachers consider as catalysts for their processes of change? Through the stories of a very experienced elementary school teacher, one learns that teaching is a dynamic job, impregnated with short and long-term changes. Contradicting the image of teaching as repetitious, this teacher sees the development of her mathematics teaching as a continuous learning process that has gone through many phases and incorporated many changes.

If a group of elementary teachers from the early 20th century could travel in time and visit a 21st century classroom, there would be few elements they would not recognize. For the most part, however, these educators from the last century would be able to understand what the classroom teacher was trying to do and could take over the lesson. This parable, used by Papert (1993) to claim that education has not changed as much as it should over the past century, brings to mind an image of teaching as a repetitive, monotonous job in which changes seldom occur. Although in his book Papert presents innovative teachers and separates issues about teachers as individuals from those about schools as institutions, images of teaching as a static job and of teachers as professionals who perpetuate certain practices are pervasive in the educational literature. Teachers, it appears, do the same things one day after the other, one year after the other. Teachers also do the same things generation after generation. After all, teachers tend to teach in the way they were taught (Ball, 1988).

In recent change- and reform-related studies in mathematics education, we have learned that despite a history of resistance to change (Cuban, 1993) teachers can successfully implement modifications in their practices (e.g., Fennema & Nelson, 1997; Ferrini-Mundy & Schram, 1997; Schifter & Fosnot, 1993; Webb & Romberger, 1994; Wood, Cobb, & Yackel, 1991). Changes in mathematics teaching, however, are usually the result of sustained partnership and leadership, on-going collaboration, and long-term support for teachers to embrace new recommendations for school mathematics. Thus, although researchers in
mathematics education have come to accept that mathematics teachers can change, the process of change is perceived as a long-term, difficult, and slow effort.

This paper discusses the issue of change from the teachers’ perspective. How do teachers’ perceive their own, professional changes? Do teachers believe they modify their teaching practices over the paths of their careers? If so, what are factors that teachers consider as catalysts for their processes of change? These are questions addressed in this report.

Analyzing data from Helen—a elementary school teacher with 31 years of teaching experience—one learns that teaching is a dynamic job, impregnated with short and long-term changes. Contradicting the image of teaching as repetitious and static, Helen sees the development of her mathematics teaching as a continuous search process that has gone through many phases and incorporated many changes.

The Research Project

My research aims at better understanding elementary school mathematics teaching. Toward such a broad goal, it is necessary to identify the knowledge elementary teachers construct, and understand how such knowledge changes throughout the teachers’ careers. It is also important to relate changes in practices to changes in knowledge, connecting specific practices to knowledge that supports it. One of the specific objectives of this study was to trace the history of teachers’ personal knowledge and teaching practices, identifying turning points and factors that, from the teachers’ perspective served as catalyst for change. This report focuses on the teachers’ perceptions about changes in practices.

During the past decades, researchers’ understanding of teachers has greatly expanded. Beginning in the 80s, there has been an ongoing movement to strengthen teaching as a profession (Carnegie Forum, 1986; Holmes Group, 1986), and the development of teachers’ knowledge-base for teaching has become of utmost relevance. Various theoretical positions have led to different typologies that categorize teachers’ knowledge and its sources, as well as research programs that target the topic (Fenstermacher, 1994; Gauthier, 1998; Schulman, 1986, 1987; Tardif, Lessard, & Lahaye, 1991). Despite differences, it is accepted that teachers construct professional knowledge through their teaching practice.

To understand teachers and their knowledge, an “epistemology of professional practice” is needed. Tardif (2000, p.13) defines this epistemology as the study of the set of knowledge used by professionals in their everyday working space to accomplish all their tasks. From this perspective, teachers’ knowledge is personal and time dependent. It depends on teachers’ life histories and develops throughout their careers. Tardif and Raymond (2000) propose that to learn about a teacher’s

1 Names are pseudonyms.
knowledge one should ask her/him the history of her/his personal knowledge-base for teaching. Connected to such history is the history of the teacher’s mathematics teaching practices.

This report is part of a larger project in which I worked with 5 elementary school teachers, exploring their stories about mathematics teaching. All teachers have over 20 years of teaching experience, and they have been teaching at the same school for the past 10 years. I identified factors that, from the teachers’ point of view, were important in the establishment of their ways of teaching mathematics to young children, and factors that served as catalysts for change in their mathematics instruction.

To discuss her career and consider factors that were relevant in the establishment of her mathematics teaching, I interviewed each teacher three times. The instruments used in these interviews were a timeline based on the teachers’ responses to an inventory of their teaching experiences, a logic-spider with knowledge for teaching mathematics as the central theme, and a life-line (Connelly & Clandinin, 1994). The goal of these instruments was to offer teachers different approaches and opportunities to recall their experiences in different schools and classrooms. The research instruments also helped teachers organize their accounts, looking for continuity and change. In a final group interview, teachers discussed issues that were repeatedly mentioned in individual interviews.

All interviews were audiotaped and transcribed. Teachers received copies of the transcriptions. Data was analyzed through constant comparison method using initial descriptive categories such as knowledge, early teaching, later years, types of change, catalysts for change, and developing own teaching. Although the stories of all 5 teachers were interesting and had many similarities, the case of Helen was selected for presentation in this paper because she is the participant with the most teaching experience. Many ideas presented by Helen, however, were true for other teachers as well. In particular, the notion that becoming a teacher is an on-going change process was addressed by these experienced teachers.

Helen, Mathematics Teaching, and Perceptions on Change

Helen earned a B. S. in Elementary Education in 1969 and a master’s degree in Elementary Education in 1970. She began teaching 3rd grade in 1970. After that, she taught 2nd grade, 5th grade, and remedial middle school mathematics. Since 1984 she has been teaching 1st grade, and in 1990 she began teaching at the school where she is now. During her many years of teaching, Helen has completed graduate level courses in education and has attended staff development courses in mathematics education.

Helen thinks her mathematics teaching has greatly improved during her career, particularly during the past decade. She considers herself a good teacher, especially because she thinks her students are excited about mathematics; they
enjoy studying it, they think it is fun, and they appreciate when Helen tells them “it’s math time.”

I think I am a good teacher. I have taught a long time and I have changed some things, some things that didn’t work. You know, you have to change. … I would say the last third of my teaching career has been my best years of teaching math, because of the changes that I have made in the way that I have taught math. … I am more satisfied with what I have done. Because I can feel a sense of pride whereas before, you know, there was not that much. … I think that my teaching style developed, it sure matured. Then you become so much better at it. And I think any time you have children involved in what they are doing and have a say in it, then it is better teaching.

For Helen, teaching mathematics is an ongoing learning and change process. In her path to becoming a better mathematics teacher, Helen believes she formed her own way of teaching mathematics. She feels great ownership of her current mathematics teaching, which she calls eclectic. Her teaching approach represents a mixture of teaching resources she acquired throughout her career. Helen claims teachers need to try a variety of ideas in their classrooms and keep the ones that work, that is, that help students learn. In this way, after many years of teaching experience, teachers build a rich web of ideas for the classroom.

You can’t just say, okay, open up your math book and do page so and so. You can’t do that. I mean, that is not teaching. So I think that you have to just pull from every source, and do everything that you can, and try new things. And then, if they don’t work, then okay, I have tried it, it didn’t work, so I will move on to something else that will work. … There is a time when you have to do some paper and pencil things. I mean, there are times when you have to do that. But then there are some times when you can teach it another way that is not paper and pencil, there are some manipulatives that you can use and games that you can use. … [Because] there is no one best teaching method. You know, you have to pull from everything. You just can’t do it one way. … If you use a variety of teaching methods you will have better math students.

Developing this eclectic approach, that combines different resources, ideas and teaching methods, symbolizes for Helen her growth in mathematics teaching. This development is a learning experience that occurred over time and required many changes from Helen. Her current teaching was constructed and no one could have given it to the teacher. Helen’s eclectic combination of ideas is the result of her many experiences in mathematics and the different trends she faced in the teaching of mathematics. It was built through many trials, revisions, reflection, and changes.
[In my personal life] I don't like change very much. I mean, I stress over it. Whereas in teaching, you have to change because there are so many things going on, you know, so many cycles that you are going through. ... I think I was taught in college right out of the book. And so when I started my teaching that was what I did. It was right out of the book, there was no hands-on.... I put a lot of board work up, you know, lots of problems on the board and all. And for a long time, that was the way we did it. ... And then I found out, you know, that really isn't the way to teach math. And probably some of the greatest experiences would have been with, when I came here and they were doing Math Their Way which I was not familiar with. And it was so hands-on. It was just such a different type of math that, really, you could understand the why of math.

Helen attributes the changes she has made in her mathematics teaching style to a few different factors—for example, the courses she took on Math Their Way, a late 1970s activity-centered mathematics program for early childhood education. Among the factors that mostly influenced her changes, Helen mentions moving to a different school, sharing teaching ideas with colleagues, and attending workshops.

I think probably one of the things that have had a great impact was the change in schools and the different colleagues. I think that probably has had one of the greatest impacts on my teaching of mathematics. ... There have been a lot of opportunities here [at this school] where you can grow and do a lot of things, and then the teachers in my hall worked so well together, so if somebody is doing something that you like, you know, you can say, hey, you know, let me do that. ... [In other schools] there was no sharing. ... I think probably some of the influence of the Math Their Way when I came here which I had not had in other systems. And when I saw how it was being taught and that whole philosophy, how to teach math was so different from these other things. And using so many different ways to teach one concept. That had a big impact on me. ... And then going on to math workshops and finding out what is going on.

Schools, colleagues, and participation in workshops are factors one can consider as directly related to Helen’s own career and personal choices. Helen also attributes some of her changes to another set of factors more related to changes in education in general, and mathematics education in particular. Over her many years of teaching experience, Helen has lived various recommendations for school mathematics. She has experienced different trends and the availability of different resources for mathematics teachers.

And then also, the new ideas that came from, that came into being. Like when I was telling you earlier. When I first, those first years when I went
into teaching, individualized structure, now, that was the catch phrase. And then after that it was open classrooms, where we had centers. Well, then that was kind of passé and they went into using a lot of manipulatives and that kind of thing. And then we came into Math Their Way. So, I mean, it is just the different, all of these different things have been floating around ... A lot of times we do have a math book, then all of the things that are taught in there are taught according to whatever is the “hot” way to do it at the time. So, that influences, too. And also, then all of the monies that are available in the school. And they will say, “You can spend the money on something, what do you want to buy?” Well, then we are looking through [lists of resources] and seeing all of the things that seem to be working in classrooms ... [You are also] influenced by the materials that are bought.

Discussion

It is interesting to observe that, in Helen’s stories, recommendations for change in mathematics teaching that are “floating around” make their way in to the classroom. These recommendations are mediated by school administrators, mathematics consultants for school districts, books and other resources available for teachers. As education goes on different pendulums, so do teachers. And as teachers swing, they learn new ideas, incorporate new suggestions, and develop their eclectic teaching. Teachers learn from different sources. They use all they can to do what they believe is best for their students. Thus, as new educational ideas come around, teachers change; as new recommendations for mathematics teaching are proposed and shared with the greater educational community, teachers change teaching of mathematics.

This study is based on teachers’ careers, their perspective on their development in mathematics teaching, and their history in teaching mathematics. It is not an evaluation of whether teachers are teaching in accordance with this or that recommendation for the classroom. It is also not a judgment of the teachers’ implementation of reform rhetoric. With this approach to the study of teachers’ practices and change, it is quite striking to notice to the many changes teachers are making in their practices.

The history of Helen’s professional career in no way resembles the image of teaching as a job in which changes seldom occur. Quite the contrary, listening to Helen’s stories, one becomes immersed in change, new experiences and searches for professional growth. Helen’s ongoing quest for new ideas, together with changes in working milieu and new educational trends, have led her onto a path of many revisions and alterations of her teaching practice. From Helen’s point of view, change is not a slow, difficult process; change is a necessary component of good mathematics teaching, it is part of teachers’ everyday experiences.
The difference between the two perspectives on mathematics teachers’ practice—one more static and one more dynamic—deserves attention. One way to approach this difference is to take into account the idea that researchers and teachers may have different perspectives on classroom practices (Simon & Tzur, 1999) and different meaning for what counts as change. Many researchers have an ideal image of what should constitute mathematics teaching. With this image as a starting point, it becomes hard to observe change—probably because the changes required to become like the envisioned, ideal teacher are too big. Also, researchers are typically looking for profound changes that affect teachers’ practice in all of its dimensions. These changes are probably less often, and represent turning points in teachers careers. Finally, researchers focus their studies on particular points in time, looking at teachers during specific moments of their careers. Loosing a career perspective might make it harder to detect changes.

Teachers, on the other hand, understand change in a way that is more in tune with their step by step, everyday attempts to improve teaching. From this perspective, changes become a long-term and a short-term process at the same time. It is about everyday life in the classroom as well as about opportunities that appear throughout one’s career. Change, from teachers’ perspectives can be about trying new ideas, changing the way a certain lesson is structured, changing the books used for the introduction of a certain topic, adding a new assignment to their syllabus. In the case of very experienced teachers, the vision of change is strengthened by the privilege of exploring it from a 30-year perspective.

When researchers approach teachers with a static perspective of mathematics teaching, they fail to capture the many changes teachers implement in their daily practices and in the paths of their careers. They also fail to notice the many ways in which research recommendations for change might be reaching the classrooms, and the ways in which the mathematics education reform rhetoric circulate within schools. Not understanding teachers from their own perspectives, one might not recognize small steps toward change as important components in the development of mathematics teachers. In this case, teachers on-going development and growth goes unnoticed.

It is time we better understand teachers and their mathematics teaching. There are many questions to be answered, some of which related to the issue of change in mathematics teaching practice. It is worthwhile to notice that, as Helen puts it, teachers learn from each other. In schools where many teachers are searching for new ideas for improving elementary school mathematics teaching, transformation and growth might gain bigger momentum and happen in an easier, quicker fashion. Studying teachers who work such schools might allow us to improve our understanding of mathematics teaching and change.

CONSTRUCTION OF KNOWLEDGE AND ITS CONSOLIDATION: 
A CASE STUDY FROM THE EARLY – ALGEBRA CLASSROOM 
Michal Tabach & Rina Hershkowitz 
The Weizmann Institute. Israel 

Abstract 
The process of abstraction is central to construction of knowledge. It has been discussed intensively, but only seldom studied experimentally. The following study exemplifies a way for tracing processes of knowledge construction and its consolidation. In doing so, we extend the nested model of abstraction elaborated by Hershkowitz, Schwarz, & Dreyfus (2001), to study two 7-graders, collaborating to investigate algebra problem situations in successive activities, along the year, in technological learning environment. The analysis demonstrates the construction of knowledge in an ongoing dialectical process, between construction and consolidation, which took place along three activities, when pieces of knowledge incrementally accumulate from one activity to the other.

This study is part of a longitudinal study, which examined the collaborative work done by two 7-grade students, in five activities of investigating problem situations along the academic year. One activity was analyzed in Tabach, Hershkowitz & Schwartz (2001). Here we will analyze selected episodes from other 3 activities, where all of them deal implicitly with the exponential growth phenomenon.

THEORETICAL FRAMEWORK 
Mathematical activity, like any other human activity, is embedded in a socio-cultural environment (e.g., Voigt, 1995). This view is increasingly accounted for by the mathematics education community, which sees mathematics learning as a culture of mathematisation in practice. Such approach gains from combining collective with individual activities, analytic with reflective stages, and integrating intra with inter-processes that are at the root of mathematical development (Hershkowitz & Schwarz, 1999a, see related ideas of scientific enculturation in classrooms in Woodruff & Meyer, 1997).

Abstraction is at the heart of mathematisation (Freudenthal, 1991; Gravemeijer, 1995). To study abstraction experimentally, Hershkowitz, Schwarz, and Dreyfus (2001) gave an operational definition of abstraction: an activity of vertically reorganizing previously constructed mathematical knowledge into a new structure. They suggested a model, which is based on three observable epistemic actions, nested one in each other: Constructing (C) is the central action of abstraction. It consists of assembling knowledge artifacts to produce a new structure with which
the participants become acquainted. The action of Recognizing (R) a familiar mathematical structure, occurs when a student realizes that the structure is relevant to the problem situation in which participants are engaged. The Building-With (B) action consists of combining existing artifacts in order to comply with a goal such as exploiting a strategy or justifying a statement. The term Consolidation denotes (according to Hershkowitz, Schwarz, and Dreyfus, 2001; Dreyfus & Tsamir, 2001) the progressive familiarization through observable recognizing and building-with actions, in four types of situations: Reconstruct the new structure or actualizing it by recognizing it in various contexts. Use it with increasing facility for building-with in various contexts. Use it in the construction of higher structures for which it is a necessary prerequisite. Verbalize about it – possibly during or after an activity of reflection, such as reporting or summary discussion in class. The RBC model of abstraction will be used in this article to trace the construction and consolidation of new mathematical knowledge along various activities.

THE STUDY

We focus here on the work of two Grade 7 students who participated in a one-year algebra course. The basis for choosing of these two students was their high verbal ability. Three activities, which deal with exponential change phenomena, were chosen out of the algebra course of the CompuMath project. The approach adopted by the development team of the CompuMath project is a function approach to algebra (Hershkowitz et al, in press). The activities goals are the construction of some generalizations of growth phenomena patterns within problem situations, and the use of these generalizations to build the phenomena numerically and graphically, using spreadsheet program (Excel). The problem situations, which are the milestones of the algebra course, were designed to give opportunities to students' construction of new knowledge structures concerning mathematical concepts (algebraic variables and models) and of various mathematical processes (hypothesizing, making generalizations, testing hypotheses, interpreting representational information, solving and justifying). In the present study, we examined three aspects, in which these constructions take place. That is, we observed (a) the types of interactions while collaborative work is taking place (due to space shortage it will not discussed here). (b) The construction of a shared knowledge of the pair and, (c) The contribution of each participant, as well as what is left of it in the individual. All these aspects are examined within and between the three activities as one continuum along the academic year.

All activities were open - no guidance for solution was provided to students and no instruction if and how to make use of Excel was given.

The class work of the pair was videotaped and written works were collected. The
videotapes were transcribed. Following Chi (1997), the protocols were divided into "cognitive segments".

In this presentation we will analyze selected parts from these 3 activities (They were the first, third and forth activities of the research sequence of activities). In all of them creation of new structures of knowledge, concerning exponential change phenomenon takes place, while students collaborate together. The designers of the Algebra Course intention was that students will be involved in investigating such a phenomenon, but not via the explicit algebraic formulae of exponential growth.

In the next part we will describe shortly each problem situation, and the work done by the pair of students Avi&Ben on it. In our analysis here we will present selected utterances from the full transcript of their work in these activities, as evidences to our claims.

THE PROBLEM SITUATIONS

Efrat’s Savings activity

Efrat received her weekly savings as follows: at the end of the first week two cents, (which are 0.02 $), and in every weekend she received the same amount that she had in her saving box in the last week. Efrat saved all the money.

The students were asked to hypothesize how much money will be in Efrats’ saving box by the end of the year, in comparison with other four linear ways of savings, which they explore during the week before (for more details, see Freidlander & Tabach, 2001). Then the students were asked to investigate the phenomenon in the computer laboratory with the help of Excel, and to check if their hypothesis was correct. It is important to note that it was their first meeting with the exponential growth.

The students’ initial hypothesis is that the amount of money in Efrat’s saving box will be the lowest among all other linear ways of saving. In the computer laboratory Avi&Ben try to find an algebraic generalization that will help them to construct the numerical representation of the phenomenon in the computer. Avi says: Because she started from two. What, one times one, one times one, one times one, what, we should start from two (A31). Avi is trying to develop an algebraic generalization for that change. Avi feels that this phenomenon has some thing to do with repeating multiplication, and maybe he is starting to see the generalization as an expression, which includes powers. Ben doesn’t understand what Avi is saying, but both are aware to the need for an Excel formula. Avi says: We should write a formula (A36), and Ben reacts: Exactly, so I will do A2 (B37). And then Ben continues: Oh, yes, =B2+B2 (B39). Ben suggests a ‘translation’ of the verbal representation of the situation to a local
connection, \[ -B2+B2 \]. Ben ignores Avi’s suggestion to consider powers: *No, no, just a second, if we have here powers it will be good* [pointing to the screen] (A40), and drags “his Excel” formulae until B20, then the whole phenomenon appears numerically. They are both quite surprised from the large numbers they receive, and react: *Until 20. Yooo!* (A45).

The explicit algebraic generalization of Efrat saving, \[ 0.02 \times 2^x \], were \( x \) stands for the week number, is beyond 7 graders knowledge. And yet, Avi tries to reach such generalization. However, as we can see, Ben easily creates the whole phenomenon by recursion relation between the savings of two successive weeks, and the “dragging” operation in Excel. That is, by writing in cell B2 \( 0.02 \), and in cell B3 \[ -B2+B2 \], and by ‘dragging’ this formula to the next cells in the same column. In that way Avi&Ben get the whole phenomenon in its numerical representation.

Next, they are asked to sketch a graphical hypothesis of the same phenomenon, and then to check their sketch on the computer screen. They accomplish it quite quickly, with no evidential difficulties. Yet, if we compare their sketches, we can see that Avi’s is much more accurate in his graphical hypothesis then Ben’s.

In this activity Avi&Ben constructed some new knowledge regarding the exponential growth: at the beginning they underestimated the exponential growth, but when they received its numerical representation, they were surprised by its rapid growth. Their graphical representation sketches were quite close to graphical representations of the exponential change. And yet, we can’t be sure what kind of knowledge concerning exponential growth was emerged.
Aunt Berta activity.

Five months later, the students are asked to solve the Aunt Berta activity. (It is important to mention that during this five month, they didn’t meet any situation regarding exponential change).

Yosi received a letter from his rich aunt Berta.

Dear Yosi!

I have reached the age of 65, and my life is comfortable. I would like to give you some of my money. You can choose one of the options:

One. I will give you this year 1,100 $, next year 1,200 $, and so on. Each year 100 $ more then the last year.

Two. I will give you this year 2,000 $, next year 1,900 $, and so on. Each year 100 $ less then the last year.

Three. I will give you this year 100 $, next year 150 $, and so on. Each year 1.5 more then last year.

Four. I will give you this year 8 $, next year 16 $, in two years 32 $, and so on. Each year 2 times more then last year.

The agreement will go on while I am still alive. Let me know your decision soon, yours, Berta.

The students were asked to help Yosi to make the best choice, meaning to make hypotheses, taking into consideration that aunt Berta will live at least until the age of 80. Then they are asked to investigate the phenomenon in the computer laboratory with the help of Excel, and to check whether their advises to Yosi (their hypotheses) are correct.

Avi&Ben’s advice to Yosi is to take the forth option. Ben estimates that the amount of money will grow quickly after it will reach 100$, and Avi estimates that the amount of money will grow in several millions.

They try to construct the generalization with the help of Excel. For the third option Ben starts to build a recursion generalization: 100, equals D2, ahh... (B40). Avi helps by saying: times 1.5 (A41). They drag the generalization \[ \text{[D2*1.5]} \] were in D2 they put \[ \text{100} \]. In investigating the forth option, Ben takes the lead again by starting to build a recursion formula. Avi interferes by saying: Make Power (A43). Ben objects: No, No, I will just double it, don’t you think so? (B44). Avi hesitates: no,...try it on (A45). So Ben writes \[ \text{= E2*2} \], drag it, and they both agree on the numerical results. Avi’s reaction to the numerical data is: I was wrong here (B49). He explains that his estimation was for 80 years, and he tries to drag the generalization more, up to 80 years. But, since the column width is limited, he does not get a proper reaction from the computer, and he remains frustrated: irritating, O.K. (A69).
In Aunt Berta Activity, Avi&Ben had no doubt that the forth option is the best. How can we explain the over estimation they gave, especially Avi? It seems that the source of this over-estimation is the surprise they had in the first activity, concerning the large numbers, which were received. This over-estimating may serve as evidence that during the first activity they indeed construct the knowledge that exponential growth is very fast. This knowledge is consolidated here, as evidenced by the correct choice they made, and their over-estimation. Moreover, this time Avi has no doubts that he can use powers for the forth option. The way Avi tries to check his estimation, shows that he understands intuitively that the exponent is responsible for that rapid growth.

The Crazy Candy activity.

\begin{tabular}{|l|}
\hline
\textbf{Lets assume that in the next years the rate of inflation will be 10\% per year.} \\
\textbf{Write the name and price of your favorite candy.} \\
\textbf{What will be the price of that candy when you will reach the age of 120?} \\
\hline
\end{tabular}

\begin{tabular}{|l|}
\hline
\textbf{Suppose we could do the following changes:} \\
\textbf{Cut down by half the price of your candy, and increased the inflation rate to 11\% (and not 10\%).} \\
\textbf{Is this deal profitable?} \\
\hline
\end{tabular}

The students are asked to make hypotheses concerning the prices of their candy, and then they are asked to investigate the phenomenon in the computer laboratory with the help of Excel, and to check their hypotheses.

The current price of Avi&Ben’s candy is 3.5\$. Ben’s estimation is that in 100 years it will be \(\sim 100,000\). Avi’s estimation is about 11,000,000. They try to build the right expression, and Ben’s suggestion is: \(\text{oh, } B2/10+B2. \text{ Is it?} \) (B52). They are both surprised by the “low price” of the candy after 107 years. Avi tries again to “drag” the expression for some more years, and is disappointed.

The generalization of the price in an explicit algebraic formula, \([A1*1.1^x]\), were \(x\) stands for the year number and \(A1\) is its present price, is again far beyond the knowledge of 7 graders. However, finding a local recursion connection between the prices of two consecutive years is quite easy. If we write in cell B2 the current price, and in cell B3 we write \([B2*1.1]\), and “drag” the formulae to the next cells in the same column, we will receive the whole phenomenon numerically.

Here it is interesting to note that: (a) both students knew that the phenomenon has a rapid change. As they dealt with \(1.1^x\) and not with \(2^x\), they over-estimated this change. (b) The generalization Avi&Ben used is of additive nature \(=B2/10+B2\).
which might be explained by the fact that this time the verbal representation of the situation involved percentages, a topic in which their knowledge is quite poor.

Reading the second part of the problem, Ben immediately said that this deal is not profitable. However, when trying to generalize it, Ben offered the expression $-\frac{B2}{11}+B2$, which is obviously a wrong one, but it supports the assumption about their poor knowledge concerning percentages.

Their right hypothesis shows us, the researchers, that another piece of knowledge was constructed and consolidated here: intuitively, they understand that the exponent basis, weighs more in the rate of change of the exponential phenomenon.

CONCLUDING REMARKS

Tracing the action of abstraction (including the construction of new structures of knowledge and their consolidation) is a complicated task. The evidence for the construction of knowledge is sometimes by actions that took place in the same activity, as was shown in Tabach, Hershkowitz & Schwarz (2001). In other cases, the experimental evidences for the construction of knowledge took place in later activities, while the constructed knowledge is consolidated, in the sense it was described in the theoretical framework section. Therefore, longitudinal studies like the one that was described in this paper are needed, in order to trace such evidences for construction and consolidation of knowledge.

The knowledge of Avi & Ben regarding the exponential change is not yet fully formalized – for example, they do not know the explicit expression of it. And yet, we can see from one activity to the other how the knowledge incrementally accumulated: At first they approached the exponential growth with an under estimation, and they were surprised. As a second step in this activity we observed their graphical hypotheses which were quite close to the right exponential graph. Whether they constructed some knowledge concerning the exponential growth or whether they succeeded to “translate” from table to graph is not clear yet. In the second activity they over estimated the same phenomenon, but this time Avi was sure that this change has some thing to do with powers. Avi than reflected critically on his own hypothesis in the light of the findings he got, and dragged the generalization down to the eighty row. This action evidences a kind of consolidation leading to further construction (reconstruction). In the third activity they again over estimate the growth, but this time is due to the small basis of the exponent ($1.1^x$ and not $2^x$). In the second part of the third activity they have to choose between $1.1^x$ and $1.11^x$, and surprisingly they made the right choice. This is an additional evidence for the dialectic process of construction and consolidation of incrementally accumulative knowledge between and within activities.
Reference

This paper investigates the novice university students' understanding of the formal definition of "equivalence relations", especially their understanding of the quantifiers in the definition. Even though the definition is relatively simple and only involves the universal quantifier, we find that half of a class of highly qualified university students are unable to test whether an explicit relation on a set with three elements is an equivalence relation. Analysis of the data, from a questionnaire answered by 277 students and interviews with 36, reveals subtle influences of language and of conceptual embodiments. In particular, the transitive law, which is shared with the notion of order relation, may evoke an embodied image of order that is highly misleading.

INTRODUCTION

Chin & Tall (2000) proposed a theory of development of formal thinking, moving from informal concepts, to the introduction of definitions, to 'definition-based' deduction and on to 'theorem-based' deduction, in which we hypothesised that successful students would compress formal concepts into cognitive units appropriate for powerful formal thinking. In particular, we focused on 'equivalence relations & partitions' which students claimed to be the most difficult topic in the course. Our purpose was to determine why the students found the topic to be problematic.

In our first study above, there was evidence of responses in the categories of informal responses, definition-based deduction, theorem-based deduction, with some evidence of a few students having cognitive units that linked the notions of equivalence relation and partition. Our second study (Chin & Tall, 2001) followed the development over a period of time and revealed a general shift from 'definition-based' deduction using the formal definition to 'theorem-based' deduction referring to already proven theorems. However, it also revealed quite different developments for 'equivalence relation' and 'partition'. An equivalence relation has an apparently simple definition that almost all students are able to reproduce but it does not seem to have a natural embodiment. A partition has a subtler definition but has a simple prototypical embodiment as a set broken into subsets. Even though equivalence relations and partitions are mathematically equivalent, they develop as qualitatively different cognitive units linked by a formal theorem.

Our focus here is on the way that students employ the definition of 'equivalence relation'. Is the definition operable in the sense that it can be used as the basis for formal deduction (Bills & Tall, 1998)? In particular, do they have a full...
understanding of the use of the quantifiers, as, for instance, in ‘\(a \sim a \text{ for all } a \in S\)’, or are there other aspects of the definition that the students use intuitively or implicitly?

THEORETICAL FRAMEWORK

Formal definitions and deductions are the essential ingredient in advanced mathematical thinking (Tall, 1995), but they are known to cause great difficulties (Vinner, 1991). Some formal thinkers attempt to use logical deductions, others use a natural approach that relies more on their concept image (Pinto, 1998). The latter often involves thought experiments using embodied images in the sense of Lakoff and Johnson (1999, pp16-44). Our earlier papers showed that the notion of equivalence relation did not have a strong embodied image in the same way as the notion of partition. So, precisely how do students reason when they use the definition? For instance, how do they use the universal quantifier which occurs in the reflexive law ‘for all \(a \in S, a \sim a\)? The use of quantifiers in definitions has been considered “one of the least often acquired and most rarely understood concepts at all levels, from secondary school on up — even, in many cases, into graduate school” (Dubinsky, et al., 1988, p.44).

The definition of equivalence relation, uses only the universal quantifier:

An equivalence relation on a set \(S\) is a binary relation \(\sim\) on \(S\) that is

- reflexive: \(a \sim a\) for all \(a \in S\)
- symmetric: if \(a \sim b\) then \(b \sim a\) for all \(a, b \in S\)

and transitive: if \(a \sim b\) and \(b \sim c\) then \(a \sim c\) for all \(a, b, c \in S\).  

(Stewart & Tall, 1977)

However, the quantifier here plays a very subtle role, as is shown by the following question, (which the first author well remembers being unable to answer for several days whilst studying Birkhoff & Maclane (1953) as an undergraduate):

Given an equivalence relation \(\sim\) on \(A\). Let \(a \sim b\), then \(b \sim a\) (by symmetry) and \(a \sim b, b \sim a,\) implies \(a \sim a\) (transitivity). So symmetry and transitivity imply reflexivity.

The subtlety is two-fold. The first axiom asserts that the relation \(a \sim a\) must hold for all \(a \in S\). The second and third axioms use implication in a more subtle way, that if the premises holds, then the consequence follows. We decided to use a specific instance of this idea to test if the students’ definitions are truly operable.

EMPIRICAL STUDY

The study was performed on 277 (first year mathematics) students taking a course on ‘foundations’ in one of the top five ranked mathematics departments in the UK, 151 from a class of pure mathematics majors and 126 in a class consisting of those following courses such as statistics, economics, or physics. Both classes covered the same material over a ten-week period with three-hour lectures per week supported by weekly examples classes in groups of up to four students. The second author acted as supervisor for 12 pure mathematics students selected to cover a range of abilities. The topic of ‘equivalence relations’ and ‘partitions’ was formulated in the
third week and developed in subsequent weeks. The students conceptions were studied by a questionnaire given to all students in the ninth week, (six weeks after the definition of equivalence relation was given and subsequently developed) and the responses were triangulated with interviews with the other 24 selected students, fourteen in pure mathematics and ten in other mathematically-linked subjects, together with field notes made in tutorials with the 12 pure mathematics students.

In this study we focus on the following question to investigate how the students understand the definition of “equivalence relations”:

Let \( X = \{a, b, c\} \) and the relation \(-\) be defined where \( a \sim b, b \sim a, a \sim a, b \sim b, \) but no other relations hold. Is this an equivalence relation? If not, say why?

**Student Responses & Analysis**

The student responses to the main question were categorised as follows:

- Correct deduction & answer,
- Incorrect deduction with correct answer,
- Incorrect deduction & answer,
- Don’t know/ no response.

The following examples illustrate the categories.

To be classified as ‘Correct’, an answer must either have a general statement that the reflexive property does not hold for all elements, or specifically note that \( c \sim c \) does not hold. For instance, ANNWAN (pure mathematics) wrote:

\[
\text{No because } c \notin X \implies c \notin X \not\implies \text{not reflexive. Not an equivalence relation.}
\]

GILWIN (other mathematics) was classified ‘Incorrect deduction with correct answer.’ Not only did he miss the universal quantifier in the reflexive property, he tested the symmetric property only with the distinct elements \( a, b \), then denied transitivity because \( b \sim c \) doesn’t hold” for making \( a \sim b, b \sim c \Rightarrow a \sim c \). However, he even did not notice that \( a \sim c \) does not hold either when making the deduction. In the interview, he explained what he means is it needs three different elements to make transitivity hold.

\[
\text{Does it follow then? } a \sim a \checkmark, b \sim b \checkmark, \text{ symmetry.} \\
\text{a \sim b, b \sim c \Rightarrow a \sim c, but b \sim c \text{ doesn’t hold, so this is not an equivalence relation.}
\]

JOAITE (pure mathematics) was classified as ‘Incorrect deduction and answer’.

1) \( a \sim b, b \sim a \)
2) \( a \sim a, a \sim b \)
3) No occurrence. Yes it is an equivalence relation.

He used only the four related pairs and assigned each of them to his own versions of the three rules, (presumably in the order 1: symmetry, 2: reflexivity, 3: transitivity) without exhibiting any conception of the subtlety of the universal quantifier.
Table 1: Responses to the "use of quantifiers" question

The distribution of the categorisation is shown in table 1. Visibly, the pure mathematics students give more correct responses (in terms of both deduction and answer) than the other mathematics students ($\chi^2=19.34$, $p<0.0001$). These 'correct' responses show a satisfactory use of the universal quantifier in the reflexive property at either a general or specific level. (This is not to say that a student who gives a correct response to the reflexive property necessarily understands the whole definition, for there are seven students who correctly assert the falsehood of the reflexive property who are categorised as having an 'incorrect deduction' because of difficulties with the symmetric or transitive properties (usually the latter)).

We investigated whether the nature of these responses correlated with the quality of the definition that the students offered for an equivalence relation. To determine the latter we combined the results of the following question:

Say what "equivalence relation" means to you,

and a later question focusing on their concept definition:

Look back at what you wrote about the meaning of "equivalence relation", do you consider it to be a formal definition? If you consider it is not a proper formal definition, please write down the formal definition.

The combined response to these questions were placed into four categories:

- formal-detailed (including full use of quantifiers),
- formal-partial (giving the three properties in symbolic form without quantifiers),
- informal outline (mentioning 'reflexive, symmetric, transitive' only)
- other, or no response

The student responses are cross-tabulated in tables 2, 3. There is no statistical correlation between the responses of the pure mathematicians and the quality of their definitions ($\chi^2=10.94$, $p=0.28$). But for the other mathematicians, the correlation is highly significant ($\chi^2=29.39$, $p<0.001$). However, closer examination shows that the significance arises from the correlation between those students responding 'other/no response' in both categories. If these are removed, then the correlation on the remaining data is $\chi^2=3.11$, $p=0.54$ for the pure mathematicians and $\chi^2=5.91$, $p=0.21$ for the others. Thus the statistical difference is due solely to the fact that a significant minority of the other students cannot handle the definition at all.

Our attention focuses on those students who gave unsatisfactory responses.

Table 3. Other mathematics students: giving definitions versus making deduction

Unsatisfactory responses declaring the relation to be an equivalence relation

Forty eight students asserted incorrectly that the relation is an equivalence relation. Thirty gave no explanation. Of these, three were interviewed and in each case the response indicated that the students concerned did not think deeply about the problem. For instance, one was capable of giving a ‘formal/detailed’ response with full quantifiers in the interview, but was unable to explain any further.

Of the 18 students offering a written explanation, there was a tendency to simply overlook the role of the quantifier in the reflexive property. SANSON (pure mathematics), for example examined the reflexive rule for all four given relational pairs, then indicated one clear example of the transitive law, but did not consider symmetry in detail.

This is reflexive because if and then by

This is transitive because and but & and etc.

I think it will also be symmetric : it is an equivalence relation

MAROOD (pure mathematics) wrote out the definition in full, but then did not apply the definition to the specific example.
In general, even though many of these students could give the definition in detail, they failed to implement it in the given case.

**Saying the relation is not an equivalence relation**

The case of students who asserted the relation was *not* an equivalence relation, but made errors in explanation, is the most revealing category of all. *Eighty two percent of them* (19 of 24 pure mathematicians and 37 of 44 other mathematicians) *offered the same reason: “the relation is not transitive so it’s not an equivalence relation”*. Their reasons varied. SUSDLE (pure mathematics), who could give a formal/detailed definition, correctly dealt with the reflexive property, but noted incorrectly, that the symmetry law needed to hold for more elements:

$$\text{No, because it wasn’t, so it must be symmetric}$$

$$\text{anc and cna, and bnc and ctb.}$$

$$\text{For it to be reflexive, cnc.}$$

In the interview, he was asked how about transitive property. He replied that it must include all the relations between each two out of any three *different* successive elements. He also explained that he thought in this way because the universal quantifier is used in all three axioms.

LUCCCO (other mathematics), classified as ‘formal/detailed’, misunderstood transitive property because he did not think $a\sim b$, $b\sim a \Rightarrow a\sim a$. He clearly pointed out there should be three elements for transitivity to hold.

$$\text{No because } a\sim b, b\sim a \not\Rightarrow a\sim a.$$  

$$\text{Need 3 elements for transitivity to hold.}$$

SUSURT (pure mathematics), classified as ‘formal/ partial’ because he omitted quantifiers in his definition, missed the universal quantifier in reflexivity, only examined symmetry with the distinct elements $a$ and $b$, then disagreed with transitivity “as $c$ is not involved”.

$$\text{a\sim a hence reflexive}$$  

$$\text{a\sim b & b\sim a hence symmetric}$$  

$$\text{Hence not transitive as c is not involved. \therefore not}$$

In the interview SUSURT was asked why he thought $c$ should be involved for transitivity to hold. He echoed the thinking of LUCCCO and GILWIN (quoted before) by replying “because it needs three elements to make transitivity hold”. In the interviews, we found that six of the seven interviewees who asserted transitivity failed also shared this view. Furthermore, when asked, ‘If the two relations $a\sim b$, $b\sim a$
are removed from this question, what will happen?' five out of these seven replied, ‘symmetry will not hold either’. Three students said explicitly that they used the concept of an order relation as an embodiment of transitivity and two of these explicitly said they used ‘$a < b, b < c$ imply $a < c$’ as a special example for transitivity in their concept image.

**DISCUSSION**

In our data, approximately half the students are unable to handle the definition in a simple example using only three elements. The reasons are diverse, but 82% of those giving an incorrect reason for the example not being an equivalence relation focus on the transitivity law where there is a sense that ‘the transitivity law must involve three elements’ and even that the transitive law is interpreted using an embodiment that is the same as the axiom in an order relation. This has been a fundamental underlying conception in mathematics even amongst those who insist on formal thinking. In his famous address to the International Congress of Mathematicians in 1900, David Hilbert said:

> Who does not always use along with the double inequality $a > b > c$ the picture of three points following one another on a straight line as the geometrical picture of the idea “between”? (Hilbert, 1900)

The students involved in this study have been given an exposition of the theory in which the concept of relation is defined first, then, in quick succession, the special cases of function, order relation and equivalence relations. We therefore hypothesise that what is happening is that the students fail to get a workable mental image of each of these three conceptually different kinds of relation. In the case of an order relation, it is a natural thought process to imagine the elements ordered in a line, and, in the absence of an embodied image of the notion of equivalence relation, in using the transitive law, it is natural to link to the self-same image.

This phenomenon is an essential element in the transition from elementary to advanced mathematical thinking. In moving from a way of thought that uses related imagery at will to a formal way of thinking that is intended to be formal, the student can not have conscious control over all the mental connections that are made. Lakoff and his colleagues (Lakoff & Johnson, 1999; Lakoff & Nunez, 2000) argue powerfully that all thought is embodied. However, it is tautological to claim that human thought occurs in a physical brain. A more useful distinction needs to be made. Mathematicians are acutely aware that their formal thought occurs in an embodied mind, but they struggle to make their deductions as free from embodied influences as is humanly possible. Tall (2002) theorises how embodied thought experiments can suggest formal theorems and how formal deduction can prove them, sometimes giving structure theorems that have new, more sophisticated, embodiments.

What is happening with these students is that their introduction to formal thought concerning equivalence relations, order relations, and functions as examples of...
relations occur in a brain in which the concepts are intimately linked together. Some make connections in a manner familiar to the mathematical community, but most, if not all, have a variety of other mental linkages which need to be addressed for serious progress to be made.

Connecting Children's In-School With Out-school Mathematics By Using Mathematical Writings

Wen-Huan Tsai
Tsai@mail.nhtc.edu.tw
National Hsinchu Teachers College, Taiwan

Abstract

The purpose of this study was to explore the process of mathematical enculturation in children's cultural activities through the use of mathematical writings. There were ninety-nine second graders participating in the study. Three stages were developed in the use of mathematical journal writings. The results indicated that (1) the daily activities mathematics embedded into that were perceived by second-graders included drastic disasters, causal accidents, and surrounding environments. (2) The quality of children's mathematical writing was improved by evaluating each other on their writing journals. (3) Five commentary levels of mathematical writing were characterized. They were moved toward advanced commentary level. (4) Children became flexibly and efficiently in resolving the mathematical problems they posed.

Introduction

School mathematics experiences at all levels should include opportunities to learn about mathematics by working on problems arising in contexts out of school of mathematics (NCTM, 2000). Therefore, the opportunity for students to experience mathematics in variety of contexts is important. In recent years, many studies have focused on mathematical cognition relating to individual competence in daily life context (Bishop & Abreu, 1991; Carraher, 1988; Lave, 1988; Saxe, 1991; Tsai & Post, 1999). A review of children's out-of-school mathematics raises critical questions about how children come to understand mathematics and how they connect informal knowledge out of school with formal knowledge in school (Hibert & Carpenter, 1992; Millory, 1994; Resnick, 1987). In keeping with the connection between in- and out-school mathematics for children, the researcher has developed a teaching model called the Cultural Conceptual Learning-Teaching Model (CCLT) (Tsai, 1996) that attempts to combine individuals, activities, concepts, and culture together. The previous studies focusing on CCLT suggest that the linkage from children's cultural activities to school mathematics contributes to children's better performance in school mathematics and their abilities in solving problems in daily life (Tsai & Post, 1999; Tsai, 2000; Tsai 2001). However, An important question is how children applied school mathematics they learned in the CCLT model into real life situation. Thus, this study intended to provide children an opportunity with the mathematical journal writing to help them make sense
school mathematics implicitly embedded in everyday activities.

Mathematical writing is considered as a tool of assisting children in making sense of, formulating, and solving mathematics problems in daily activities and since it provides an opportunity to construct one's own knowledge (Countryman, 1992). This process is part of mathematical enculturation (Bishop, 1991).

**The Cultural Conceptual Learning Teaching Model (CCLT)**

The CCLT (see Figure 1) contains three learning environments and six learning stages. Play Stage provides children with cultural activities. In this stage, children share, negotiate, and construct their immediate experiences to achieve the emergent goals of arithmetic problems with peers and more advanced children (the expert children). In the Construction Stage, the teacher designs a worksheet that has structural objectives those need to be accomplished by students. In the Connection Stage, based on children’s experiences or strategies, the teacher tries to help children construct a connection between their experiences and concrete materials like ten-based blocks or mathematical symbols and procedures. In the Reapplication Stage, the teacher provides another similar or same cultural-conceptual activity for children to reapply to the learned mathematical concept. In the Practice Stage, children try to practice school mathematics in everyday situations by using opportunities provided for them. In the Reflection Stage, children are trained to monitor their thinking and to be aware of where and how they can apply school mathematics in everyday activities. The CCLT model contains two parts: play stage, construction stage, and connection stage are the first part of the area of cultural matematization; Reapplication stage, practice stage, and reflection stage are the second part of the area of mathematical enculturation.

![Figure 1: The Cultural Conceptual Learning Teaching Model](image)

In the first part, several studies show that learning arithmetic through children’s cultural activities based on the CCLT model not only affect children learning of school mathematics but also improve their ability to solve task problems (Tsai &
Post, 1999; Tsai, 2000; Tsai 2001). This study focused on the second part that created a learning environment by using mathematical journal writing for children to perceive school mathematics in which of daily life cultural activities.

**Methodology**

The ninety-nine participants were second grade students from three classes in one school. The class size includes thirty-three students. Limited space prevents to report how the students make sense of mathematics in daily settings from each class. An illustration of the effect of journal writing on children perceiving mathematics in daily settings is only taken from one class.

To improve second-grade students’ abilities to formulate and solve problems, three stages were considered in the use of mathematical journal writing. First, children were expected to be aware of mathematics in which of activities or events in daily cultural activities. They were asked to answer the question: What are activities or events you encountered in daily situation involved in mathematics? Second, the students were asked to write down or draw a picture to represent the mathematical problem embedded in daily activities or events. Finally, the students were asked to solve the mathematical problems that students created in the first two steps. Between the second and the third stage, students were administrated with a critical task that mutually makes comments and criticizes on the problems students created. The first two stages were undergone at the beginning of the study. At the period of the second stages including critical task, each student was asked to write mathematics journal entries twice for every month and class discussion about students’ commentary once for every month. One circulation from first stage to the third stage took two months to accomplish. Four circulations of using mathematical writings have been carried out throughout the entire school year.

In terms of the critical task, the classroom teacher attached all students’ journal writings on blackboard and asked them to chose one or two journal entries in which they valued good or bad, followed by making comments on the 76.2cmx76.2cm Post-it-Notes and attaching the Post-it-Notes on the journal writing. Likewise, the student who wrote the journal entries was asked to give follow-up responses whether s/he agreed with the comments from others. The responses are written on different color Post-it-Notes. The critical task provided students the opportunity of mutual support with learning from other students how mathematics is relevant with daily cultural activities. Besides, the critical task was designed to improve the quality of making comments for second-grade students.

**Results**

The results indicated that not only students improved their writing journal but also progressed on the critical thinking on the writing comments. Several narratives delineate how students perceived, formulated, and solved mathematics problems in everyday settings. The comments and follow-up responses children made are described in the second part. The development of quality of comments will be described in the third part.
Cases analysis in writing journal

The results showed that the students used more efficient and flexible methods to solve the problems they formulated. The use of writing journals contributed to deepening and connecting the concepts what they learned in classrooms.

(1) Mathematics embedded in an accident event

The data of Table 1 portrays that S1 drew a picture representing the situation of the 921 earthquake happened in Taiwan. To assisting the people ruined in the disaster in rebuilding their houses, S1’s school had an activity for collecting money. He posed two mathematics problems about buying the tickets. When he solved the first problem described in Table 1, he counted the money one by one. But in the second problem, he used a unit of five-tickets to calculate the answer. Therefore, he used a flexible strategy to solve a complicated problem.

Table 1: S1 used mathematics in an accident event

<table>
<thead>
<tr>
<th>Setting:</th>
</tr>
</thead>
<tbody>

</tr>
<tr>
<td>(2) 1000+1000=2000</td>
</tr>
<tr>
<td>2000+1000=3000</td>
</tr>
</tbody>
</table>

(2) Mathematics embedded in a casual accident

The data of the Table 2 shows that S2 and his mother caught a cat with 4 kittens. S2 and his mother go to find Doctor for help.

Table 2: S2 used mathematics in a casual accident

<table>
<thead>
<tr>
<th>Setting and problems:</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mother and I caught a cat with 4 kittens in our community. Mother and I bring the cat to zoo hospital for treatment. The doctor said that a cat gave birth to 4 kittens in a year, how many kittens would be after two years? If half of cats are female.</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Solutions:</th>
</tr>
</thead>
<tbody>
<tr>
<td>S3 used the tree diagram to solve the problem, and then she felt surprise and said “Whoa! After two year, the cat would give birth to 60 kittens. It is amazing!”</td>
</tr>
</tbody>
</table>

Doctor gave him a mathematical problem to solve: A cat gave birth to 4 kittens in a year, how many kittens would be after two years? If half of cats are female.
S2’s solution was represented with a tree diagram in which square represents female cats and triangle represents male cats. S2 posed a complex problem but used an elegant method to represent his way of thinking. The second-graders have not been taught the tree diagram. He used an efficient way to solve mathematical problems in his familiar situations.

(3) Mathematics embedded in surrounding environments

The data of Table 3 shows that S3 was aware of the amounts of bricks on the floor equivalent to the area of the floor in each living room, kitchen, and restroom. The second-graders did not learn the formula of an area until the fourth grade. However, S3 has extended what he learned the fundamental meaning of area into a familiar situation to her. Moreover, she did not learn the multiplication with two-digit numbers until she entered into third grade. In accordance with her solutions, she was able to extend the operation of multiplication with one-digit into two-digit numbers. The result indicates that mathematical journal writing not only connected the mathematics students learned in school with daily situations but also made connections within mathematics.

Table 3: S3 used mathematic in her house

| Setting: | S3 described how to count the bricks in living room, kitchen, and restroom. He tried to understand the amount of bricks in each row multiplying by the amounts of rows in each room. |
| Problems: | 1. In the living room, there are 9 rows and each row has 21 bricks, how many bricks have totally?  
2. In the restroom, there are 9 rows and each row has 9 bricks, how many bricks have totally?  
3. In the kitchen, there are 9 rows and each row has 13 bricks, how many bricks have totally? |
| Solutions: | 1. \(21 \times 9 = (189)\)  
\(21 \times 1 = 21, 21 \times 2 = 42, 21 \times 3 = 63, 21 \times 4 = 84, 21 \times 5 = 105, 21 \times 6 = 126, 21 \times 7 = 147, 21 \times 8 = 168, 21 \times 9 = 189\). There are (189) bricks.  
2. \(9 \times 9 = (81)\)  
\(9 \times 1 = 9, 9 \times 2 = 18, 9 \times 3 = 27, 9 \times 4 = 36, 9 \times 5 = 45, 9 \times 6 = 54, 9 \times 7 = 63, 9 \times 8 = 72, 9 \times 9 = 81\). Restroom has (81) bricks.  
3. \(13 \times 9 = (117)\)  
\(13 \times 1 = 13, 13 \times 2 = 26, 13 \times 3 = 39, 13 \times 4 = 52, 13 \times 5 = 65, 13 \times 6 = 78, 13 \times 7 = 91, 13 \times 8 = 104, 13 \times 9 = 117\). Kitchen has (117) bricks. |

Improving children’s journal writing by evaluating each other

The exchange of points of view was an essential part in using journal writings. The result indicates that it was a powerful way to evaluate journal entries each other for improving the quality of journal writing.

The data of table 4 shows that the writer of the journal and the commentator interacted frequently when they inspected the journals. S4 would teach the new idea to the commentator. S5 accepted the commentator’s suggestion and applied...
the suggestion to the next journal. S6 explained the process of solution to commentator. S7 and S8 asked the commentator to indicate which part was good or clear. In the increasing use of journal writings, the students were required to write the journal or comment as clear as they could; otherwise, other students would criticize on unclear parts.

<td>Father gives me 60 dollars. Mother gives me 50 dollars. How much money do I have in total?</td>
<td>60+50=110 60 +50 110</td>
<td>Ya-tang! You need to work hard and I will give you 100 scores.</td>
<td>Chung! Can you tell me what the problem is? I do not know what you mean? Next time, please tell me clearly, OK?</td>
</tr>
</tbody>
</table>

Five levels of comments were identified in this study

Five levels of comments were identified in this study, when analyzing students' comments on Post-it Notes: unrelated comment, general comment, question comment, suggestion comment, and evaluation comment. (1) **Unrelated comment** is that students gave comments irrelevant with the problem. For instance, “Your paper is very clean!” “You need to write the date”. “If you change your temper you will write better”. (2) **General comment** is that students gave general comments but did not indicate what is or where is clear. For example, “I do not understand what you say” “Your problem has a contradiction” “Your problem cannot be solved”. Those comments do not specify the clear part of the problem. (3) **Question comment** is that students gave comments that pointed out the problematic parts but did not give further suggestions. For example, “You do not write the price of apple so how you can calculate the answer” “39+52=81 is wrong”. (4) **Suggestion comment** is that students gave some suggestions but did not illustrate the reasons. For example, “You can use multiplication to do it”. When a student calculates with 30+50=80, 100-80=20, A suggestion from others is that “You can calculate it by 100-30=70, 70-50=20”. (5) **Evaluation comment** is that students identified the problematic parts and also gave some suggestions. For example, “Your answer 71 is wrong, you should write 43+26=69".
Those five levels of comments are characterized as from the lowest level to highest level. Suggestion level is higher than question level. The students who were able to identify the problematic parts moved toward the advanced level that gave further suggestions without illustration. Evaluation comment contains the questions addressed and suggestions.

### Developing the levels of comments in this study

From Figure 2, initially, students didn’t know how to write comments when they inspected others’ journals. The number of students’ comments stayed at unrelated comment, then decreased from general comment to question comment. In the second month and the third month, students’ comments decreased the unrelated level and increased to question level and suggestion level. In the fourth month, students’ unrelated comments disappeared and moved toward the evaluation level.

![Graph of the Levels of Comments Within Four Months](image)

**Figure 3: Graph of the Levels of Comments Within Four Months**

### Conclusion and Discussions

The result indicated that most students performed well in solving the problems they created from daily activities by using mathematical journal writings. The daily activities mathematics embedded into that were perceived by the students included drastic disasters, causal accidents, and surrounding environments. It appears that children could use flexible and efficient strategies to solve the problems relevant with familiar situations. Nevertheless, the strategies were been not taught in school for the second graders. One possible interpretation was that the mathematical problems they formulated were based on their familiar situations; as a result the solutions were the ways of sense-making to them. The other interpretation was that there was a close relationship among the three steps so that students understood the relationships among setting, problem, and its solution. A significant finding was that the mathematics concepts students learned were easily extended and connected by the use of mathematical journal writings.

The critical task involving the study provided the opportunities for children to take-and-share perspectives and sequentially resulted in the improvement of writings and comments. The students evaluated each other and discussed in class about the way of writing journals and what comments are valuable for journal writers. The higher quality of comments brought about the higher quality of mathematical writings. Finally, children were aware of the mathematics they learned in school embedded in various cultural settings and daily activities through the use of journal writings. As a result, their abilities in formulating and solving the mathematics problems were improved.
Reference

Countryman, J. *Writing to Learn Mathematics.* Portsmouth, N. H. Heinemann Educational Press.

This paper describes a study regarding Israeli and Italian students' solutions to algebraic inequalities. Fischbein's notions of intuitive and algorithmic knowledge are used to analyze the data. The findings presented here show similarities in students' correct and incorrect solutions, in both countries. The findings indicate that students intuitively considered the balance model, saying that it is always permitted to "do the same thing on both sides" of a given inequality. Most students were intuitively drawing analogies to the solutions of related equations, either by excluding only zero values when dividing both sides of an inequality by a not-necessarily positive value, or when dividing by an expression without the exclusion of zero values as well.

There is a wide call for using students' correct and incorrect ways of thinking in teaching (e.g., NCTM, 2000). While this recommendation seems to be "speaking for itself", any attempt to take it from theory to practice, shows how complex this is. Among the prerequisites for such teaching, are familiarities with students' correct and incorrect reactions to various related tasks, with possible reasons for students' errors, and with available teaching approaches to be considered under specific circumstances. All of the above are needed, but do not guarantee that the student whom we teach will gain mathematical understanding. In this paper we use Fischbein's notions of intuitive and algorithmic knowledge as a theoretical framework to analyze students' solutions to inequalities, and consequently, we suggest possible implications for teaching.

Fischbein's theory deals with the formal, the intuitive and the algorithmic components in one's mathematical performance (e.g., Fischbein, 1993). According to Fischbein, formal knowledge is based on propositional thinking. It relates to rigor and consistency in deductive construction, being free of the constraints imposed by concrete or practical characteristics. Intuitive knowledge is a kind of cognition, which is accepted directly and confidently as being obvious, imparting the feeling that no justification is required. Algorithmic knowledge is the ability to use theoretically justified procedures. Each of the three components plays a vital part in students' mathematical performance, but since they are usually inseparable, the relations between them are not less significant. Fischbein explained that "sometimes, the intuitive background manipulates and hinders the formal interpretation or the use of algorithmic procedures" (ibid. p. 14). Consequently, he identified and investigated with his colleagues a number of algorithmic models related to various mathematical operations, such as subtraction of natural numbers, and methods of reduction in processes of simplifying algebraic expressions (e.g., Fischbein & Barash, 1993).
They explained, for instance, that the distributive law serves as a prototype in the algorithmic models of simplifying algebraic expressions, triggering students to present \(3(a+b)^2\) as \(3a^2+3b^2\). Here, the algorithmic model is expressed in the shift from \((a+b)^2\) to \(a^2+b^2\) to if these are equivalent expression, like \(2(a+b)\) and \(2a+2b\). This paper discusses Italian and Israel secondary-school students’ intuitive ideas and algorithmic models when solving algebraic inequalities.

Usually, publications in mathematics education journals present instructional suggestions with no research support. They recommend, for instance, the sign-chart method (e.g., Dobbs & Peterson, 1991), the number-line method (e.g., Parish, 1992), and various versions of the graphic method (e.g., Dreyfus & Eisenberg, 1985; Parish, 1992). Only little attention has been paid to students’ conceptions of inequalities (e.g., Bazzini, 2000; Linchevski & Sfard, 1991; Tsamir, Almog & Tirosh, 1998; Tsamir & Bazzini, 2001). These studies pointed, for instance, to students’ difficulties in grasping the role of the sign, and in using logical connectives.

The present study was designed in order to extend the existing body of knowledge regarding students’ ways of thinking and their difficulties when solving various types of algebraic inequalities (see also Tsamir & Bazzini, 2001). In this paper we focus on the question: What intuitive ideas and what algorithmic models can be identified in Israeli and Italian secondary school students’ solutions to algebraic inequalities?

**METHODOLOGY**

**Participants**
One-hundred-and-ninety two Italian and 210 Israeli high school students participated in this study. All participants were 16-17 year old who planned to take final mathematics examinations in high school. Success in these examinations is a condition for acceptance to academic institutions, such as universities.

In both Italy and Israel, algebraic inequalities usually receive relatively little attention and are commonly presented in an algorithmic way by discussing various algebraic manipulations. That year, the participants in this study had studied the topic of algebraic inequalities, including linear, quadratic, rational and absolute value inequalities. In both countries, the participants were taught different methods for solving the different types of inequalities, such as, graphic methods to solve quadratic inequalities, and “multiplying by the square of the denominator” for the solutions of rational inequalities.

**Tools**
Italian and Hebrew versions of a 15-task questionnaire were administered to the students. Here we focus on three tasks dealing with “dividing an inequality by a not-necessarily-positive factor”. Two tasks ask to judge statements regarding parametric inequalities, and the third task, poses a parametric “solve” inequality.

Research findings indicate that when solving rational inequalities, students frequently multiplied both sides of given inequalities by a negative number without changing the direction of the inequality (e.g. Tsamir, Almog & Tirosh, 1998). It was also reported
that students encounter difficulties when solving mathematical tasks, presented in a way different from the way they are used to. For example, when having to deal with parametric equations and inequalities that are commonly not discussed in class (e.g., Furinghetti & Paola, 1994; Ilani, 1998). Taking into account these data, we constructed tasks I, II, and III.

**Task I:** Examine the following claim: for any \( a \) in \( \mathbb{R} \), \( a \cdot x < 5 \implies x < 5/a \)

**Task II:** Examine the following statement: for any \( a \neq 0 \) in \( \mathbb{R} \), \( a \cdot x < 5 \implies x < 5/a \)

**Task III:** Solve the inequality: \((a-5)x>2a-1\) \( x \) being the variable and ‘\( a \)’ a parameter.

The tasks were designed to provide information regarding students’ distinction between the sufficiency of mentioning \( a=0 \) as a counterexample in Task I, and the insufficiency of the ‘\( a \neq 0 \)’ condition given in Task II, a condition, which is sufficient in the case of equations. Our aim was to see whether students regarded this limitation as sufficient for the inequality as well. While Tasks I and II asked the students to examine the claim regarding the equivalence of parametric inequalities, Task III dealt with the same issue in a different manner, asking the students to solve a similar given parametric inequality.

**Procedure**

The students were given approximately one hour, during mathematics lessons, to complete their written solutions. In order to get a better insight into the students’ ways of thinking, forty-five students were individually interviewed, usually being asked to elaborate on their written solutions. Each interview lasted 30 to 45 minutes.

**RESULTS**

The results will be presented in the following order. First, we present an analysis of students’ responses to Task I, Task II and Task III. Then, we present the intuitive ideas and the algorithmic models we identified in the students’ reactions to the three tasks. It should be noted that no significant differences were found between the Israeli and Italian students’ solutions.

**Students’ Reactions to Task I**

Most of the participating students correctly responded to this task (see Table 1). About three-quarters of the students accompanied their correct judgement with an acceptable justification – 18% of them elaborated on the role of the sign of the value substituted for \( a \) in determining the direction of the “\( > \)”, and 54% mentioned only the “zero case” as a counterexample to the given statement.

In their explanations, students who related to the sign of \( a \) wrote, for instance, “for \( a>0 \) this is a correct statement, but for \( a\leq0 \) it is not”; or “there are three cases: when \( a>0 \) the statement is correct, for \( a=0 \) it is impossible to divide by zero, and when \( a \) is negative the conclusion is that \( x<5/a \)”. Others explained more briefly that, “this statement is correct only for positive ‘\( a \)’s’; or “when \( a \) is negative the direction of the sign changes”. 

In their explanations, students who related to the sign of \( a \) wrote, for instance, “for \( a>0 \) this is a correct statement, but for \( a\leq0 \) it is not”; or “there are three cases: when \( a>0 \) the statement is correct, for \( a=0 \) it is impossible to divide by zero, and when \( a \) is negative the conclusion is that \( x<5/a \)”. Others explained more briefly that, “this statement is correct only for positive ‘\( a \)’s’; or “when \( a \) is negative the direction of the sign changes”.

Others explained more briefly that, “this statement is correct only for positive ‘\( a \)’s’; or “when \( a \) is negative the direction of the sign changes".
A number of students provided specific counterexamples, such as, “if a=(-1) the statement is not correct”; or “if -5x<5 the conclusion is that x>(-1), instead of x<(-1)”. A few added “I gave one example, but a single counterexample is sufficient for proving that the statement is false.”

* Correct solution

Most prevalent was the students’ tendency to use only the ‘a=0’ case, as a counterexample to refute the statement. They wrote, for instance, “this statement is false when a equals zero”; or “the statement is false, because of the case of a=0”. Many added “division by zero is undefined, therefore the statement is not always correct.”

In their oral interviews these students’ typically commented,

Sophia: the statement here refers to any number. BUT, since it is false for a=0, the statement is not true for ANY number. It is, therefore, false.

Gabby: It is enough to show that the statement is false in one case, and zero is such a case.

Dana: One counterexample is sufficient for proving that the statement is incorrect. Zero, that is a=0 is such a counterexample.

A number of them added,

Gabby: It is similar to equations.

Dana: I am sure, because I know it from equations.

The few students, who regarded this statement as correct, explained, “we divided both sides by the same thing”. One student based his incorrect “true” judgment on an example: “this is correct. For example, if 2x<5 then x<2.5”.

In their oral interviews these students added,

Naomi: I divided both sides by a [pause]. It’s OK. I operated in the same way on both sides.

Jonathan: It’s OK to do the same thing on both sides. When doing the same operation on both sides, the equivalency is preserved.

Interviewer: What do you mean?
Jonathan: In equations, it is allowed to add, subtract, and multiply [pause] to do any operation with the same number on both sides.
Interviewer: What do you mean by “allowed”?
Jonathan: [thinking] it does not change the solution…
Interviewer: You related to equations, but here we have an inequality…
Jonathan: It’s the same…

**Students’ Reactions to Task II**
Only 30% of the participants correctly responded that the claim is false and accompanied their response with a valid justification (Table 2). All of them related to the role of the sign in their decision. They explained, for instance, “if a is negative then $x>5/a$”; or “the claim is correct only for positive a”. Some students added specific examples, “It is false, because it holds only when a is positive. For example, if $a=(-2)$, then $-2\times x<5 \implies x>(-2.5)$”. Students were usually satisfied with a single counterexample, occasionally explaining, “one counterexample is sufficient in order to show that the proposition is false”.

</tbody>
</table>

* Correct solution

Most prevalent in both countries (over 50%) was the incorrect response that the statement is true, which was explicitly based on the given that $a \neq 0$. Students wrote, for instance, “It is correct because of the given condition that $a \neq 0.” In the interviews, these students’ elaborated explanations pointed to connections they made between equations and inequalities. In the interview Daniel explained,

Daniel: I can show how this works in an easier case [pause]…
Interviewer: What do you mean?
Daniel: I am looking for an example of a similar, but easier, task… like $2x=6$. Yes, here, x simply equals $6/2$ [pause], then, $ax=6$ means that $x=6/a$, but this is true only if a is not zero. If $a=0$ than it is impossible to divide… by zero.
Interviewer: Your example is an equation, and here we have an inequality.
Daniel: It’s the same [pause]. In a way inequalities are a certain type of equations. Just that equations are easier, so I use simple examples of equations when I have a difficult inequality.

Several students gave explanations, similar to the following one given by John,
John: In equations and inequalities, dividing by zero is problematic. But if we deal with this problem, operating with identical numbers and by means of the same operation on both sides is not only permitted, it is actually the way to solve the given tasks.

Students' Reactions to Task III

Fewer than 15% of the participants provided a comprehensive analysis of the various (positive, zero and negative) options for 'a' (Table 3). About 50% of the participants did not solve this task, and more than a quarter used an "equation-like" approach, writing that \( x > \frac{(2a-1)}{(a-5)} \) for \( a \neq 5 \). In their interviews, a substantial number of them clearly mentioned drawing analogies to equations. Bettina, for instance, explained,

Bettina: I divided both sides by the same expression, but I had to make sure that it is a non-zero expression. So, I wrote that a cannot be 5, because then a-5 equals zero...

Interviewer: Are you sure that five is the only problematic value here?
Bettina: [confidently] sure. I have done that a million times when solving equations.

</tbody>
</table>

* Correct solution

About 15% of the students gave the \( x > \frac{(2a-1)}{(a-5)} \) solution (with no mentioning of the \( a \neq 5 \) limitation), and in the oral interviews they frequently mentioned the use of equation-ideas. All of them explained that it is allowed to "do the same thing on both sides of an inequality". Many, like Anna, related to equations and to inequalities,

Anna: I divided both sides by a-5?
Interviewer: Is it OK to divide both sides by a-5?
Anna: Yes. I have done the same thing on both sides. If you do the same thing on both sides of an equation [pause], I mean an inequality [pause], actually both, you reach an equation or an inequality that has the same solution as the given one.
Interviewer: Always?
Anna: It is not only allowed, it is necessary to do that in order to solve the problem.

DISCUSSION

We opened this article by referring to Fischbein’s notion of algorithmic models, rooted in the application of intuitive ideas and/or formal overgeneralizations to rigid
algorithms (e.g., Fischbein, 1993). These models are usually coercive, used with confidence and grasped as being self-evident, even though they frequently lead to erroneous solutions. According to Fischbein, algorithmic models evolve when students' intuitive ideas manipulate their formal reasoning and/or their use of algorithmic procedures. In this spirit we posed the question: What intuitive ideas and what algorithmic models can be identified in Israeli and Italian secondary school students' solutions to algebraic inequalities?

An initial examination of the Italian and Israeli participants' written solutions to Task I revealed almost no intuitive, erroneous ideas. Most of the students correctly rejected the statement: \( \forall a \in \mathbb{R} \ a \cdot x < 5 \implies x < 5/a \), and based this rejection either on a comprehensive analysis of the sign of \( a \), or on a single counterexample. In the latter case, many students used zero as their counterexample, and most of them, correctly stressed that one counterexample is sufficient for the refutation of a proposition.

Had we stopped here, we might have assumed that most students have a good formal understanding of such parametric inequalities. However, an examination of their responses to tasks II and III revealed that this was not the case. The students' solutions to the latter two tasks, and their explanations in the interviews, clearly pointed to their intuitive grasp of inequalities as being "similar to", "the same as", "a certain type of" or analogous to equations. That is to say, equations were found to serve as a prototype in the algorithmic models of solving inequalities. This algorithmic model had two appearances: (1) "do the same operation with the same numbers on both sides"; or (2) "exclude the possibility of zero in the denominator, and then, do the same operation with the same numbers on both sides".

Those who applied the concise version of the algorithmic model (1), could easily be identified, since they incorrectly solved Tasks I and II by judging the statements to be true, or erroneously wrote in Task III that \( x > (2a-1)/(a-5) \) is the solution to the inequality \( (a-5) \cdot x > (2a-1) \). These students used the balance model when incorrectly solving equations, assuming that "doing the same thing" on both sides of an equation always leads to an equivalent equation, and consequently to the solution. When solving inequalities, they based their solutions on the equation-model, and thus, made no restriction when dividing (same operation) both sides of the inequality by the same expression. They were so sure that equations and inequalities follow the same set of rules, that they occasionally confused the two terms when explaining their solutions (See interviews with Anna, Dana and Gabby).

Most participants applied the second version of this algorithmic model. That is to say, they knew that when solving equations they should be careful not to divide by zero, and since they held the equation-model for solving inequalities, they imposed the same condition. These students usually answered Task I correctly, providing the 'a=0' case as a counterexample to refute the given proposition. However, they frequently, incorrectly regarded the proposition of Task II as valid or suggested \( x > (2a-1)/(a-5) \) \( a \neq 5 \) as the solution for Task III. The use of the equation-model by these students could not be identified by their written solutions to Task I only.
We have seen three, parametric inequalities that may be helpful in triggering students who hold different equation-based models to answer differently, and occasionally also incorrectly. We would like to suggest such tasks to be presented and discussed in class, in order to promote students’ awareness of their intuitive ideas and the resulting algorithmic model they intuitively use. How to implement such instruction and their impact on students’ performance should further be investigated.

In the presentation we will show, how the equation-model was identified in students’ solutions to additional inequalities in our study.

FROM THEORY TO PRACTICE: EXPLAINING SUCCESSFUL AND UNSUCCESSFUL TEACHING ACTIVITIES (CASE OF FRACTIONS)

Ron Tzur
North Carolina State University

Abstract: In a teaching experiment I examined a theoretical model of mathematics teaching and learning in practice. In this paper I focus on how the model can guide the teacher's thinking about students' understandings and the generation of activities that foster intended transformations in those understandings. As a researcher-teacher I taught, twice a week for four months, basic ideas of fractions to 28 third graders in a public school in Israel. The analysis of both classroom data and researcher's documented reflections indicates how the model can empower the generation and explanation of successful teaching activities, as well as thinking about and adjusting unsuccessful ones. It also highlights the importance of research-based, content-specific models of students' understandings for successfully implementing the model in practice.

Recent reform documents in the USA (NCTM, 1991) stressed that a primary goal of mathematics teaching is to promote students' conceptual learning of key mathematical ideas and procedures. In line with a constructivist principle of active learning, teachers are encouraged to use valuable methods such as problem solving, manipulatives, and whole class discussions. Sometimes the techniques bring about conceptual understandings of the intended ideas but often times they don't. In both cases, what seems to be missing is a systematic, developmentally appropriate guidance for teachers how to generate and adjust activities that advance students to intended understandings. To provide such guidance, my colleagues and I (Simon et al., 2000; Tzur & Simon, 1999) have recently developed a model that relates learning with teaching of new mathematical conceptions. The purpose of the present study was to examine in practice how this model can guide the teacher in (a) generating and/or selecting activities that successfully bring about the intended learning and (b) thinking about and adjusting unsuccessful teaching activities.

CONCEPTUAL FRAMEWORK

The study was part of a four-month teaching experiment that drew on a social-constructivist approach (Cobb & Bauersfeld, 1995). This approach coordinates social and psychological perspectives of teaching-learning processes. The model at issue is an elaboration of the cognitive perspective and, itself, served as a framework for the study. Since the study focused on relationship between teaching activities and students' learning, I briefly present only components of the model that served in the data analysis of successful and unsuccessful teaching activities (for details see Simon et al., 2000; Tzur & Simon, 1999). I also present key constructs of a content-specific model of children's fraction learning that served me, as the researcher-teacher, in making sense of students' thinking.

Knowing, Learning, and Teaching. The model regards knowing and understanding as using a conception—a dynamic mental compound that relates between an activity and its effect(s) (abbreviated as A-E relationship). The compound is not mainly the activity nor the effect(s) but the dynamic relationship consisting of both. In this paper I will use the
term A-E relationship and conception interchangeably. Learning is regarded as the process of transforming current conceptions into new ones and/or coordinating anew established conceptions (Piaget, 1985). The mental mechanism that enables learning is reflection on A-E relationship (abbreviated as Ref*A-E relationship). The term reflection refers to the continual mental comparison between one’s goals for and effects of his or her activities. Note that from the learner’s point of view, Ref*A-E relationship does not need to be directed toward making specific conceptual advances (awareness is not implied). Teaching is regarded as a cycle of four principal activities. It begins with inferring learners’ current conceptions. It proceeds through hypothesizing a learning trajectory (Simon, 1995) from those current conceptions to the intended ones. It moves to designing and engaging learners in activities they can assimilate and use as a means to form the intended conceptions. Finally, it implies orienting learners’ reflections on A-E relationships via probing questions and tasks which also serve to infer learners’ conceptions, and so on.

Conceptualizing Addition of Fractions. The content-specific model that I used in the study does not regard unit fractions (1/2, 1/3, etc.) merely as parts of equally partitioned wholes. Instead, it regards unit fractions as particular relational quantities, that is, entities that stand in a multiplicative relation to a given whole (cf. Behr et al, 1992). For example, a given quantity called “a third” is not just one-out-of-three equal parts; rather it is a third because another quantity, which was designated as “a whole,” is three times as much as the given quantity. (Children often say, “The given piece fits-in-the-whole 3 times.”) Thus, learning to add unit fractions requires that learners establish those units as relational and symbolically meaningful entities in and of themselves. Only then addition, which learners have established for whole numbers, can be coordinated with and applied to those entities.

METHODOLOGY

For four months I conducted a classroom teaching experiment (Cobb, 2000), while teaching 28 third-graders in a public school in Israel twice a week. Prior to the period reported herein the students formed their conception of unit fractions (1/n) via the Repeat Strategy that they used in tasks of equally sharing a given whole among a number people. To partition the whole (24 cm long paper strips), they estimated the size (share) of one person, repeated it the number of times implied by the number of people, and compared the iterated whole with the given whole. Then came the critical step of the repeat strategy: adjusting the size of the initial piece and reusing the previous steps (if the iterated whole was longer than the one to be shared--they shorten the initial piece; If the iterated whole was shorter--they made the initial piece longer). When the present study began, 26 out of 28 students had established unit fractions as unique quantities. This was indicated by their ability to order unit fractions while explaining the inverse relationship between size and number of parts (e.g., 1/5 is larger than 1/7 because to fit-in-the-whole 7 pieces one must make each piece smaller).

Data for the present study consist of:
1. Videotapes of 7 lessons conducted between December 10, 2000, and January 7, 2001. I taught the lessons on Friday and Sunday to create a sense of continuation while allotting the time needed between lessons for ongoing analysis and planning.

2. Tapes and transcripts of my reflections, recorded (audio) after every lesson.

3. Tapes and transcripts of audio-recorded conversations with the homeroom teacher (who observed and assisted my teaching) that took place 3 hours after every Sunday lesson.

4. Students’ written works from classroom.

A retrospective analysis of the data focused on relating teaching activities and students’ learning. The term ‘successful teaching activity’ is used to imply that it brought about students’ learning of the intended idea (‘unsuccessful’ if it did not). The 7 lessons chosen represent both unsuccessful and successful activities.

ANALYSIS

This 3-part section tells the story of successfully teaching the students addition of like-denominator fractions. In the first part I portray my inference of the students’ powerful understandings which prompted my decision to begin teaching them addition of unit fractions. In the second part I analyze my first, unsuccessful attempt to teach that topic. In the third part I analyze my second and very successful attempt to teach it.

Part 1: Students’ Thinking. Before teaching addition of unit fractions, I evaluated the students’ thinking to make sure that for them - these units were meaningful entities. On December 12, I engaged the students in a simple task. I gave each small group one long paper strip (the whole) and an envelope with nine, exact-size paper strips that I cut in advance (1/2 through 1/10). They were to randomly pick a piece from the envelope and find what fraction it was. After each group had picked at least three pieces we shifted to a whole class discussion. (‘R’ stands for researcher-teacher.)

R: (Holds an envelope like theirs) I pick a piece and I want to know what fraction is it of the whole on the board? Who can tell me how to figure it out? (Only a few students raise hands.)
R: Please go ahead and talk about this question again in your groups. (Group work, one minute.)
R: Okay, so what would I have to do?
Sally: Measure how many times the piece fits-in-the-whole.
R: How should I do that? Nora?
Nora: Put the piece exactly under the whole; mark its right end; then move it to the right and...
R: (Stops Nora before she explains the entire process) Okay, before I do this, what am I trying to find?
Ruth: To find what fraction is it.
R: How would I know what fraction is it by doing what Nora said?
Ruth: You’ll count how many such pieces fit-in-the-whole.

Reflecting on their activity of picking pieces from the envelope and stating what one would have to do was not a trivial task for the students. Thus, I asked them to re-discuss it over in the small groups so that their reflection would be based on what they found key to their activity. Then, by stopping Nora’s articulate way of explaining the process, I attempted to orient students’ reflections on the multiplicative relationship between their goal and activity. Key to my intervention was to let them carry out the activity in their mind, not in actuality. As a result of both interventions, Ruth was able to clearly state the intended relationship.
Following Ruth’s reply we executed Nora’s suggestion and all said that the piece was one-tenth because it fit-in-the-whole 10 times. So I asked, “What if I drew a piece that fits 7 times?” and Bob replied, “It would be one-seventh.” To the same question only with ‘3 times’ and ‘6 times’ Yoel and Ellen replied ‘one-third’ and ‘one-sixth,’ respectively.

The lesson on December 15 began with short individual work on a worksheet. Then, I presented a new situation. I put a long, red paper strip and said it was a whole, then put another red piece under it and the students easily detected that it was half of the longer strip. Then I put a green strip, shorter than the red whole but longer than its half, and under it a green strip that the students easily detected as one half of the green whole.

Before I could say anything, Aaron brought up my intended issue.

R: Aaron raised a point that I would like you to discuss as a question in your groups. (Holds up the green and the red halves) Both the red half and green half are halves, but the red half is longer than the green half. How do you explain this? (Group work, 1.5 minutes.)

R: (To the whole class) Okay, what if I would put a red third and a green third on the overhead. Would the red third be longer or shorter than the green third?

Jack: The red third will be longer.

R: Why?

Jack: Because the red whole is longer than the green whole. Therefore, [all] parts of the red should be longer than parts of the green whole. So the red third must also be longer.

R: (A little later) Why is the red third longer than the green third?

Noel: Because to fit-in-the-red [longer] whole three times the third has to be longer.

Judah: And to fit-in-the-green [shorter] whole three times the third has to be shorter.

(A little later, without any prompt, Lee says he has a different idea and comes to show it.)

Lee: If you take this (puts the green third below the red half) it also comes as a half.

The students’ work on different-size halves and thirds indicated a significant understanding of unit fractions: they saw them as multiplicative relations with respect to a given whole. They could anticipate the effects of the activity to determine a fraction and hence could shift their attention from one whole to another as a means to compare parts of those wholes. Moreover, Lee’s initiative indicated a powerful understanding—he was able to re-designate a part as a whole and compare it to a part of a different whole. I thought they were ready for addition.

Part 2: Unsuccessful Attempt. On December 15, toward the lesson’s end, I distributed a worksheet that introduced a coloring activity with which I planned to initiate adding of unit fractions. They worksheet showed a whole partitioned into 6 equal parts. I asked the students six questions that involved coloring certain parts and they completed the first two questions. The first asked them to color a part and say what fraction it was (answer - ‘1/6’); the second asked to color another part on that whole and say what fraction was that part only (answer - ‘1/6’). To my genuine surprise, some replied ‘1/5’ to the second question whereas others simply did not know. In my written notes on the matter I wrote:

Journal entry. Saturday, December 16: I thought again on tomorrow’s lesson, Dec. 17 [my initial plan was to go on with coloring]. Already by the end of class I thought, ‘What might have been the reason that the [coloring] activity caused some students difficulties to disembed [dissociate] the pieces of the partitioned whole?’ In class I thought that this is only a difficulty of unclear convention, hence I’ll have to tell them to count the colored parts. Then I realized - I should focus on the A-E relationships involved in the task, which re-focused my attention on ‘What activity could be focusing the students’ attention when coloring?’ The coloring activity creates a background-foreground problem and masks the counting activity to which I wanted to orient them. Coloring is an activity of pointing at the specific unit [to count] but it creates problems that I must also think about in terms of conceptualizing the situation,
not merely in terms of conventions. The specific conception is the understanding that each part is 1/6 no matter what its color. Because the students completed only the first two tasks I had the time to reflect on their thinking and on my initial tendency (in class) to dismiss the problem [convention]. My focused reflection about the activity as a plausible source for the students' difficulties led to a change in my plan for the next class. First, I'll ask every child to point to each part, colored or not, and ask what fraction was it of the whole [anticipated – '1/6' for each]. Only when I'll be clear how students 'see' the colored parts [separately] shall we move to adding fractions.

The entry above indicates both the power and limitation of the model. It provided powerful guidance to focus my reflection on plausible conceptual sources for students' difficulties. In particular, it guided me to infer the particular activity that the students might have been using to assimilate the task. My knowledge of content-specific models of students’ fraction learning, brought forth the ‘disembedding activity’ notion. I used this notion to bridge (so I thought) the gap between my expectation that coloring parts will simply serve to point at individual parts to be counted and the students’ difficulty to see the parts individually. The limitation is that a teacher’s inference can be inappropriate. Here, I did not infer that a problem to isolate parts could result from the coloring activity itself. In that case, just asking students to identify each part as 1/6 could not help because it only dealt with effects of the coloring activity.

On December 22 we returned to the coloring activity via the 6-question worksheet. This was a daunting, teacher-led lesson. I read out loud the first question. The students replied that the first colored part was 1/6 of the whole. I read the second question. A few students replied that the second colored part was … 1/5 of the whole. On the spot I thought that we must establish some convention, so I told the students that we also have to count the colored parts.

I then asked the third question, ‘What fraction were both colored parts combined?’ which fostered a very interesting learning experience. During a 3-minute small-group work, four (out of six) groups had figured out that the two parts combined would fit-in-the-whole three times, hence it is one-third. I devoted 8 more minutes for a whole class discussion about this exciting, student-generated idea. Then, 10 minutes to the end of the lesson, frustrated for not achieving my goal, I decided to present the conception of adding non-unit fractions as if it was a matter of learning a new convention. I told them that just like when one adds apple plus apple to get two apples or a flower plus a flower to get two flowers, one adds one-sixth plus one-sixth and gets two-sixths. Never before or after this repetitive teaching activity had I used such a method and, not surprisingly, it was unsuccessful. For example, when asked to color and add the third part students responded, ‘I don’t know,’ ‘1/3,’ ‘1/2,’ and only a few wrote ‘3/6.’ Students’ difficulties on December 22 perturbed me greatly and led me to back to the model as a guide for resolution.

Journal entry. Sunday, December 24: Immediately after Friday’s class, I thought that the coloring activity failed to foster the intended learning because it might not be appropriate. The homeroom teacher said that the students would need to work on something concrete, to ‘feel the units in their hands.’ I thought, ‘True, but coloring is a concrete activity.’ Reflecting on that thought, I realized the need to have an activity that focuses students’ attention on counting, where they separately point to each part while accumulating the parts. This need to figure out such a counting activity focused me back on the problematic issue of disembedding. I immediately asked myself why didn’t I think about that issue earlier. This self-criticism pushed me to re-examine my reasoning about the failure and I realized that a
wrong inference about the students' current understanding was also a possible. Thus, I decided to re-evaluate students' thinking before using a different activity for coordinating their established counting operations with the newly established unit fractions.

The entry above indicates the practicality of a model that combines general constructs of learning and teaching with articulated, content-specific constructs. The model implies to re-examine not only the activity but also students' thinking and enables the teacher to analyze specific component understandings needed for successfully learning to add unit fractions. Thus, consciously using the model to guide my reflection on students' work resulted in executing a specific plan that, here, rectified my previous inferences. On the basis of my re-examined inferences I generated a teaching activity that was more likely to foster the intended coordination between students' counting operations and unit fractions.

Part 3: Successful Attempt. On December 31 the students worked on a 2-page worksheet that contained 4 problems designed for the re-examination. I read every student's worksheet as soon as he or she finished it and this re-confirmed my inference. Thus, I began teaching them the game that I designed in line with my December 24 reflections. Each pair received a paper strip - the whole. Each student received 6 pieces marked 1/10. First, they checked that a part was, in fact, 1/10. Then, taking turns, they rolled a die and laid down as many 10ths as it indicated. Each student was supposed to say the names of the fractions as they accrued, write the fraction that each of them laid down on a chart, add their two fractions, and figure out game points (0, 1, 2, or 3, governed by chance) that the pair received in that turn. Before the lesson ended we had enough time to let two students demonstrate one turn of the game.

On January 5 the students quickly got engaged in the joyful game, which quickly brought forth their counting activity as a means to add fractions. They realized that what matters in adding and writing the results is the two non-unit fractions each player had and hence applied addition of whole numbers. The pairs quickly completed 10 turns of the game (10ths) and I gave them another worksheet for a game with 8ths. I moved about pairs to watch their work. Although successful, I was aware of two issues that may be hidden. First, several sums were improper fractions (e.g., 5/10+6/10, 6/8+4/8) and I needed to know what sense they made of them. Second, I wanted to make sure that as they were coordinating counting with unit fractions they were not losing the meaning of the units added.

R: (About 15 minutes to the end of lesson) Here's a question that we would talk about later. Some of you saw that sometimes we go beyond the whole. Please pay attention to the number of parts in such situations.

R: (A whole class discussion about 8 minutes later) There were times when you both rolled the die and got a number of pieces that exceeded the whole. Let's talk only about the game with 10ths. We have a whole and we have 10ths. When does it go beyond the whole? Please raise your hands if you can explain it. You may like to recall what you've just done in the game. (Several students raise hands.)

Let's hear from Joe.

Joe: With twelve- and with eleven [pause], 10ths.

(R. takes a minute to write on the board Joe's examples, 6/10+5/10=11/10, 6/10+6/10=12/10.)

R: Joe says that in these cases we have more than the whole. If you think that Joe is right please just raise your hand quietly. (A majority of the students raise their hands.)

R: Who thinks that Joe is wrong? (Nobody raises a hand.) Aaron, would you explain Joe's idea?

Michael: (Bursts out) Because the whole is ten 10ths.

R: (Hisses them) Only Aaron.
Aaron: Because, because ten 10ths is one whole.
R: And so if we have 11/10, or 12/10 (points accordingly on the board), then it is more than the whole?
Many students: This happened to us, too.
Tom: This did not happen to us with 10ths but it did with 8ths.... We got ten 8ths!

The model-based question I asked in the first line of the protocol above meant to orient the students' reflection on relations between their activity and an effect of mathematical interest (to me). Consequently, students related between their activity—adding unit fractions beyond the whole—and the numerosity of the partitioned whole. Thus, I fostered an understanding beyond simply being able to add unit fractions. This was particularly indicated in Tom's voluntary contribution, he learned to conceive the partitioned whole as an entity and could then make the abstract application to his personal experience of 10/8.

R: (On Jan. 7, after returning the all-correct worksheets to the students) Today, I want us to make a rule that will help you from now on. (Writes on the board and says) 'How do we add fractions?' We want to come up with a rule that always works. And just as usual, we want to see that everybody understands why this is the rule. (A little later) Okay, now I'll write the question the board. (Writes on the board while saying) 2/7 + 4/7 = . We want to know how much is it, this time with no dice and no pieces. And I wrote these two only as an example. Because the question is not simply if you know the answer but if you can state a rule how will we always know. (About half of the class raises hands.) Hmm, okay, Jan?

Jan: Six-sevenths.
R: And how should I write it [on the board]?
Jan: (Directs R.) Six; fraction-bar; Seven.
R: Jan, how did you know this was 6/7 and not 9/10 or 85/12?
Jan: I did it in my head.
R: What did you do in your head?
Jan: I added 2 and 4 and got 6.
R: (Asks who agrees. About half agree, no one disagrees. R. calls on Tom who said he was not sure.)
Tom: Ah, 2+4 is, in fact, 6. But I was not sure that she has to write: 'fraction-bar, 7.'
R: Good observation. Tom says that Jan added the 2 & 4, but why do we have to write 7 here (points to the sum's denominator)? Why don't we add 7+7 and write 14? Many think it's obvious but Tom asks us why.

Aaron: I think she cannot explain if it's supposed to be 7 or 14, but her answer is fine.
R: Why can't we explain this?
Aaron: Because...
R: 'Because' is not an answer that helps us to understand. (A little later, Noel raises his hand) Noel?
Noel: Ah, this is what we learned, six is with sevenths (his hand movement indicates, 'this is obvious').
R: Why is it with 7ths and not 10ths, 14ths, 3rds?
Noel: (Voluntarily gets up and goes to the board) Look. These (the 2/7) are 7ths. And if you add 7ths to it (points to the 4/7), it must come out with 7, not with 14.
R: (A little later) Noel, why must it be 7 and nothing else?
Noel: Because if you have 2 and 4, and they are 7 [he seems to mean 7ths], and you add them together, the '7' does not go away [i.e., the parts, 7ths, do not change].
R: (To the entire class) Look, we added the 2 and 4 but we did not change the 7. Why?
Nora: (A little later) We knew we had two-sevenths and four-sevenths, so we say it's six-sevenths.

(A little later R. engages them in small-group work to write their rules. Five out of six groups write rules that clearly indicate their understanding. A student from each group reads their rule.)

Judah: When adding fractions of the same size [denominator], the number on the bottom always remains the same and you have to add the numbers on the top.
R: (Two minutes before the end of the class.) We would now use your rule to solve some problems. (R. distributes a worksheet of 28 problems of adding like-denominator fractions, e.g., 3/9+4/9, 2/5+4/5. All 27 students in attendance completed the entire worksheet, all correct, in less than 5 minutes.)

The last two protocols indicate that the model-based game successfully fostered students' coordination between counting activities and unit fractions. It was a powerful activity that
promoted students' thinking about the unit fractions as invariants. Thus, it succeeded where the coloring activity failed. Key to the creation of a successful activity was my model-based reflection on the previous failure: analyzing students’ understandings and articulating ways in which their understandings support counting activities.

DISCUSSION

This study examined how a general model of teaching-learning a new mathematical conception, combined with content-specific models of students’ thinking, can guide a teacher in practice. It demonstrated how useful models are in devising successful teaching activities and in analyzing and adjusting unsuccessful ones. It highlighted the critical role that well articulated, content-specific models play in making sense of students’ evolving understandings and in creating tasks and activities that both ‘meet’ the students’ current conceptual state and foster an intended advance. That is, it indicated that the model can help the teacher to understand the activity from the student’s point of view and thus to consider the pedagogical potential of an activity. A particular, content-specific implication of the study is that coloring activities, which are frequently used in schools, may be very difficult and sometimes misleading even for students with robust understandings.

The study also supported the key role that the postulated mechanism of learning a new conception—reflection on A-E relationship—plays in advancing students’ conceptions. This implies a critical role for teachers. Engaging students in thoughtful activities must be followed with thoughtful probing of reflective processes in directions that can foster the intended learning. In this sense, the study implies that the model of teaching and learning is a plausible goal for teacher education. That is, in order for teachers to be articulate about their teaching activities, especially unsuccessful ones, they need to develop understandings of both general constructs of learning and teaching and content-specific models regarding students’ thinking so they can intentionally focus students’ reflections.

SECONDARY SCHOOL STUDENTS' ILLUSION OF LINEARITY: EXPANDING THE EVIDENCE TOWARDS PROBABILISTIC REASONING

Wim Van Dooren¹ 2, Dirk De Bock² 3, Fien Depaepe², Dirk Janssens² and Lieven Verschaffel²

¹ Research Assistant of the Fund for Scientific Research – Flanders (F.W.O.)
² University of Leuven and ³ EHSAL Brussels; Belgium

Many secondary school students have a strong tendency towards improper linear reasoning in the domain of geometry, e.g. by believing that if the sides of a figure are doubled, the area is also doubled. In this paper, the evidence for this "illusion of linearity" is expanded to a new application domain: probabilistic reasoning. The paper reports an empirical investigation on the ability of 10th and 12th grade students to compare the probabilities of different situations. It is shown that most students have a good capability of comparing two events qualitatively, but at the same time incorrectly quantify this qualitative understanding into linear relationships between the varying quantities. It is shown how the research findings can shed a new light on some well-known probabilistic misconceptions.

THEORETICAL AND EMPIRICAL BACKGROUND

Because of its wide applicability for understanding problems in mathematics and sciences, the linear (or proportional) relationship is a key concept in primary and secondary education. However, together with its intrinsic simplicity and self-evidence (see, e.g., Rouche, 1989) the reinforcement of the linear model may lead students to "the seduction to deal with each numerical relation as though it were linear" (Freudenthal, 1983, p. 267), a tendency which is sometimes referred to as the "illusion of linearity". This phenomenon can appear at different levels and in many domains of mathematics and science education, such as elementary arithmetic, geometry, algebra, probability and physics (see, e.g., De Bock, Verschaffel, & Janssens, 1999). The best-known case of the overreliance on the linear model is situated in the domain of geometry: many students of different educational levels believe, for example, that when the sides of a figure are doubled, the area and volume will be doubled too (National Council of Teachers of Mathematics, 1989). In the past years, we performed a series of empirical studies to evidence this irresistible tendency in secondary school students, to identify influencing task variables (see, e.g., De Bock et al., 1999) and to unravel the underlying problem-solving processes (De Bock, Van Dooren, Verschaffel, & Janssens, 2001).

Besides continuing our studies in the domain of geometry, we set up a new line of research which aims at searching for the illusion of linearity in other mathematical domains. The first new domain that we chose for exploration of the
overgeneralization of proportionality, is probabilistic reasoning. As explained in Van Dooren, De Bock and Verschaffel (in press), this domain is particularly interesting since the learning of probability is often hindered by students' primitive conceptions, wrong intuitions, fallacies, etc. (see, e.g., Shaughnessy, 1992). Moreover, the notion of chance itself shows some very strong similarities to the notion of proportion (Fischbein, 1975; Truran, 1994), suggesting that the overreliance on proportions might very well occur when students approach probabilistic situations. Recently, we have performed a review of the literature on probabilistic misconceptions, and made an inventory of those specific misconceptions which are conceptually related to the (unwarranted) application of proportions. This inventory contains a wide variety of erroneous reasonings (both famous and intensively studied misconceptions and anecdotal phenomena) for which the illusion of linearity yields a proper explanation (see Van Dooren et al., in press; Van Dooren, De Bock, Verschaffel, & Janssens, 2001). The current paper reports the next phase in this new research line: after the conceptual analysis of linearity-related probabilistic misconceptions, we empirically tested whether the overreliance on the linear model is actually present in students' probabilistic thinking.

FOCUS OF THE CURRENT PAPER

The empirical study reported in the current paper focuses on one particular class of misconceptions that was distinguished in the theoretical inventory (Van Dooren et al., 2001, in press): the scope is on those misconceptions that could possibly be explained by erroneously assuming a linear relationship between the variables \((n, k\) and \(p\)) of a binomial chance situation, on the one hand, and the final chance for success \((P)\), on the other hand, and that can be illustrated by the following example:

The participants in a television game can roll 12 times with a fair die. If they obtain at least 4 times a six, they win a car. At Christmas day, the game leader is in a generous mood and tells the participants that they get 24 instead of 12 trials, so that their chance for winning the car is doubled.

The probability \(P\) of winning the car in the regular game is about 12.5 %, and it is determined by three variables: \(n\) is the number of allowed trials (12), \(k\) is the required number of successes (4) and \(p\) is the probability for success in a single trial (the chance to obtain a six with a fair die is \(1/6\)). The game leader is mistaken, however, when he claims that the chance \(P\) for winning the Christmas game is doubled at the moment when the number of trials is doubled \((n = 24)\). He wrongly assumes a linear relationship between \(n\) and \(P\), and he would be surprised that in fact, the probability of winning the Christmas game is not \(2 \times 12.5 = 25.0\) % but 58.4 %!

In the above example, the mistake was a wrongly assumed proportional relationship between \(n\) and \(P\). Analogously, we can think of situations where a variation of \(k\) or \(p\) is expected to have a proportional effect on \(P\): the game leader might think that the chance for winning the car \((P)\) is doubled when \(k\) is halved (e.g. only 2 instead of 4 sixes are needed to win the car), or that \(P\) is tripled when \(p\) is tripled (e.g. the goal is
to obtain even numbers instead of sixes). Moreover, also the combination of two variables can lead to erroneous reasonings. For example, one could reason that the regular game is equally favourable as a game in which you get 24 trials, but have to obtain at least 8 sixes ($n$ and $k$ are doubled), or a game in which you have to obtain 4 even numbers, but at the same time get only 4 trials ($p$ is tripled, $n$ is divided by three).

**RESEARCH QUESTIONS AND HYPOTHESIS**

The goal of the current study is to test to what extent the above-mentioned linear misconceptions in binomial chance settings are actually present among secondary school students with and without formal instruction in probability in general and in the binomial probability model in particular. More specifically, the study aims at answering the following research questions:

- Do secondary school students have a good qualitative insight in the effect of a variation of the different variables ($n$, $k$ and $p$) that determine a binomial chance setting?
- To what extent do these students have a tendency to quantify these qualitative insights as proportional relationships between $n$, $k$ and/or $p$, on the one hand, and $P$, on the other hand?

Our hypothesis is the following. Since several authors (e.g., Fischbein, 1975) have claimed that even very young children have an elementary understanding of probability, we expect secondary school students to have a good qualitative insight in probabilistic situations. But because of the intrinsic simplicity and self-evidence of the linear model and students' well-established tendency to overrely on the proportional model in other mathematical subdomains, we expect that most of them will erroneously translate these correct qualitative insights into linear relationships between the available variables.

More concretely, we make the following predictions: First, we expect that the students will be able to make appropriate judgements when they have to qualitatively compare the probability of two events that differ with respect to one of the variables $n$, $k$ or $p$. We expect that this capacity is present in students without formal probability instruction, and that the formal learning of probability will have an additional positive effect on it. Second, we predict that the large majority of the students will quantify these correct qualitative insights in terms of a linear function between $n$, $k$ and/or $p$ on the one hand and $P$ on the other hand. We expect this tendency to be persistent: it will be present in students with and without formal instruction in the binomial probability model.

**METHOD**

A paper-and-pencil test was taken from 225 secondary school students divided in two age groups: 107 10th graders and 118 12th graders. Participants had one hour to solve a test consisting of 7 experimental items and 3 buffer items, which were offered in

</tr>
</tbody>
</table>

**Table 1: Design of the experimental items**

The 7 experimental items were multiple-choice problems in which the students had to compare the probability of two specific events. All 10 problems were situated in the context of rolling fair dice. The design of the test is shown in Table 1. It can be seen that for each of the variables $n$, $k$ and $p$ there were two sorts of items: students had to make either a qualitative or a quantitative comparison between two situations. Additionally, there was one item in which $n$ and $k$ were varied simultaneously. Table 2 gives an example of a qualitative item, a quantitative item (in which the variable $n$ is varied), and the item where $n$ and $k$ are varied simultaneously.

**Table 2: Examples of experimental items**

<table>
<thead>

<tr>
<td>I roll a fair die several times. The chance to have at least two times a three if I can roll four times is larger than the chance to have at least two times a three if I can roll five times.</td>
<td>I roll a fair die several times. The chance to have at least two times a six if I can roll twelve times is three times as large as the chance to have at least two times a six if I can roll four times.</td>
<td>I roll a fair die several times. The chance to have at least two times a five if I can roll six times is equal to the chance to have at least once a five if I can roll three times.</td>
</tr>
</tbody>
</table>

For the qualitative items, the student had to indicate whether the first event had a higher, lower or equal probability as the second event. The correct answer always was either "larger than" or "smaller than". The quantitative items were necessarily formulated differently: they contained an explicit quantified comparison of the probabilities of the two events, and the students had to judge the correctness of this statement. The quantification was always done proportionally (e.g., in the example in Table 2: $n$ is tripled, thus $P$ is tripled). As a consequence, the correct answer always was "This is not true". For each item, the students were asked to indicate the correct alternative and, moreover, to write down an explanation for their answer.

**RESULTS**

Tables 3 and 4 give an overview of the answers of the 10th and 12th grade students respectively on the seven experimental items.

As predicted, the large majority of the students in both age groups performed very well on the qualitative items. In about 90% of the cases, the correct alternative was chosen, indicating that even before formal instruction in probability, students have a good qualitative understanding of how the probability in a situation evolves when an aspect ($n$, $k$ or $p$) of this situation changes. Contrary to our prediction, the 12th

Graders, who had already met the binomial probability distribution in their curriculum, performed only slightly better on these qualitative problems than the 10th graders (89.5% versus 88.2% correct answers), but considering the already high performance of 10th grade students, there might have been a ceiling effect. This good qualitative understanding of the chance situation was present for all of the three items. For the k-problem, there was a higher error rate which is probably due to the inverted effect of k on P: if more successes are needed, there is less chance of succeeding.

As expected, the high performance on the qualitative items is in sharp contrast with the low score on the quantitative problems. For this last category, the students most frequently chose for the incorrect alternative, which expressed a proportional relationship between n, k or p and P. Apparently, the vast majority of the students agreed with a proportional quantification of their correct quantitative insights. Also for the problem in which n and k were varied simultaneously (see Table 2), most of the students believed in the linear effect. The 12th graders performed slightly better on the quantitative problems (on the average, 25.8 % correct answers) than 10th graders (18.2 % correct answers) but as expected, the tendency towards linear modelling is still strongly present in these students. In particular, 12th grade students had a better score on the k-problem than 10th graders. Apparently, after instruction in probability, more students were aware that when the number of required successes is doubled, the probability is not necessarily halved.

We will also perform a qualitative analysis of the written notes and explanations of the students to investigate what specific strategy led the students towards the correct
or incorrect answering alternative. A first round of qualitative analysis of the written notes and explanations accompanying the incorrect answers on the quantitative problems already revealed that more than 80% of the incorrect answers on the quantitative problems can be clearly identified as resulting from students' overreliance on the linear model. Examples of such statements - referring to a linear relationship between the variables in the n-problem in Table 2 - are:

In the first case, you can try three times more to obtain the same result (two sixes), so it is evident that you have three times more chance of winning.

The chance of getting 2 sixes in 12 trials is a lot bigger than getting 2 sixes in 4 trials. And 12 is three times larger than 4, so the statement is true.

A more fine-grained analysis of students' written notes and explanations will provide richer data on the mechanisms and origins of students' improper proportional reasoning in binomial probability situations.

CONCLUSIONS AND DISCUSSION

The results of this study have confirmed our global hypothesis. Secondary school students have a good qualitative understanding of probabilistic situations, and are able to compare two such situations that differ in one variable. The understanding is even present in students without formal instruction in probability. At the same time, however, most students have a strong tendency to incorrectly quantify their correct qualitative insights as linear relationships between the variables in a binomial chance situation. In our multiple-choice items, the large majority of students chose for the alternative that stated a linear increase (or decrease) of the probability of the described event if one or two variables in the situation were increased (or decreased). This tendency towards linear reasoning is strongly present in all students in the research group, even those who met the binomial probability distribution in their mathematics curriculum.

Further qualitative analyses of the answers, as well as in-depth interviews with selected students will have to clarify how different components in the students' mathematical knowledge base lead them towards unwarranted linear reasoning.

Another remaining question, which we will address in our future research, is to what extent our findings are significantly affected by the way in which the test items were administered to the students. It could be argued that so many students fell into the linearity trap because they were seduced to do so, by confronting them with proportional statements with which they either had to agree or disagree. The tendency to reason linearly might considerably decrease when an open-answer format is used.

Finally, we want to show in an exemplary way how our research can shed some new light on a number of other well-documented misconceptions in the domain of probability, by looking at them from the perspective of the improper assumption of linear relationships between quantities. A first example is a problem used by Tirosh and Stavy (1999, p. 190):
The Carmel family has two children, and the Levin family has four children. Is the probability that the Carmels have one son and one daughter larger than/equal to/smaller than the probability that the Levins have two sons and two daughters?

More than half of the 7th to 12th grade students in their study answered that the probabilities are the same. According to Tirosh and Stavy (1999, p. 190), students here applied the intuitive rule Same A–Same B: "Because the target boys:girls ratio in the two families was the same (1:2), the probability would therefore be the same." A second example comes from Fischbein (1999), who found that the majority of 5th to 11th grade students answered erroneously on the following problem:

The likelihood of getting heads at least twice when tossing three coins is smaller than/equal to/greater than the likelihood of getting heads at least 200 times out of 300 times.

For a similar problem, Fischbein and Schnarch (1997, p. 103) argue that "The principle of equivalence of ratio imposes itself as relevant to the problem and thus dictates the answer."

Taking into account our own research findings, we believe that these misconceptions can be explained in a related, but somewhat different way, with a stronger emphasis on linear functions instead of ratios. In the study reported above, we observed that many students believe that (1) $P$ is doubled when $n$ is doubled (2) $P$ is halved when $k$ is doubled and (3) these two effects can also play simultaneously. The improper assumptions of linearity might also be a valid explanation for Tirosh and Stavy's and Fischbein's findings. We are even able to provide a useful framework for understanding a famous historical problem: Chevalier de Méré knew that it was advantageous to bet on at least one six in 4 rolls of a single die. He deduced that it should be equally advantageous to bet on at least one double-six in 24 rolls of a pair of dice. This did not yield the financial gain he had hoped for... Probably, most of our students would also agree that multiplying $n$ by 6 and dividing $p$ by 6 is a neutral operation for $P$.

REFERENCES

According to the Flemish curriculum, probability (and the binomial probability model in particular) is a part of the mathematics curriculum in the 11th grade.

2 As can be seen in the $n\times k$-problem, the simultaneous variation of two variables (in a proportional way) necessarily implies a quantified statement (i.e. the equality of the probabilities). Therefore it was impossible to formulate a qualitative item for this category.

3 The buffer items were manipulated so that they were similar to the qualitative items (but 'equal to' was the correct alternative) or to the quantitative items (but this time, 'This is true' was the correct alternative).
MECHANICAL LINKAGES AS BRIDGES TO DEDUCTIVE REASONING: A COMPARISON OF TWO ENVIRONMENTS

Jill Vincent, Helen Chick and Barry McCrae

The University of Melbourne

This paper reports part of a study investigating the use of mechanical linkages as contexts for establishing a classroom culture of conjecturing and proof in geometry at Year 8 level. The focus is on a comparison of students’ use of a physical model and a Cabri Geometry model of a linkage, examining in particular how the students exploited the features of Cabri to assist them in producing conjectures and proofs.

The lack of success with traditional methods of teaching geometric proof has prompted researchers to seek alternative approaches, involving new and old technology. Recent research on proof has focused on the role of dynamic geometry software, for example Cabri Geometry II™, as an environment for geometry learning, with debate as to whether these environments assist or, rather, hinder the development of deductive reasoning. Hoyles (1998), for example, expresses concern that unless we can develop a ‘need for proof’, dynamic geometry software may merely contribute to a ‘data’ gathering, empirical approach to geometry.

Bartolini Bussi (1998) reports on the use of historic drawing instruments to create an environment where students can ‘relive’ the work of mathematicians in theorem production. She describes the conjecturing and proof construction processes of a group of five year 11 students who investigated the geometry of Sylvester’s pantograph, working with a physical model.

Bartolini Bussi notes that “producing the conjecture was difficult and slow” (p. 742), and that the students’ written proof was incomplete and not in a logical sequence, but when they refined it with the teacher’s help, it remained meaningful for them:

The order of the steps recalls the sequence of production of statements, as observed during the small group work, rather than the logical chain that could have been used by an expert. Nevertheless it was easily transformed later with the teacher’s help into the accepted format ... yet, what is important, the time given to laboriously produce their own proof ensured that the final product in the mathematician’s style, where the genesis of the proof was eventually hidden, retained meaning for the students. (p. 743)

What is it, then, about an environment that assists students’ conjecturing and proof?

THE STUDY

The research presented here forms part of a study on mechanical linkages, using both physical and computer models, as an environment for Year 8 students to conjecture, argue, and construct proofs (see Vincent & McCrae, 2001). The linkages were carefully selected on the basis of appropriate geometry for Year 8. This report focuses on a comparison of students’ use of a physical model and a Cabri Geometry model.
focuses on a comparison of students' use of a physical model and a Cabri Geometry model of a linkage, examining in particular how the students exploited the features of Cabri to assist them in producing relevant conjectures.

The participants, who had no previous formal exposure to deductive reasoning, were from an extension Year 8 Mathematics class at a private girls' school in Melbourne. Prior to the research the following geometry was taught/revised: angles in parallel lines, triangles and quadrilaterals; Pythagoras' theorem; and similar and congruent triangles. Tchebycheff's linkage for approximate linear motion (Vincent & McCrae, 2001) was used to introduce the students to the need for proof by showing them that, although the midpoint of one of the links appeared to move on a linear path, closer investigation showed that the path was in fact not exactly linear. For each of the linkages studied, the students worked in pairs, constructing their linkages from plastic geostrips and paper fasteners, as well as having access to a Cabri model of the linkage which had been previously prepared by the teacher-researcher. The students were video-taped during their conjecturing, argumentation, and proof construction. At the conclusion of each task, the students were asked which model they considered most useful in helping them in their conjecturing and proof construction, and which one they most enjoyed working with.

**Sylvester's pantograph: Case studies of two pairs of students**

Before investigating Sylvester's pantograph, the students had completed pencil and paper proofs for the angle sum of triangles and parallelogram properties, and had worked with at least three other linkages. The students constructed the rhombus version of the pantograph, using the diagram shown in Figure 1, where OA = OC = AB = BC = AP = CP' and \( \angle PAB = \angle PCB \). They explored the linkage (Figure 2) for approximately 10 minutes before being given access to the Cabri model. They were then free to choose the model with which they preferred to work. Each pair of students worked for two 50-minute lessons, conjecturing, arguing, and constructing their proofs, with the teacher-researcher (TR) occasionally intervening.

---

**Figure 1.**

**Figure 2.**

**Students Ce and Ch**

Ce and Ch drew a shape on paper and traced over the shape with point P of their geostrip pantograph so that P' traced an image of their shape (Figure 3).
Ce: It's the same but it's not in the same direction. It's been turned.

Ch: [Spreads her thumb and fingers to compare the size] It's the same size. It's turned 45 degrees.

TR: How do you know it's 45 degrees?

Ch: Just guessing, 'cause it was about half 90.

Figure 3.

Ce and Ch were confident that the image was the same size as the original, but they were less confident of their conjecture about the angle of rotation, particularly as there seemed no obvious reason why it should be 45 degrees. When given the Cabri model, their initial reaction was to use the same approach as for the geostrip model, but they were not sure how to proceed. With Trace on P', Ch carefully dragged P in the shape of a square so that P' traced the same shape. She then switched on Trace for P and tried to drag P so that P' moved around its previous path. However, she had trouble controlling the mouse to follow the small shape and began to move P haphazardly, before dragging it horizontally across the screen (Figure 4), when she suddenly noticed that the paths of P and P' were converging:

Ch: [Excitedly] Goody goody goody ... we've got 'em to meet! And then look ...

Ce: Oh, we've got the angle there ...

Ch: We'll make a segment. And from there down to about there. [Draws segments over traces of P and P' — see Figure 5] Measure the angle ... 30.1. [Measures angles PAB and P'CB] 30! 30 and 30. So it rotates the angle of that [PAB or P'CB]!

Ce: Yes!

Ch: They're the same distance [indicates from P to O and from P' to O] ... maybe if we draw segments. [Ch draws segments OP and OP' — see Figure 6]

Ch: Let's measure that angle ... [POP'] ... it looks like the same angle again.

Ce: 30! So that [OP'] is always turned around 30 degrees from that [OP].

Ch and Ce recognised that their method of drawing segments over the converging traces (see Figure 5) involved some error, so they seemed unconcerned by the discrepancy between the measured angles, 30° and 30.1°; the size of angle POP'
seemed to carry greater significance. Ch and Ce were now confident about the rotation of the image: “The image rotates [through] the angle of BAP”.

Figure 4.

Ce and Ch were now able to explain why their drawing and its image were the same size, and were able to write the geometric proof (Figure 7):

Ch: They’re congruent triangles [OAP and OCP'].

Ce: Yeah, ’cause the sides are the same [OA, OC; AP, CP'] and so are those angles [OAP and OAP'].

TR: Why are those angles equal?

Ch: The [opposite] angles in the rhombus are equal and then they both have the same fixed angle bit added on.

Ce: So therefore OP and OP' are equal.

TR: And what does that tell you?

Ch: That’s why the copy is the same size.

Figure 6.

Prove: OP = OP'

Proof: \( \angle OAB = \angle OCB \) (rhombus)
\( \angle PAB = \angle P'CB \) (given)
\( \angle PBO = \angle P'CO \)
\( \triangle POC = \triangle P'O'C \) (SAS)
\( \Rightarrow OP = OP' \)

Figure 7.

Their next task was to prove their conjecture that the angle of rotation POP' was equal to the fixed angles PAB and PCB. Ch drew segments from P to B, B to P' and P to P' on the worksheet diagram (see Figure 8).
Ce: Well ... could we make a triangle there? [points to O and from P to P']
Ch: But B's not in line ... see ... why don't we use the angles in the rhombus?
Ce: OK, let's put some letters in. We'll call this [PAB] a and these [BCP' and POP'] a.
TR: We don't know yet ... that's what you're trying to prove.
Ce: Oh, yeah, we'll call it [POP'] b, and we'll call this [OAB] c and this [OCB] is c too.
Ch: And call those d [points to AOP and COP'].
Ce: And those [APO and CPO] are d as well.
Ch: Oh, yeah ... isosceles triangles.
Ce: And this [ABC] is e. OK ... e equals 2d plus b.
Ch: d plus d plus a plus c equals 180 'cause that's a triangle
Ce: And 2d plus b plus c equals 180 'cause angles in the rhombus.
Ch: So b must equal a!
Ce: Yeah, that's it!

\[ e = 2d + b \]
\[ 2d + a + c = 180^\circ \]
\[ 2d + b + c = 180^\circ \]
\[ \therefore a = b \]

Figure 8.

Both students then wrote correct proofs; Figure 9 shows the proof written by Ch.

| Prove: \( \angle POP' = \angle BCP' = \angle PAB \) |
| Proofs: \( \angle COP'=\angle CPO \) (isosceles triangles) |
| \( \angle COP = \angle OPA \) (congruent triangles) |
| \( \angle OAC + \angle OCB = 180^\circ \) (rhombus) |
| \( \triangle ABC \) |
| \( \therefore a = b \) |

Figure 9.

Students Lu and Li

Like students Ch and Ce, Lu and Li were reasonably confident that the geostrip pantograph was producing a congruent image but they too were less certain about the angle of rotation and unsure how to determine the angle with the geostrip model:
Lu: Well, it creates a mirror image … well, not exactly a mirror image but …
Li: … if it was more accurate.
Lu: A congruent shape of the shape and it goes in a circle. If you kept on following the trace it would go round and round [points to rotation of the linkage about O]
Li: Maybe that angle [points to the fixed angle, PAB] … I'm not sure … maybe not …
Lu: When you move it [points to P] up at the beginning it [points to P'] moves around and then it just makes the rest of the shape.

Li: I was thinking that many degrees [points to angle PAB] … but I don’t know why.

At this point the girls were given the Cabri pantograph. They used the same approach in Cabri as they had done with the geostrip model, drawing a triangle and moving P around it so that P' traced the image (Figure 10). Because of the transitory nature of Cabri traces, Li then drew a triangle over the image trace.

Figure 10.

Lu measured angles PAB and P'CB as 30 degrees (Figure 11), then carefully dragged the original triangle, placing it over the image in order to measure the angle between the two triangles. Seeing the linkage as an accurate geometric diagram seemed to encourage the girls to add construction lines and to notice congruent angles.

Figure 11.

Having drawn and measured segments OP and OP', and measured angle POP', the girls now understood how the pantograph was working:
Lu: 29.1 ... it’s point 9 off.
TR: So what is your conjecture?
Lu: The angle which the copy of the shape rotates is that angle of the pantograph [PAB].

Lu and Li then began writing their proofs, with Li demonstrating that she had a clear understanding of the side-angle-side condition for triangle congruency. The girls discussed and sorted their statements into a logical sequence as they wrote, for example:

Li: Let’s do the sides first. OA equals AP equals OC equals CP’ ... then angle OCP’ equals ... OAP because they both have 30 degrees ... they share 30 degrees ... we shouldn’t do that yet [erases] ... angle OA ... angle OAB equals ...

Lu: Angle OCB.
Li: And angle BCP’ equals BAP because given ... OCB plus BCP’ ...

Lu: Those two added together, that whole angle ... that means ...

Li: Once we’ve proved that angle, then the whole thing’s easy ’cause side angle side ... see if you have two sides and how big it’s going to be in between ... when you join them up the triangles will be the same ...

DISCUSSION

In their responses to the linkage questionnaire which they completed after working with the pantograph, all the students agreed that operating models of the linkage made the geometric properties more obvious. Even though three of the four girls had enjoyed working with the geostrip model more than with the Cabri model, they all believed the Cabri model to be more useful than the geostrip model for finding out why the linkage worked. Significantly, perhaps, Ch — who had become quite excited by the converging traces of P and P’ (see Figure 4) — indicated that she had enjoyed the Cabri model more than the geostrip model.

The students’ use of Cabri was by no means restricted to dragging. The function of the pantograph led naturally to the use of the Cabri Trace facility, and transformation of the screen construction indicated where additional construction lines, for example, OP and OP’, might be useful. In other linkages explored by the students, tabulation of angle measurements was also used. The students’ prior familiarity with the features of Cabri was therefore an important aspect of their successful use of the Cabri linkage in helping them to produce their conjectures and construct proofs.

The ease with which they could trace the paths of points, add construction lines, and accurately measure angles and distances meant that the students made little attempt to return to the geostrip model after they had been given the Cabri model. Once the students were confident of their conjectures, they tended to work with paper and pencil diagrams during the proof construction. This was, however, not always the
case; the students worked with a number of linkages during the classroom research and with some of these they would sometimes go back to the physical linkage to check an observation they had made with the Cabri model, or return to the Cabri model while they were constructing their proof.

The students in the study described by Bartolini Bussi (1998) were required to produce their own geometric drawing of the linkage from the model and to provide a description from which another person could construct it. This resulted in the need to determine the structure of the linkage, for example, by measuring the lengths of the linkage bars. This was, of course, an important aspect of Bartolini Bussi’s project, which aimed to make these historic drawing instruments ‘transparent’ to students.

The Cabri model, on the other hand, provided a ready-made geometric figure, which allowed the students to focus more immediately on the functional relationships within the linkage, rather than its basic structural properties. This may have contributed to the ease with which these Year 8 students were able to present their statements in a logical order, compared with the initial difficulty experienced by the Year 11 students in the study described by Bartolini Bussi (1998).

It would seem, then, that the imagery, both static and dynamic, of the Cabri environment made a substantial contribution to the conjecturing process, but also challenged these students to produce an explanation. The features of dynamic geometry software — constructions based on Euclidean geometry, accurate measurements, the tracing of loci and the drag facility — make the software highly suitable for exploring the geometry of linkages. Rather than eliminating the need for proof, the convincing evidence and the unique opportunities for exploration and discovery which the software provided gave the students the confidence and desire to go ahead and prove their conjectures. However, the tactile experience and satisfaction of working with actual physical linkages may also represent a significant motivational aspect, at least for some students, and should not be over-looked.

ABOUT THE FLEXIBILITY OF THE MINUS SIGN IN SOLVING EQUATIONS

Joëlle Vlassis
University of Liège

ABSTRACT
Among the difficulties the students have in solving equations with negative numbers, the ‘detachment from the minus sign’ (Herscovics & Linchevski, 1991) and solving an equations such as \(-x = 7\) are often pointed out in the research literature. However, the study of their origin was not yet debated a lot. This article intends to propose an analysis of these difficulties. It reports results from a clinical study carried out with 8th grade students. The analyses stress that the presence of negative numbers in equations needs some level of flexibility in conceiving the minus sign that most students have not yet reached. They show that, beyond the equations and negative numbers, this lack of flexibility leads to an erroneous or superficial understanding of algebraic operations and symbolism.

INTRODUCTION
Many researchers showed that the presence of negative numbers in first degree equations with one unknown leads to several errors (Cortès, 1993, Gallardo & Rojano, 1994; Gallardo & Rojano, 1990; Herscovics & Linchevski, 1991; Vlassis 2001). Three obstacles are regularly pointed out by these authors and they thus seem to indicate major difficulties for students: (1) the avoidance of a negative solution (Gallardo & Rojano, 1990; Gallardo & Rojano, 1994; Glaeser, 1981; Vergnaud, 1989), (2) the ‘detachment from the minus sign’ (Herscovics & Linchevski, 1991; Linchevski & Herscovics, 1994; Vlassis 2001) and (3) solving an equation such as \(-x = a\) (Cortès, 1993; Gallardo & Rojano, 1994; Vergnaud, 1989; Vlassis, 2001). The difficulties raised by the negative solution of an equation have already been analysed (Gallardo & Rojano, 1990; Gallardo & Rojano, 1994; Vergnaud, 1989; Vlassis, 2001). However, whereas errors linked to ‘the detachment from the minus sign’ and those linked to solving ‘\(-x = a\)’ have been often mentioned, their origin has not yet been clearly established. Historical epistemological arguments are usually pointed out when negative numbers are involved. We think that this perspective has to be enlarged to other analyses in order to define more completely the origin of these obstacles. In this article, we intend to propose an original approach of the difficulties stemmed from the ‘detachment from the minus sign’ and the solving process of \(-x = a\). Problems associated with a negative solution to an equation will not be developed in this proposal. Our analyses are based on interviews of 18 students of the 8th grade. They show that beyond equations and negative numbers, those errors are due to a lack of flexibility in the conception of the operation signs, leading to a wrong or superficial understanding of the concepts involved in algebraic operations and symbolism.
We interviewed 18 students of the 8th grade level at the end of the school year. These students learnt elementary algebra (reduction of expressions, distributive law, ...), the solving of first degree equations with one unknown and the negative numbers during their 7th and 8th grades. These students came from two different schools, one of them recruiting in a favoured population (6 students), the other one in a non-favoured population (12 students). The student selection was based on test results. Here is the 18 students distribution: 4 students of good level (results in the 80% range); 6 students of middle level (in the 70% and 60% ranges); 4 students of low level (in the 50% and 40% ranges); 4 students of very low level (less than 40%). The students that obtained 90% and more were not interviewed.

The aim of the interview was to list and analyse students’ reasoning when they are confronted with negative numbers in solving ‘arithmetical’ and ‘non-arithmetical’ equations (Filloy and Rojano, 1989) and in the reduction of polynomial expressions. The interview also aimed at considering the students’ conceptions of mathematical objects and operation signs in an expression such as ‘-18a - 2y + 5a - y’. The students were invited to tick the negative numbers of the expression. They also had to say what the letter represented and to give some examples of numbers that could replace ‘y’ in -2y and -y, and ‘a’ in -18a and + 5a.

**THE DETACHMENT FROM THE MINUS SIGN**

**Results**

In 1991, Herscovics & Linchevski already stressed the following result: ‘The detachment from the minus sign was somewhat of a surprise to us. The high incidence of this mistake indicates that the problem is not idiosyncratic but may well reflect unsuspected cognitive obstacles.’ (p. 179). These authors defined that issue as ‘a tendency to ignore the minus sign preceding a number’. In their experiment, that error concerned the 7th grade pupils that had not yet received any algebra teaching As for our 18 interviewed students, they had been learning algebra for two years. However, ‘the detachment from the minus sign’ still remains often observed and raised the following errors:

1) *In solving an equation*

<table>
<thead>
<tr>
<th>Error (a)</th>
<th>Error (b)</th>
</tr>
</thead>
<tbody>
<tr>
<td>(2 - 3x + 6 = 2x + 18)</td>
<td>(2 - 3x + 6 = 2x + 18)</td>
</tr>
<tr>
<td>becomes</td>
<td>(-2x) becomes (-2x)</td>
</tr>
<tr>
<td>(3x + 8 = 2x + 18)</td>
<td>(2 - 1x + 6 = 18)</td>
</tr>
</tbody>
</table>

Eight students on the 18 are concerned by one or the other of these errors.

- In case (a), 4 students simplify the first member and copy it, forgetting the minus sign before 3x. Cortès (1993) also stressed the high incidence of that error. This one is mainly made by good-level students (3 of good level and 1 of middle level). Here is how Coralie explains her error:
1 Interviewer: Which error did you made here?
2 Coralie: h'm, ... it's -3x.
3 Interviewer: Why did you forget your minus sign before 3x?
4 Coralie: Because there was a number before it.
5 Interviewer: Yes, and what did you think so?
6 Coralie: I deleted the 2 and the 6. Then I looked at the 3x and I forgot the minus sign before.

In case (b), 4 students want to cancel -2x in each member and get 2 - 1x + 6 in the first member. This error is more typical of lower level students (2 of middle level, 2 of low level). The lowest students are not concerned since they did not begin any solving process. During the interviews, all the students who made that error explained that they removed 2x from 3x and that they obtained 1x. Then, three of them reintroduced the minus sign before 1x.

In both cases, the minus sign before a literal term is either completely forgotten (error a), or forgotten and then reintroduced (error b).

2) In the reduction of a polynomial expression

2.1. The following expression was presented to the students: -18a - 2y + 5a - y =

In order to simplify this expression, they had to group like terms. Four of them made a mistake when simplifying ‘y terms’. They made - (2y - y) = -y instead of -2y - y = -3y. The reasoning is related to error (b) in the equation solving: again, the students took in consideration 2y and not -2y. In this case, the operation sign was forgotten and then reintroduced since they obtained -y. The error consisting in forgetting the minus sign before the 18a did not appear. No student operated -18a + 5a = 23a nor -23a. One of my hypotheses about the error on the ‘y term’ was that moving terms, in order to group them, ‘made easier’ the omission of the minus sign before 2y. Obviously, in order to solve the equation as well as to reduce the expression, it was needed to ‘build’ a new expression with the like terms (-3x - 2x in the equation and -2y - y in the expression).

2.2 In order to check that hypothesis, the following expression was proposed to the students: ‘-24b + 4b - 6a - 2a =’

I thought that, since it was not needed to change the place of the like terms, the error consisting in ‘forgetting’ the minus sign would appear less regularly. In such a case, in my opinion, the error consisting in operating 6a - 2a rather than -6a -2a should have appeared less regularly. I was disappointed. Five of the students simplified the terms -6a and -2a in -4a. The explanations were the same for the 5 students: ‘I made 6a - 2a, that is 4a, and then, as there was a minus sign, I put it back before’. Again, the students concerned by this error are not the lowest ones. Here is their distribution: 1 is good level, 3 are middle-level and only 1 is low level. The error consisting in forgetting the minus sign before b was made by only 1 student, who obtained -28b for -24b + 4b.
Comments : from arithmetic operations to a combination of signed entities.

I was quite surprised by those results because, on the one hand, the ‘detachment from the minus sign’ concerns students of various competence levels, and not only low-level students. On the other hand, it is important to note that the students do not understand easily their error. Some of them, even among those of good level, did not see why I underlined an error in the first member of their equation when they wrote : 2 - 1x + 6. I had thus to re-formulate the operation like this : ‘-3x - 2x is -1x ?’, and to insist on the minus signs to make them finally become aware of their error. And even in this case, it was really very difficult for some of them to admit that -3x -2x produced -5x and not -1x. Those results made emerge three main analyses :

1) The students do not always forget the minus sign

The ‘detachment from the minus sign’ could be assimilated to ‘an avoidance syntome’. Gallardo and Rojano (1990) already stressed on that difficulty in solving equations. A link could be established between that students’ error and the historical development of the negative number where, at a given moment, scientists used some processes to avoid the obstacle of negative numbers (Glaeser, 1981). The ‘avoidance syntome’ actually exists by students (in the interviews, I could observe that equations such as 4 - x = 5 were modified into x = 5 - 4) and could explain errors such as the omission of the minus sign when copying a simplified equation (error (a) in equation solving). The results nevertheless show that not all the students forget the minus sign. On the contrary, most of them put it aside to make their operations, and then reintroduce it. Some students even tell us they put the expression between brackets and copy the minus sign before the answer they found. I would thus slightly qualify the Linchevski and Herscovics’s definition (1991), adding that this error consists in ignoring or temporarily omitting the minus sign preceding a number or a literal term.

2) Moreover, the omitted minus sign is not any minus sign.

The omitted minus sign is located in the expression, before a number or a literal term. Coralie explains (line 4 of the interview here above), that what disturbs her is the number before the sign. The minus appearing in the beginning of the expression, such as in the expression -18a -2y + 5a - y is not or almost not omitted by the students. Another example of that difficulty can be found in the question about the mathematical objects of the expression -18a -2y + 5a - y. When the students have to tick the negative numbers of the expression, almost all the students tick -18a, but -2y and -y are ticked more randomly. For the students I interviewed, the term -18a is the ‘prototype’ of a negative number and cannot be considered the same as -2y and -y. The minus signs in the middle of the expressions have an double status : they have to be considered like operation signs (‘subtraction’ level of Gallardo, 1994) and like signs attached to the number (‘signed number’ level of Gallardo, 1994). The difficulty does not depend on reaching one or the other level of conceptualisation, but rather on being able to go to one or to the other, according to the situation. The students that omit the minus sign do not consider that duality. On the contrary, they
seem to keep an arithmetical and inflexible conception and do only consider the minus sign inside the expressions as the symbol of subtraction. This can explain why some of them put it aside in order to operate (it is the symbol of subtraction and it is thus not attached to the literal term), and then re-introduce it, once the operations are made.

3) The meaning of the operations changed

The introduction of negative numbers in algebraic expressions undoubtedly leads to another conception of the operations. In primary school, the students are used to operate on concrete entities, which means without signs, they have to subtract or add up. In expressions involving positive numbers, the students can keep most of that operation conception. For instance, in the expression $5b + 3c + 2b + 4c =$, the plus signs can be seen only as operation signs. The students can then add up the ‘b terms’ and the ‘c terms’ which are seen as objects without sign. With negative numbers, that perspective isn’t possible anymore. The students cannot consider anymore the operations as a set of numbers without signs (about numbers with and without signs, see Vergnaud, 1989) that have to be subtracted or added up. The duality of the operation signs implies to consider the expressions as a combination of signed entities, i.e. as ‘-18a followed by -2y, by +5a and by -y’. That notion requires a deep understanding of these mathematical objects. Signs need to be considered as attached to every term while acting also as operator. But, when it is needed to make the operations, the meaning of addition and subtraction is modified and becomes abstract. The first concrete arithmetical representations becomes then an obstacle to that evolution because, when it is about simplifying $-3x - 2x$, for example, the result (-5x) seems to be that of an addition (that of 3x and that of 2x). This perhaps explains one of the difficulties faced by the students. During the interviews, Julie (a middle-level student) helped me to think in that sense. When she understood her error ($-3x - 2x$ is not $-1x$) and gave the correct answer (-5x), I was trying to make her say she had forgotten the minus sign before 3x.

Interviewer: What did you forget while making $3x - 2x$? (expected answer: the “minus” before 3x)

Julie: to add them up.

I did not understand immediately what she meant. As to me, I did not see where it was about adding up. In fact, each of us referred to two distinct models. Julie was reasoning in very concrete terms, linked to her first arithmetic learning (if $-3x - 2x = -5x$, it is just like an addition); as to me, I referred to the model of the number line. It is possible that, for some students, the answer $-5x$ is counter-intuitive, even if preceded by the minus sign. The meaning of the subtraction is still related to elementary arithmetic (the operation must produce a smaller result). The reference to the number line does not seem to be a conceptual instrument for these students, even though they have experimented that model during their learning of algebra.
Another example of the students’ lack of flexibility about the minus sign was pointed out when solving the equation \(-x = 7\): many students made a confusion between the minus sign before the \(x\) and that of the solution \(-7\). The difficulties in solving that kind of equation have already been underlined by Cortès (1993), Gallardo and Rojano (1994), Vergnaud (1989) and Vlassis (2001). Vergnaud (1989) thinks that difficulty comes from the negative solution. I do not think the explanation is mostly based on the negative value of the solution. Without denying the obstacle related to a negative solution, it is shown that other equations produced the same type of solution but didn’t present so much problems to the students. According to Gallardo and Rojano (1994), the problem is that the students don’t decode \(-x = 7\) as \(-1x = 7\). Our analyses also show that students do not interpret the equation in that way. We did not find out any explanation of that kind in our interviews. It seems that this formulation is difficult to be understood by students at that school level (Vlassis, 2001). It does not represent, however, the only possible way of solving.

**Results**

A major part of the issue seems to come from the ambiguity of the minus sign before the \(x\). Among the 15 students who solved the equation, five of them gave 7 as the answer of the equation and 10 gave the correct answer. The students who gave 7 as the solution were not able to consider \(-7\) as the solution since the minus sign was already noted. But the most interesting analyses come from the students who gave the correct answer. I first asked them to explain how they had found their solution. Here are the types of answers I obtained: (a) the value of \(x\) is 7 and, since there is a minus sign before, I added it up (2 students). (b) I transferred the minus sign to the other member (5 students). (c) The value of \(x\) is \(-7\) since, when I put \(-7\) instead of, I get \(-(-7) = 7\) (2 students). (d) I took the opposite (1 student). Seven of the 10 students justify their answer only on basis of algebraic rules - true or invented- (answers a and b). When I asked to these students to explain me more about the method they follow, they told me it was just like that, that it was a trick in algebra. Thus I invited the 10 students to check their solution. All the students, but the two who had done it spontaneously, were perturbed by my question. Most of them did not understand what I wanted. When I reminded them that the solution of an equation is checked by replacing the letter by its numerical value, some of them thought their answer was wrong: ‘If I replace \(x\) by \(-7\), I get \(-7 = 7\), which is not correct, so my answer is wrong’. It turned out to be quite difficult to make them understand that the minus sign before the \(x\) was not the same as that which was attached to the \(7\) of the solution and to make them copy the equation again, replacing the \(x\) by \(-7\).

**Obstacles to solving \(-x = 7\)**

The difficulty in solving this equation is due to the multiplicity of concepts it covers:

- First, the students must be able to detach the minus sign from the letter \(x\). They must consider the sign attached to the numerical value of the letter, *independently* from the sign attached to the letter. The students’ answers show it is an obstacle.
quite difficult to overcome. It seems that -x is considered as a ‘prototype’ of a negative number (as well as -18a) and that they see -x in an inflexible way, as a ‘signed number’. Another example of that difficulty appeared during the discussion about the expression -18a - 2y + 5a - y. When the students had to decide whether the letter y of -2y could replace a positive number, a negative number, or both, most of them answered without hesitation a negative number. Only one student told me it was not possible to answer the question because he did not know whether the letters replaced negative or positive numbers. Finally, when the students were asked to give examples of numbers that could be replaced by y, they gave examples of positive numbers, without looking disturbed by the apparent contradiction of their reasoning. I then asked whether ‘y’ could replace, for instance, -6. The answer given by a large half of them was ‘No, since the minus sign is already wrote’.

- The students must be able to enlarge their notion of ‘signed number’, but also to juggle with high levels of conceptualisation of negative numbers (Gallardo, 1994): that of ‘isolated number’ (the solution is a negative number), that of the formal conception of a ‘negative number’ (a letter replaces a number: the negative numbers are part of the numbers that could be replaced by a letter). The ‘relative number’ level (the opposite) is not compulsory but it rather represents a way to give sense to the equation.

- Decoding -x = 7 in -1. x = 7 seems to be a problem because it needs not only to detach the minus sign from x, but also to attach it to a “hidden” number (number 1) and to consider the presence of an operation (that of a multiplication), whereas a lot of students still just see a number in -x. It seems that such decoding of the implicit imbedded in the algebraic symbolism is out of sight for numerous students of that school level.

CONCLUSION AND FINAL DISCUSSION

The analyses presented in this article show that the presence of negative numbers in the equations causes some errors with various origins: they are related, not only to negative numbers and equations, but also to essential algebraic concepts. These difficulties appear indeed as an expression of a lack of understanding of the concepts involved in the algebraic operations and symbolism. The ‘detachment from the minus sign’ is performed by students that are not aware of the duality of the minus sign in algebraic expressions: they always consider these expressions as operations performed on numbers without signs. To give some meaning to the reduction of these expressions, they must be able to consider them as a combination of signed entities. This ability needs not only some flexibility in the meaning given to operation signs that are both attached to every term and operation sign, but also an abstract vision of subtraction and addition. That flexibility of the minus sign is also required to solve significantly an equation such as -x = 7. The minus sign in the initial equation is the sign attached to the letter x, but it is not attached to the value of x, which can be itself
positive or negative. Students meet some significant difficulties at that level. Even those who find the correct answer explain it with algebraic rules and are not able to re-write the equation, replacing x by its value -7. The minus sign before the solution -7 is very often mistaken with the minus sign attached to x. We can conclude that the students’ expertise doesn’t consist only in reaching such or such level of conceptualisation of the negative numbers, but also in being able to adapt this level to the situation. It also seems that a part of those difficulties is linked to a pseudo-structural notion of algebraic expressions, as think Sfard and Linchevski (1994, p. 222). « Students acted as if they were handling some kind of objects, but their thinking was completely inflexible and the appropriate kind of structural interpretation was unavailable... The majority of pupils could not provide any sensible justification for the permissible operations and it was obvious that for them these were no more than arbitrary « rules of the game »

References

A performance assessment for grade 8 students was administered in the Netherlands in 1995. The test consisted of practical, investigative tasks. Dutch curriculum experts considered this test to fit well with the Dutch mathematics curriculum, which is based on Realistic Mathematics Education (RME). However, Dutch students scored lower than expected on this practical test. This result demanded follow-up research. Therefore, the performance assessment was repeated in the Netherlands, in 2000. Trend data (1995-2000) show that the achievements of Dutch students show little gain. Also, the research gave new evidence on issues pertaining to reliability and comparability in practical tests.

INNOVATING ASSESSMENT IN MATHEMATICS

When measuring student achievement in mathematics for a large population, in many cases, paper-and-pencil tests have been developed and issued to students. Especially, multiple-choice items have been popular because of automated scoring and their presumed high reliability. Yet, this method for measuring student achievement has come under debate, especially with respect to multiple-choice questions. These are associated with low-valued factual knowledge, asking for limited thinking processes. Assessment methods have been altered, although it proves difficult to break with traditions and find valid and reliable alternatives. The labels used for innovated assessment are for example: performance assessment, practical assessment, alternative assessment, and authentic assessment (see e.g. Burton, 1996; Clarke, 1996; Niss, 1993; Wiggins, 1989). The descriptions show considerable overlap and the terminology applies if some of the following criteria are met:

- testing through open questions and for higher order skills,
- being open to a range of methods or approaches,
- making students disclose their own understanding,
- allowing students to undertake practical work,
- asking for performances and products,
- being as an activity worthwhile for students' learning, and
- integrating real-life situations and several subjects.

To assess student achievement, the used formats can be portfolio, observation, interview, and so forth. But in large-scale testing, these formats can be too labour-intensive. Baxter & Shavelson (1994) compared the exchangeability of different
assessment methods. These were observation, notebook reports, computer simulation, short answer questions and multiple-choice questions. They found that observation yielded most detailed information on the achievement, with notebook reports providing a reasonable "surrogate". All other tests failed to approximate the same information.

An example of a large-scale study attempting to realise an innovation in assessment is the TIMSS Performance Assessment. In 1995, this test was optional within TIMSS (Third International Mathematics and Science Study), the international, comparative study. In TIMSS, a test is developed and translated into different languages and then issued to students of different nations, in order to compare their achievements internationally. Within TIMSS, in 1995, two different tests were available. Besides a standard written test, a practical test with hands-on items was developed. The practical investigative tasks of this Performance Assessment were considered to complement the written test with a higher focus on practical skills and a lower focus on knowledge reproduction. This practical test was developed from the educational vision that seeks coherence between procedural, declarational and conditional cognition. Students are expected to investigate systematically, contrary to cookbook-demonstrations. Being provided with manipulatives and instruments, they are tested through open tasks like: designing and executing an experiment, observing and describing their observations, using calculators, looking for regularities, finding notations and interpretations of their measurements, etc. The TIMSS Performance Assessment can be associated with Gal'perin's view of learning by doing in which mental acts (manipulating objects in the mind) develop from material acts (manipulating tangible objects) (Van Dormolen, 1993). Though, in the assessment, manipulatives and instruments are not seen as mere demonstrators of taught concepts. They are integrated into the assessment to trigger investigative activities (Harmon et al., 1997; Garden, 1999).

**TASKS OF THE TIMSS PERFORMANCE ASSESSMENT**

The TIMSS Performance Assessment is administered in a circuit format in which students take turns in visiting stations. At each station they find a task, which guides them to carry out a small investigation. They write their answers on a worksheet. There are mathematics tasks, science tasks or combined tasks (overlapping between science and mathematics). There are five tasks with a clear mathematical focus:
- The task *Dice* is related to probability: students are given a die and a transformation rule for each throw (even: plus 2, odd: minus 1). They are asked to throw 30 times, record their findings and explain why one result (the “4”) has a higher frequency.

- The task *Calculator* is related to number sense: students are given a simple calculator and are asked to discover a pattern in the multiplications of 34x34, 334x334 and 3334x3334. As the calculator holds only eight positions in the display, this is not an obvious task. The second part of the task consists of factorising 455 into two integers between 10 and 50.

- The task *Folding* is related to symmetry and spatial abilities: students have to make certain required figures by cutting, using a pair of scissors. Because only one cut is allowed for each figure, the paper has to be folded.

- The task *Around the bend* (see Figure 1) is related to scale drawing and finding rules: students are given a cardboard model of a corridor and have to cut rectangles (modelling furniture). By testing which rectangle fits through the corridor, they have to find a rule for the critical lengths.

- The task *Packaging* is related to measuring and the design of nets: students are given four table tennis balls and have to design different boxes for these.

Besides tasks with a mathematical focus, the test also contains tasks from biology, chemistry and physics. In these tasks, science investigations meet with mathematical activities, as students have to measure using instruments (using stopwatches, rulers, thermometers, and scales). But other mathematical activities are also required. For example, the task *Rubber Band* covers the topic of extrapolation. In this task, a number of washers are attached to a rubber band. Students have to measure the stretching of the band, related to the number of washers. With only ten washers given, students are asked to predict the length of the rubber band, if twelve washers were attached. Another task, named *Shadows*, is related to geometrical transformations. Students are given a torch, a card and a white screen. They have to project a shadow, which is twice as wide as the object, and find a rule for the distances between torch, card and screen. Finally, the task *Plasticine* asks for problem solving heuristics. Students are provided with a two-sided (uncalibrated) balance, two weights (20g and 50g) and a lump of plasticine. They are asked to make smart combinations in order to produce pieces of plasticine of 10g, 15g and 35g. Details of all tasks can be looked up in Harmon et al. (1997).

### THE TIMSS PERFORMANCE ASSESSMENT IN THE NETHERLANDS

In 1995, the Netherlands participated in TIMSS for grade 8, both with the standard written test and the practical test. This was not without debate, as the mathematics curriculum in the Netherlands differs from the mathematics curriculum in many other countries. The Dutch mathematics curriculum is based on the principles of Realistic Mathematics Education (Freudenthal, 1975; De Lange, 1983). Dutch students learn mathematics starting from real-life contexts. Also in assessment, each test item has a
theme like transport, retail prices, or sports. Each mathematics test item has narrative texts explaining the context. The mathematical tasks are embedded into the theme.

Objections to participating in an international comparative study pertained to the validity of the comparison: if Dutch students had learnt mathematics through a different approach, they would not be able to show their particular competencies. From the RME-point of view, the written TIMSS test was too traditional and therefore, results based on it were not authoritative (Bos & Vos, 2000; Kuiper, Bos & Plomp, 1997). On the other hand, Dutch mathematics curriculum experts valued the additional test, the TIMSS Performance Assessment. It was considered to match well with the intentions of the Dutch curriculum. Instead of narrated contexts, students would now apply their mathematical skills in tangible contexts.

DUTCH STUDENTS' RESULTS IN TIMSS-1995

In 1995, 18 countries participated in both the written TIMSS test and in the TIMSS Performance Assessment for grade 8. Most countries reached a position in the international comparison on the practical Performance Assessment, which had a comparable ranking to the position in the standard written test. If a country ranked high on the league-table of one test, it would rank high on the other test. But the Netherlands was a marked exception here. Despite the fit of the TIMSS Performance Assessment with the Dutch intended mathematics curriculum, Dutch grade 8 students did not score as expected. Unlike on the written test, their achievement was at the level of the international average and not significantly above.

Therefore, an understanding of Dutch students' achievements was needed. Maybe, TIMSS in 1995 had come too early. The new RME-based curriculum was only introduced in 1993. At some schools the textbooks had not yet been replaced. And maybe teachers had not yet had time enough to adopt their instruction to the new curriculum. Thus, if the TIMSS Performance Assessment could be replicated at a later stage, trend data could establish whether the new curriculum was starting to settle. The repeat of the TIMSS Performance Assessment was planned for 2000. Unfortunately no other countries were interested in participating.

DESIGN OF THE STUDY AND RELIABILITY ISSUES

The TIMSS Performance Assessment was repeated by copying all international TIMSS protocols of 1995 (see Harmon et al., 1997; Garden, 1998). A two-stage stratified sample of 50 schools was drawn. The instruments of 1995 were re-used. The science tasks were maintained because of their mathematical aspects and to maintain the task-interaction effects during testing. For 2000, a sample of n=234 students at 27 schools was realised. This response of 54% is good according to Dutch standards. In 1995, with more funds being available, withdrawing schools had been replaced, resulting in n=437 students at 48 schools being tested.
Also for coding of students' answers, the 1995 procedures were followed. But this proved to be an ambiguous task. As already pointed out in the international 1995 TIMSS Performance Assessment report (Harmon et al., 1997), inter-scorer agreement can vary considerably. As a check on coding, two independent coders coded 10% of students’ work. In the extreme case of one sub-item in the task Shadows, the Dutch coders only agreed in 52% of the cases on the correctness of students’ work. As Zukovsky (1999) has pointed out, the coding of answers is conditional to the coders' background (e.g. coding experience, subject matter knowledge, teaching experience, etc). Some tasks showed such a low inter-scorer agreement that the results had to be doubted.

In another case, with the task Rubber Band, the protocol did not cover a strategy that was used by a considerable number of Dutch students. In this task the students had to measure and record the stretching of the rubber band with each washer. The result would yield an irregularly increasing graph (growing with 2-5 mm per washer) with slightly diminishing growth. But approximately 10% of Dutch students did not measure. Instead, they drew a graph that grew consistently with exactly 5 mm per washer. Their graph was a perfect straight line. There was no appropriate code for this styling strategy (a heuristics which reduces realism from the onset). Depending on the interpretation of the scheme, a coder could either give full or no credit.

Comparability of testing circumstances of some tasks in the Performance Assessment proved problematic. Although test instruments of 1995 were copied in 2000, there were minimal mutations in the laboratory equipment. These mutations were within the narrow range that the international protocol allowed. One example will illustrate the effect. In the task Shadows a torch is used. The torch used in 1995 gave a vaguer shadow, while the torch of 2000 gave a sharper edge to the shadow. The latter made student's measurements easier giving them more time for remaining items in the task.

To eliminate unreliable and incomparable results, two tests were carried out. First, for each task, Cronbach's alpha was calculated for 1995 and 2000 separately. Results higher than 0.6 were considered acceptable. Second, a chi-squared test was carried out, revealing that answer patterns differed because of altered testing circumstances. As a result, four science tasks (Magnets, Rubber band, Shadows and Plasticine) had to be eliminated from analysis. Fortunately, the five mathematics tasks passed these tests.

Based on these five mathematics tasks, the initial Dutch agitation about the disappointing test results dwindled. In the international reports, the results of the task Plasticine had been included into the Mathematics league table. This task had been pulling down the overall results of Dutch students. Omission of the unreliable results raised the Dutch position above the international average. Table 1 shows the results in TIMSS 1995 of the 19 countries that participated both in the standard written test and in the TIMSS performance Assessment. The first column shows the mathematics results of the TIMSS written test. The second column shows the results on the
TIMSS Performance Assessment as presented in the international TIMSS report. This average score is based on five mathematics tasks *Dice, Calculator, Folding, Around the bend* and *Packaging* plus the combined task *Plasticine* (Harmon et al., 1997). The third column shows the results based on the five mathematics tasks only. The position of the Netherlands in each league-table is indicated in grey. As can be seen in the two columns for the Performance Assessment, the average scores of each country do not change much after deletion of the *Plasticine* task. The difference between the average scores of a country is at most 2% (with the exception of the Netherlands: +3, and Iran: -6). In fact, the correlation of the two scores at country level is $r=0.97$ (n=19). Yet, the position in the league-table can vary considerably, because of the large number of countries with only slight differences in their scores. The positions of countries with ranking 2 up to 13 are based on scores that are very close. Therefore, it can be concluded, that the test in itself is robust (the average scores do not change much after deleting of a task). Yet, the presentation in a league-table is misleading because differences between almost equal scores are enlarged as average scores (on a continuous scale) are being transformed into a ranking (on a discrete scale).

Table 1: Ranking of 19 countries in 1995 on two TIMSS mathematics tests.

RESEARCH RESULTS FOR THE REPEAT STUDY

By repeating the study, a trend in the achievement of Dutch students could be established. The resulting scores are given in Table 2. For each task the average percentage of correct scores on the items was calculated.

Compared to 1995, the scores do not show any significant changes on the five mathematics tasks. The average score correct of 66 on these tasks in 1995 does not differ significantly from the average score of 67 in 2000. Also, on each task separately, the shifts were statistically insignificant.

These results show that Dutch students have not gained in practical, investigational skills. This could be caused by the classroom practice, in which they never encounter hands-on tasks like the ones in the TIMSS Performance Assessment. Students told us, during testing, that they had never done this before. Still, the tasks match well with the intended Dutch curriculum. But the testing practice has stuck with a paper-and-pencil format in which students have to read the texts in which real-life contexts are described. Tangible real-life contexts with manipulatives are habitually not utilised in Dutch testing. However, as an additional result, the TIMSS Performance Assessment proved to be an eye-opener to many Dutch mathematics teachers. During the testing sessions, they observed the tasks and how their students coped with these. Some teachers admitted that they had never thought mathematics could be tested in this way, through a mathematical practical test. As such, the TIMSS Performance Assessment could prove to be part of the exemplary material that is needed to support curriculum reform (Fullan, 1991).

CONCLUSION

The TIMSS Performance Assessment clearly has potentials in monitoring students’ mathematical investigation skills. It is a valid addition to standard, paper-and-pencil tests. It also shows, that manipulatives are useful to organise time-restricted hands-on tasks in mathematics, linking mathematics to other areas. Still, much more experience is needed when it comes to reliability and comparability issues.

TEACHER HEARING STUDENTS

Tali Wallach  Ruhama Even

Weizmann Institute of Science & Achva College  Weizmann Institute of Science

This study examines elementary school teachers' "hearing" students, i.e., understanding what they are saying, showing, feeling and doing. In the larger study there are 25 elementary school teachers who participated in a weekly four-month long inservice workshop. In this paper we analyze the case of Ruth. We identify four types of teacher interpretations of students' talk and action: describing, explaining, criticism and justifying. We illustrate the nature of hearing characteristics, and examine two possible sources for Ruth's overhearing and under-hearing.

INTRODUCTION

It is widely accepted today that teachers should be aware of and knowledgeable about their students' thinking and understanding in order to make appropriate decisions for helping and guiding students in their knowledge construction (e.g. Ball, 1997; Even & Tirosh, in press; NCTM, 1991; Shulman, 1986). Teachers who understand where students are can challenge and extend their thinking; respond to their questions, remarks and ideas in meaningful ways; conduct discussions; promote discourse; and modify or develop appropriate activities for them.

However, assessing students' knowledge, understandings and ways of knowing, learning and thinking is not an easy task. Understanding what students are saying, showing, feeling and doing—what Ball (1997) calls "hearing students"—is complex. Teacher interpretations of students' talk and action are closely connected to cognitive, social and affective aspects. For example, to teachers' own ways of understanding the subject matter and their commitment to students (Ball, 1997).

Currently, research that explores teacher "hearing" students is scarce. The study reported in this article is an initial investigation of this issue. It is part of a larger study that examines elementary school teachers' interpretations of students' talk and action when students are engaged in mathematics problem solving. In this paper we focus on Ruth's (pseudonym) hearing two of her students. We analyze her interpretations of the students' work and their ways of thinking, both with regard to the nature of the interpretations and to their possible sources.

DESCRIPTION OF THE STUDY

Participants

There are 25 elementary school teachers from several schools in a southern town in Israel in the large study. The teachers participated in a weekly four-month long inservice workshop, led by the first author at a regional teacher center. The group was heterogeneous with regard to the grade level taught, teaching experience and age. Most of the teachers were teacher-college graduates, and so was Ruth, the teacher who is the focus of this paper. Ruth had 11 years of teaching experience in
elementary upper grades. In the year of the study she taught in fourth grade. Like most elementary school teachers in Israel, she taught all subjects, among them mathematics.

The workshop

The workshop’s main component centered on work on several mathematics problems taken from Wallach and Regev (1999). The main characteristics of these problems, as indicated by a field-test conducted with elementary school students, are: challenging; require long time to solve; facilitate different ways and different strategies of solving; do not have an immediate solution; encourage mathematical thinking such as: reasoning, conjecturing, explaining, justifying, etc.; encourage cooperative work and discussions; integrate different mathematical topics and concepts from the school curriculum and encourage reflective thinking.

At the beginning of the workshop, the participating teachers were introduced to these problems. They solved several problems and then discussed their solutions in small groups. Later, each teacher chose one of the problems and presented it to a pair of students from her own class. The teachers observed and videotaped the students working on the solution of the problem. The teachers were instructed not to intervene by suggesting comments, hints or advice to the students. Then, each teacher summarized and reflected on her observation in writing and met with the workshop leader to discuss her interpretations of the students’ work and ways of thinking while focusing on one episode from the students’ video-tape chosen by the teacher.

Data collection

Data collection includes:

- Observations of all workshop sessions. The sessions were video-recorded. The first author kept a journal where she documented her ideas and reflections after each session.

- Written work prepared by the teachers, such as reflections on their students’ problem solving.

- Videotapes of the pairs of students’ problem solving sessions.

- Individual interviews conducted with each teacher for about 45 minutes. These interviews centered on one episode that the teacher chose from the videotape of her students.

- Focus-group interviews were conducted twice. Once at the beginning of the workshop to discuss the teachers’ own solutions of the mathematics problems and how they expect their students to solve them (about one hour). Another focus-group interview was conducted toward the end of the workshop to discuss the work of an unfamiliar pair of students who worked on the same problem that the teachers chose for their students (about one hour).
Data analysis

The analysis is based on the Grounded Theory method (Glaser & Strauss, 1967). We code the data using utterances as the unit of analysis and generate initial categories. We constantly compare new data with current categories, refine them and identify core categories, looking for integration and hierarchy among the categories, and using them as source for theoretical constructs.

RUTH’S HEARING AND INTERPRETATIONS

The “Shirts and Numbers” problem

After solving several problems at the workshop, Ruth chose to present two of her fourth grade students—Sigal and Ore—with the “Shirts and Numbers” problem (Figure 1). This problem deals with sport-team players who wear numbered shirts. The students are asked to divide the team into two groups, according to different criteria that are indicated in the problem. For example, in one part of the problem, they are asked to divide a team of 15 players so that in one group there are 5 players less than in the other group. In another part, they are asked to divide a team of 12 players so that in one group there is one half of the number of players in the second group. The part of the problem, on which Ruth chose to focus at her individual interview, deals with a task that has no solution, as is described below:

*********************************************************************
The task in front of you does not have a solution.
Divide a team of 15 players, so that in one group there are 4 players less than in the other group.

a) Explain why such a division is impossible:

b) Change the number of players, so that there will be a solution.
Demonstrate the solution:

*********************************************************************

Figure 1. The “Shirts and Numbers” problem
Sigal and Ore’s solution

The video recording of the students’ work on the problem shows that immediately after reading the instructions Sigal says: “Because the number 15 is odd and the number 4 is even, then it’s impossible”. Then Sigal and Ore start trying to change the number of the team’s players. During about three minutes they try to find a suitable number by thinking, reading again the problem and examining different divisions of the shirts that are drawn on their worksheet. Sigal and Ore suggest the numbers 16 and 12, but do not pursue these possibilities. After three more minutes of trying to find two groups that would satisfy the conditions, Sigal says: “Here are seven children [Ore confirms by saying “yes”], and here are three [pointing to the appropriate places on the worksheet drawing, see Figure 1]...Up to here it’s seven. And three, so it’s ten [players]. Four, seven minus four is three. Then here it is. Here are four children [players] less. Do you understand? [Sigal asks Ore] so ten children [players]”. They both agree on ten players divided into one group of seven and one of three players. They make appropriate drawings on their worksheets. Below (Figure 2) is Sigal’s drawing:

![Figure 2. Sigal’s drawing](image)

Ruth’s types of interpretation

We identified four types in Ruth’s interpretations of Sigal and Ore’s talk and action: Describing, Explaining, Criticism and Justifying. Following is an elaboration of each.

- Describing—the teacher describes students’ talk and action by direct (or almost direct) “quotation” or portrayal.

- Explaining—the teacher explains students’ talk or action. This includes ideas about students’ thoughts, reasoning, knowledge, and assumptions. The explanation is the meaning the teacher attributes to students’ talks and actions.

- Criticism—the teacher criticizes students’ talk and action, based on the “Meaning” she assigns to them.

- Justifying—the teacher justifies her criticism of, or the meaning she attributes to, students’ talk and action. This type of interpretation is different from the other three types, because here the teacher reflects on her own interpretation and not on the students’ talk and action.
The following two excerpts from Ruth’s interview illustrate these different types of interpretations. The first excerpt demonstrates the first three, and the second excerpt demonstrates the last two types.

First excerpt:

Teacher: She says, let’s take 4, she marked 4. Now she wants to divide it by 2 (Describing). Because she forgot that it is impossible with an odd number (Explaining). She forgot again. She tried to counterbalance the 4 (Explaining). This is not a method at all (Criticism).

Second excerpt:

Teacher: They got mixed-up when working on this (Criticism).
Interviewer: What would you expect them to do?
Teacher: Frankly, I expected them to work more, a lot faster and a lot more easily (Justifying).

**Ruth’s hearing her students**

Ruth’s interpretations of Sigal and Ore’s talk and action are reflections of her hearing Sigal and Ore, of her understanding what they are saying, showing, feeling and doing. Below we illustrate the complexity of hearing students, what might be entailed in interpreting students’ talk and action, and suggest possible sources for Ruth’s hearing.

**Overhearing.** We start with an example that portrays how even the relatively simple type of interpretation—describing—is not as simple as might first meet the eye. When Sigal and Ore attempted to solve the “Shirts and Players” problem, Sigal said, “Because the number 15 is odd and the number 4 is even, then it’s impossible”. Before we look at Ruth’s interpretation, let us examine this statement. What does Sigal mean?

One possible interpretation is that Sigal knows that to solve the problem she can remove 4 players from the entire team and then divide the reminder players into two equal size groups. Finally, adding the four players to one of the groups would give the solution of the problem. However, Sigal understands that in this specific case the partition is impossible because 15 is odd, and when she subtracts 4 from 15 the difference is 11, which is an odd number, and an odd number cannot be divided by two. Consequently, Sigal claims: “it’s impossible”. It might even be that Sigal understands the generalization of this method, that the partition is possible only when the number of the players is even. Because only in this case the removal of 4 players would leave an even number of players, which can then be divided into two equal size groups.

Another possible interpretation is that Sigal knows that the partition is impossible because this is stated in the text “The task in front of you does not have a solution”. She also knows and identifies that 15 is odd and 4 is even. So she connects these two
pieces of information, and without any logical argument states that “15 is odd, 4 is even, then it’s impossible”. Of course, there may be other possible interpretations.

Let us examine now Ruth’s interpretation of Sigal’s statement. During the interview, on two different occasions, Ruth “quotes” Sigal’s explanation (Describing type) as “...If you take away an even number from an odd number, you are left with an odd number, which you cannot divide by 2”. In another occasion she says “They said: Oh, for sure it’s impossible. Odd minus even, it’s impossible to divide it by two”. However, Sigal did not say all that. She refers only to the two numbers, 15 and 4 and indicates that they are odd and even respectively. She does not mention any operation on these numbers or on the difference between them. Still, what Ruth hears is different. Ruth hears Sigal talking in generalizations, without mentioning any specific number. She hears her discussing odd and even numbers, the difference between an even number and an odd number, and of its divisibility by 2. Even when the interviewer tries to shake Ruth’s confidence about her interpretation and asks: “Perhaps here Sigal did not understand what you think that she understood” Ruth remains confident and responds without hesitation “Then what, she just said it? Like a parrot?” and “It seemed to me real understanding”.

This short episode illustrates that Ruth “hears” things that were not said by the students. We define this characteristic over-hearing. Interestingly, such over-hearing is reflected even in the relatively simple type of interpretation—describing—which naturally would be expected to be an accurate duplicate of what the students said. The discrepancy between what students say or mean and what the teacher hears could be significant to teacher decision-making.

Under-hearing. When later Sigal suggests the solution of 10 players, Ruth does not seem to believe that there is any substantial reasoning underlying this solution. Several times throughout the interview Ruth is asked to explain how the students reached this solution. Her responses (Explaining type) did not focus on the students’ reasoning. For example, “The solution just came out of the blue”, or “She just said 10 off the top of her head”. On another occasion Ruth says: “Suddenly, she had a flash of the 3 and the 7. OK, 10 shirts [players]... Fine, she got it, she reached an even number” or “It seems to me that she just got it”. These explanations do not seem to get into the details of the students’ reasoning. Ruth does not refer to the process in which Sigal builds the two groups, by circling first 4 shirts followed by creating two groups accompanied with her explanation: “Here are 7 players and here are 3 [pause] so [pause] 10 players. 7 and 3 makes 10. And 7 minus 3 is 4, so 10 players”. Ruth “ignores” some of the things said or done by the students. We define this characteristic as under-hearing.

**SOURCES OF RUTH’S HEARING**

Why does Ruth “hear” what was not said or done by the students? Why does she “mishear” what was said or done by them? Possible sources of teacher hearing their students are teacher own knowledge of mathematics, conception of the solution of
the problem at stake, beliefs about the nature of mathematics learning and knowing, understanding of the nature of mathematics teaching, disposition towards the teacher role, and so on. In the following we analyze Ruth’s concern for her students’ success and Ruth’s own conception of the solution to the “Shirts and Numbers” problem. Then we examine the possibility of explaining Ruth’s hearing Sigal and Ore on the basis of these two sources.

Ruth’s concern for her students’ success
Throughout the interview Ruth expresses clearly her desire to see Sigal and Ore succeed in solving the problem. While watching the video-recording of them working, she looks happy and satisfied when they say what she considered as good and upset and disappointed when it seems to her that they are not on the right track. She says, for example, “I really enjoyed it”, referring to Sigal’s statement that 15 is odd and therefore it is impossible, or “I enjoyed it very much, I was astonished by the way she came up with it immediately”, etc. This concern to see her students succeed may emerge simply from her liking them. It may also be related to her role as their teacher, where Sigal and Ore’s success may be regarded as her own success.

Ruth’s conception of the “Shirts and Numbers” problem’s solution
When solving the problem by herself, to show that there is no solution to the “Shirts and Numbers” problem when the group-size is 15 (part (a) of the problem), Ruth subtracts 4 from 15 and receives 11. Then she points that the division of the result by 2 does not give a whole number, which means that the problem has no solution. Throughout the workshop, when discussing hers and her colleagues’ solutions, Ruth emphasizes that it is enough to state a “short version” of this solution, that “15 is odd and 4 is even. It is not possible to divide 11 by 2”. This short version includes a claim about the impossibility of solving a more general problem when the group size is odd and the difference between the sizes of the two teams is even. When discussing the solution with her colleagues, Ruth is willing to accept even a shorter version, where only two components are mentioned: “15 is odd and 4 is even”. For her, such a statement represents the more elaborated solution.

When solving part (b) of the problem, Ruth changes the number of players to 14. Analysis of the data suggests that Ruth’s solution strategy is to remove a minimal number of players to reach an even number of players. For example, in her interview Ruth says: “...It bothered me that they didn’t remove a shirt immediately, [pause] and to reach an even number. She [Sigal] knows that it [the number order] goes even, odd, even, odd. So, remove a shirt and then get an even number”. On another occasion Ruth says: “I was really surprised that they [Sigal and Ore] changed to 10, [that they] removed 5 shirts. Remove 1[pause]... I don’t know, it seemed to me that you need to remove 1 and try”.

Hearing through
Ruth’s concern for her students’ success and her own conception of the problem’s solution seem to contribute to Ruth’s overhearing and under-hearing Sigal and Ore.
Wanting to see them succeed, Ruth is receptive to interpret their talk and action in this way. When combined with her own conception of the problem solution, Ruth overhears in Sigal and Ore’s statement that “15 is odd and 4 is even” the answer she expects. However, when Sigal and Ore propose the solution of 10 players that they found by actually constructing two teams in which one has 4 players more than the other (3 and 7), Ruth’s under-hears them. She is unable to figure out how they reached this solution because their constructing strategy is different from her removing the minimum possible to reach an even number strategy. Even after watching this part of the video recording several times, Ruth under-hears her students and claims that “The solution [10] just came out of the blue”, or that “She just said 10, from the top of her head”. Ruth knows that 10 is correct but because both the strategy of solution and the resulting number are different, Ruth mishears her students.

FINAL REMARKS
In our investigation of Ruth’s hearing her students, of her understanding what Sigal and Ore were saying, showing, feeling and doing, we identified four types of teacher interpretations of students' talk and action: describing, explaining, criticism and justifying. We illustrated the complexity of hearing students, even in the relatively simple case of describing, and examined two possible sources for Ruth's overhearing and under-hearing: Ruth's concern for her students' success and Ruth's conception of the problem's solution. Ruth's case is an initial investigation of teacher hearing students that raises interesting questions, such as, Are there additional interpretation types? Are they interrelated? How? These and other questions are the focus of the next stage of our research.

TELLING OTHER PEOPLE’S STORIES: 
KNOWLEDGE PRODUCTION AND REPRESENTATION LESSONS

Margaret Walshaw
Massey University, New Zealand

This paper raises epistemological questions which have to do with how we know one another. These questions are directed towards inquiry, and ask how knowledge of other people is constructed and circulated. I begin by looking at how the scientific model stakes out certain rhetorical spaces for establishing credibility and for gaining acknowledgment, noting how our current research models limit and regulate epistemological legitimacy. In the second section I introduce poststructuralist ideas of knowledge as a useful way of dealing with intersubjective arrangements in which cognitive resources and positions of authority and expertise are unevenly distributed. The claim is that inquiry informed by these ideas necessarily invokes political deliberation.

INTRODUCTION

Posing one of the most provocative questions in the field of educational inquiry, Patti Lather asks: “How does a researcher work to not see so easily in telling stories that belong to others?” (1994, p44). Framed within the context of a contemporary interrogation into modernist descriptions of reality and truth, the question presents to those of us working in mathematics education an abrupt challenge to the way we have always done things. It invites an investigation of conceptual issues concerning what it means to know others and tell their mathematical stories. In doing so, it moves us from a preoccupation with what ideal researchers ought to do, opening up a space less comfortable than the certainties and absolutes of our research practices and all the relationships within those practices.

Certain principles have always guided our practices. The science from which those principles are derived has played an important role in cultivating the means by which those of us doing research might be empowered to make the classroom and the wider communities of knowers, a better place. That science claims to produce “paradigmatic instances of the best knowledge possible, for everyone, in all circumstances” (Code, 1995, pxi). I question those claims. Within the terms of the disintegration of the classical episteme of representation, I investigate the implications of that crisis for the gathering and analysis of qualitative data. My
purpose is to encourage a move away from the desire to establish true and accurate accounts about others and suggest how we might rethink our practices to accommodate an awareness of the limits of knowing. This question is not to anticipate the end to representation per se and abandon wholesale engagement, but to draw on the Derridean (1976) realisation about the end of ‘pure presence’, in order to suggest a transformed discursive practice.

The discussion is in two parts. First I revisit the research traditions which occasion most of the investigative work in the field. I look at how we have constructed mathematical knowledge of other people, noting how our current research models limit and regulate epistemological legitimacy. What obtains from this critique is the opening of a rhetorical space for more sophisticated analytical tools. In the second section I present a theoretical justification for a form of research which demands attention to negotiations among people who are intersubjectively constituted. In this practice the researcher assumes a self-reflexive stance, asking questions about the methodological implications for the way reality is understood and represented. This is the point where the interest moves from establishing truth onto an understanding of how meaning is produced and created and in how these productions factor into larger decisions concerning power and privilege.

HISTORIES OF RESEARCH PRACTICE

Research is about making a difference through science. Central to this taken-for-granted understanding, is the modernist belief in the perfectibility of society. If it is the modernist gesture of progressive change by which science is circumscribed, then it is this same science which came to be responsible for the administration of that progress. Foucault (1972) has provided a full conceptual articulation of how science, invested with multiple interests of regulation and redemption, became an important social force. Although twenty-first century science has long since located itself beyond the modernist project, the ideas of truth to which that project subscribes still play a major role in the structure and process of education. By creating a regime of order which organises and regulates our practices of inquiry, this particularly powerful discourse occupies a standard-setting position, determining what counts as valuable knowledge and who has access to the production, the distribution, and the legitimation of that knowledge. Research in mathematics education, as one of these practices, is complicit within this regime of truth.

Fundamental to this regime is a grand design of systematising and tidy partitioning, which lends coherence of the advancing of a universal explanation...
of the world. From this perspective, patterns of an individual’s life reveal observable facts, and hence are able to be classified, categorised, and ordered systematically and linearly as, using Foucault’s (1972) term, positivities. These facts can then be interpreted. Indeed it is a principal concern with an interpretation of gathered data which enables one to discover the truth in human terms, and by this means to normalise experiences (for example, stages of mathematical development), understandings and even our desires, with a view towards a definitive order upon which judgments can be substantiated.

To engage the idea that it is possible to make a difference through systematic order is to make an assumption of a coherent and transparent reality which awaits expression. This scheme of things is the site par excellence of a metaphysics of presence: reality is attributed evidential status as if it were existing ‘out there’ waiting to be captured (Walshaw, 2001a). Since seeing is the origin of knowing, reality assumes a fixed character, exhibiting certain qualities regardless of who is observing. Knowers are interchangeable spectators, abstracted from the particularities of their circumstances; objects of knowledge are separate from knowers, functioning as inert items in the observational knowledge-gathering process. This conceptualisation of the autonomous knower prompts and sustains a belief in the existence of a universal, homogenous and ‘essential’ human nature which allows those doing research to put themselves in another’s place and know his or her circumstances and interests in exactly the same way as she or he would know them. The researcher’s role then is that of disembodied arbiter of knowledge – one who can bestow authority and credibility onto the experiences of others and provide access to truth and certainty.

These ideas are still current, informing conceptions in both quantitative and qualitative approaches of what it means to know and what it means to know others. Both subscribe to a set of assumptions to the effect that knowledge is made by the abstract, interchangeable individual whose stories have been spoken from nowhere and everywhere. What emerges from this is a staging of truth, in which the concepts of objectivity and abstraction play a central role.

This is not in any way to suggest that all research is premised on notions of abstraction and universality. Some theorists, working to escape from the logic of the abstract, ‘generalised’, disengaged individual of the Western tradition, have argued for the concept of difference (for example, Bishop, 1988; Carraher, 1988; D’Ambrosio, 1985; Lave, 1997; Nickson & Lerman, 1992; Restivo, 1992). In their discourses, categories which have traditionally been regarded as commonplace in mathematics education are reordered and in the process common arguments about knowledge and its transference are undermined. In this way these theorists are able to demonstrate how the concepts and categories
fundamental to an epistemology of mathematics derive their authority and value from what is repressed and excluded.

Difference carries infinitely rich connotations and continues to be harnessed to a wide variety of political and cultural projects. But aren’t those who articulate the construction of difference and the reification of voice situated both within and against established traditions for doing research? Popkewitz (1997) sets forth a similar criticism of the construction of difference in contemporary social and educational theory. He argues that “the concept of voice maintains the very rules of ‘sameness/difference’ that it seeks to violate” (p25).

Recently the same kinds of arguments about the complicity that goes hand in hand with the concept of difference have been levelled at the reconstructionist feminist project (Walshaw, 2001b). Isn’t the theorising of women’s mathematical experience not, in a very real sense, entrapped in the very logic which it seeks to subvert? Doesn’t the method of feminist resistance (for example, Becker, 1995; Burton, 1995; Damarin, 1995) work within established frames by reinscribing that which it is resisting? By reconstructing the language and reversing the binaries standpoint feminism remains imprisoned within modernity’s parameters - parameters which have the effect of masking a complicity in structures of power and privilege.

Talk about the celebration and elevation of female difference bypasses the problematic of representation, and those questions which relate to social reality, to institutions and to power remain fully imperceptible from these standpoints. Clearly, the epistemic project needs to be conceptualised quite differently from one contained within a master discourse which obscures intersubjective negotiations of mathematical learners, teachers, and researchers of differential power and privilege. It needs to be superseded with a new set of perspectives, more in keeping with the unpredictability of our contemporary way of life.

RETHINKING RESEARCH

Whereas qualitative research moves forward positivist conventions of how we go about reality construction, poststructuralism offers an interrogation about those very practices, exposing the inadequacy of objectivist epistemologies. In claiming redundant a theory of knowing organised around uncontaminated situational exigencies, poststructuralism registers a realisation that modernist values, assumptions and explanations are no longer adequate nor desirable when we try to make sense of our contemporary world. Poststructuralist ideas then become key resources for showing how the conventions of research practice are mapped in such a way as to preclude it from even and equitable possibilities of establishing credibility. It offers those of us committed to understanding the
epistemic implications of knowing others well, a potential vantage point from which to rethink the way we do research. At the same time, however, this theorising elicits highly charged reactions precisely because there is so much more at stake derived from an interrogation about the limits of knowing than the existence or non-existence of a ‘correct’ research procedure.

Poststructuralism is an intellectual movement informing a constellation of theoretical positions ranging from phenomenology to deconstruction. Each of these discourses takes as its founding principle the disintegration of the classical episteme of representation. Read within those terms, poststructuralists maintain that, irrespective of our efforts to contain it, knowledge will always escape our grasp. Couching their work in a language which destabilises and challenges, poststructuralists historicise our ‘safe’ and ‘true’ understandings, offering critical interrogations of familiar ideas of knowing, description, and the rational subject. Through these interrogations they expose the limits of knowing, encouraging a scepticism about the possibility of true and accurate research findings, and, moreover, about the very possibility of knowing others and telling their stories.

Questioning the operative logic in contemporary research - an assumed homology between observation and knowledge - poststructuralists argue that representation can no longer be considered a politically neutral and theoretically innocent activity. Their work is not an argument for relativism, but a claim that representation is necessarily always partial, historically specific and interested. What this invites is a new understanding of how we go about reality construction.

A poststructural inquiry redeployds the meaning of research to offer “less false stories” (Harding, 1991) and to enable concrete social changes. Premised on the essential indeterminacy of human experiencing, these inquiries explore how knowledge production and its legitimation are historically situated and strategically practised. Mindful of the problem of unmediated access to a transparent mathematical reality, poststructuralists consider the problem of access to a mathematical reality from the perspective of local and marginalised practice. However, unlike in our research traditions, the intent is not to seek common denominators and homogeneous networks of causality and analogy in specific mathematical practices. Nor is it to promote a list of determinations and categories such as those of gender, race, or ethnicity. Rather a poststructural approach proposes an understanding of the categories by which mathematics education is organised as historically emergent rather than naturally given; as multivalent rather than unified in meaning; and as the frequent result and possible present instrument in struggles of power. Within this proposition reality emerges as fluid in nature, forever in process, continually being reshaped by the
changing categories individuals use to understand themselves, others, and the spaces they share.

A recognition of unstable competing realities points towards a different research practice. Relativising the status of all truth claims requires “changing the subject” (Henriques et al., 1984), shifting the emphasis from the learner as the site of original presence, to a decentralised, relational complex process. Actualising the site of this different research practice demands attention to how the researcher is also implicated (Britzman, 1995). If there is no “view from nowhere” (Haraway, 1988), and if representation must pass through the filter of the researcher’s discipline, biography, and social determinations, such as race, class, gender, ethnicity, and so on, then the researcher’s knowledge of mathematics education always privileges particular interests. If reality is understandable only through the use of the abstract categories which the researcher employs, then those very categories researchers are productive of shifts and movements themselves. Following from this, the researcher becomes with the learner and the teacher, a key player in the production of educational knowledge.

In Foucauldian work the claim is that all categories and concepts of practice are the effects of specific relations of power, all producing some dissonance between and within the individual. Inquiry derived from Foucauldian ideas (for example, Klein, 2000; Walshaw, 1999) investigates the power relations which make a focus on the production of mathematical knowledge both possible and an effective tool of subversion. This form of inquiry draws attention to lived moments of practice where cognitive resources and positions of authority and expertise are unevenly distributed to inform, constrain, and implicate mathematical work. By attending to these concerns and to the broader historical contexts of mathematical experiences, Foucauldian ideas then become a productive means to account for different degrees of coherence between subject positions and mathematical practice. They become a key resource for unmasking the ways in which the teaching and learning of mathematics is intimately tied to the social organisation of power.

CONCLUSION

Opting out of the impossible, yet nevertheless seductive, desire for coherency, and the impulse to access the ‘truth’ in mathematics education, the poststructural research project pushes the traditional boundaries in terms of how we know others and how we tell their stories. Concerning itself less with establishing researcher authority, and more with questioning the very construction of that authority, the investigation advances claims of multiple and contradictory positionings. It questions conventional constructions of objectification in order to take into account competing stories working through and against the stability of
meanings, identities, experiences, the treacheries of language, and the conceptual order constructed by all those involved in the research. But far from dismissing observation per se the intent is to query the uncritical appropriation of our conceptual categories and the logic we deem necessary to access 'reality'. Such an appropriation has everything to do with the power of the science, on which research is based, to disengage itself from contradiction, disunity, and multiplicity.

All research, even that named as qualitative and couched in the language and rhetoric of postpositivist discourse, operates within certain codes and conventions. The question raised by poststructuralism is not the existence of such commodified complicity, but the conditions of its deployment, and its effectivity. In drawing attention to the categories we construct and their derivative conceptual order necessary to access truth, we need to think about the way in which the political impinges upon and infuses all of our thinking and acting about research. The question we should be asking is not ‘is this research objective enough’, but rather ‘if this research is authenticated and validated, what motivates its deployment? What are the political effects?’

FLEXIBLE MATHEMATICAL THOUGHT
Lisa B. Warner*, Joseph Coppola Jr* & Gary E. Davis§
*Totten Intermediate School, Staten Island, New York, USA
§Rutgers, The State University of New Jersey

We consider different aspects of flexible thinking in mathematical contexts, and illustrate these by examples from recent mathematics classrooms. We argue that aspects of flexible mathematical thought can be encapsulated as an ability to use long-term declarative knowledge in novel situations. Both Karmiloff-Smith's representational re-description and recent work in the psychology of memory are related to flexible thinking.

INTRODUCTION

Cognitive flexibility is a well studied, but not especially well-defined, notion in the psychology of mathematics education. Flexibility of thought is often treated in the psychological literature as a given which is approached operationally through measurement (Berg, 1948; Edwards, 1966; Busse, 1968; Jausovec, 1994), or via specific problems that are thought to require flexibility for their solution (Dover & Shore, 1991; Kaizer & Shore, 1995). With a few significant exceptions, studies in mathematics education treat flexibility generally as the capacity to exhibit a variety of novel strategies for solving problems (Dunn, 1975; Carey, 1991; Klein & Beishuizen, 1994; Vakali, 1994; Beishuizen et al, 1997; Heirdsfield, 1998; Imai, 2000; see also Shore, Pelletier & Kaizer, 1990). The significant exceptions are Krutetskii (1969b), Shapiro (1992) and Gray and Tall (1994). Shapiro was a PhD student of Krutetskii in Russia in the late 1960’s. Krutetskii and Shapiro characterize flexible thinking as reversibility: the establishment of two-way relationships indicated by an ability to “make the transition from a ‘direct’ association to its corresponding ‘reverse’ association” (Krutetskii, 1969b, p. 50). Gray and Tall (1994) characterize flexible thinking in terms of an ability to move between interpreting notation as a process to do something (procedural) and as an object to think with and about (conceptual), depending upon the context:

“We characterize proceptual thinking as the ability to manipulate the symbolism flexibly as process or concept, freely interchanging different symbolisms for the same object. It is proceptual thinking that gives great power through the flexible, ambiguous use of symbolism that represents the duality of process and concept using the same notation.” (Gray & Tall, 1994, p.7)

In this paper we consider in detail what aspects of “flexibility” might be considered reasonable and desirable in a mathematical context. Although this is a theoretical analysis, aimed at clarifying the notion of flexibility, we base our discussion largely upon empirical work carried out in a grade 6/7 problem solving class.
THEORETICAL BACKGROUND

Flexibility of thought we will argue, is basically an ability to use long-term declarative knowledge in novel situations (Squire & Kandell, 2000). As simple as this statement seems it encapsulates a lot of background discussion and thought from mathematics education and psychology.

Part of the reason that the psychological literature has had so much difficulty with flexibility is that it may not be, and probably isn’t, a trait. Like bodily flexibility, some people may naturally incline to a greater degree of mental flexibility, but all people can improve their flexibility. This is an important issue to bear in mind in tests of flexibility: if flexibility is not a trait, as we suspect it is not, then tests of flexible thinking will generally have low reliability (Edwards, 1966), especially if practice on the tests substantially enhances one’s flexibility of thought.

Flexibility of thought as conceived by psychologists working on the neuropsychology of memory, is essentially long-term declarative memory – memory that has been processed in its formation by the hippocampal system (Squire & Kandell, 2000). The significance of the hippocampus is that, according to Eichenbaum (1994, 1887), it establishes a “relational space” in which prospective long-term knowledge becomes embedded relationally with other long-term knowledge. The well-known properties of the hippocampus in relation to spatial orientation are just one aspect of a more general capacity of the hippocampus to represent knowledge and memory in ways that allow flexible use in novel settings. The basic idea is that declarative memory – long-term memory that, in students, is expressed through words or diagrams – is inherently flexible in nature. Neuropsychologists, particularly those engaged in memory research, tend to speak of "flexible memory representations" rather than "flexibility of thought". This aspect of flexible thinking, involving a transition from implicit to declarative memories, is also a prominent feature of Karmiloff-Smith’s theory of representational re-description (Karmiloff-Smith, 1992). One interpretation of her theory of representational re-description is that it involves a transition, for an individual student, from short-term working memory to long-term flexible declarative memory, and thereby achieves a greater capacity for storage and retrieval of relevant memories, and also a wider applicability of those memories.

ASPECTS OF FLEXIBLE THINKING IN MATHEMATICS

Apart from a capacity for using novel strategies to solve problems, which is the most commonly used definition of flexibility in the mathematics education literature, we illustrate, below, a number of aspects of flexible thinking that are consistent with the neuropsychology of declarative memory. These all involve students in a “re-orientation”: of place, situation, of person, direction, or interpretation of notation. This re-orientation is consistent with the nature of long-term declarative memory as essentially relational (Eichenbaum, 1994; Squire & Kandell, 2000). From this perspective cognitive neuropsychology may be catching up with the ideas of Skemp (1976).
Capacity to interpret someone else’s thinking

A student might explain another student’s thinking and use it, build off it, try to prove that it is invalid, or ask questions about it. Consider the following example. A grade 6 student, Amanda, presented to her class a connection between three problems: (1) building all possible towers 4 high, using black or purple cubes; (2) finding all ways 2 teams can win the World Series playoff in 4 games; and (3) finding all possibilities for walking stairs 4 high, taking double or single steps. The following day a student, Jessica, gave a presentation to the class trying to explain what Amanda was saying, and convince the class that Amanda’s connection was not valid. Jessica showed a key that equated a black cube, b, with Y (representing the Yankees) and a 2 (representing a double step). She did the same for the other possibilities: purple ↔ M ↔ 1. She showed a four tall tower (bpbp) that should, under Amanda’s connection, be equivalent to an example of a way to play the World Series in four games (YMYM), and equivalent to a possibility for walking stairs four high (2121). She stated the connection would not work “because it would go overboard”: 2121 would make six stairs high, instead of four.

This is an example, on Jessica’s part, of interpreting another student’s thinking (in this case to show a connection was invalid). The situation that is novel for Jessica is Amanda’s schema of connections. Jessica brings to this novel situation her recollections of working on all three problems and is able to argue that Amanda’s connections do not do what Amanda intended.

Using an idea or strategy across different contexts or changing an existing strategy to fit a new context

Consider a grade 6 student, David, who mapped out an equivalence between the number of handshakes at a 4 person party (where each person shakes hands once with every other person at the party) to the "two purple case" of building towers four-tall, choosing from two colors, black and purple. He labeled the position of each block beginning at the top of a tower, working down (1, 2, 3, 4), focusing on the position of the two purple blocks. He also labeled the people at the party 1, 2, 3 and 4 and color-coded them. He began with the numerical pair “1, 1” and claimed that two purple blocks cannot both be placed in position 1, and, corresponding to his labelling, person 1 cannot shake hands with themselves. He then listed “1, 2” and said the two purple blocks would be in the top two positions and, correspondingly, person 1 would shake hands with person 2. He listed “1, 3” and “1, 4” showing how the towers would look, and represented this with two people shaking hands. He did not count “2, 1” because, according to him, person 1 already shook hands with person 2 and the purple block was already in position 1 and 2. He continued to show each possibility with towers and people and why he would or would not list each. Here he used the same strategy for two different problems, creating an exact mapping of possibilities from one problem to the other. In essence David extracted the scheme of working systematically through the number pairs “a, b” with a < b, and interpreted both the tower building problem and the handshake problem from this point of view. This
involved a double re-orientation: first interpreting towers as handshakes and vice versa, and then seeing both problems as instances of ordered pairs “a, b” with a < b. David utilized his knowledge of building towers, and of calculating handshakes, in a novel setting in which number pairs were his focus of attention.

Using multiple representations for the same mathematical problem or using multiple representations to express the same idea

Use of multiple representations is an essential aspect of mathematical flexibility. One can see it operating superbly at an advanced level in Thurston (1997), where, for example, different representations of manifolds and knot groups are utilized to enhance understanding.

We give an example of multiple representations by considering Jessica as she built towers two blocks tall from those one block tall by placing a black cube and purple cube under each possibility. She showed this by drawing an arrow from the original tower to the two new towers that she created and numbered each pair with the tower it came from. She also did this to create all towers four blocks tall from those towers three blocks tall. She later changed her recording to a tree diagram to show how to recursively build all towers of any height. Jessica re-oriented herself through encapsulation of the recursive process of building towers via a tree diagram. The tower building problem as conceived as a branching process (from our perspective, not Jessica’s) and the tree diagram was used as a representation of this branching process.

Raising hypothetical problem situations based on existing problems

These are essentially “what if” questions, and involve imagined scenarios, regarded as similar to an existing problem. For example, a grade 6 student Michelina asked in relation to building towers: "What if we have three colors to choose from, instead of two?" This question indicates that Michelina was not stuck in the constraints of the problem but imagined, what was to her, a similar problem in which she could utilize three, rather than just two, colors. Again, this involved a re-orientation into scenarios that are similar to those already encountered, but not yet acted out.
Using notation ambiguously

This is Gray & Tall’s (1994) definition of flexible mathematical thinking. They give an example of moving comfortably from using the division sign to a fraction bar representing division.

Consider the example of a grade 6 student, Jessica, who explained that the number of possibilities doubled when she moved from towers built from black and purple blocks, of a given height, to towers of height one greater. She described doubling by multiplying by two. She then switched to doubling by adding the number plus itself. This way of describing doubling apparently allowed her to see things more clearly. After she began describing doubling this way, she saw that her possibilities were doubling recursively. (Initially she had doubled the height to get the number of possibilities). This allowed her later to make a connection with doubling of the number of possible towers and her strategy of placing a black and purple cube under each tower to get all possibilities for the next height. The ability to see the process and results of calculation in different lights is a form of mental re-orientation: one obtains alternative and complementary points of view.

Transition from a ‘direct’ association to a corresponding ‘reverse’ association

This is Krutetskii (1969b) and Shapiro’s (1992) definition of flexibility of mathematical thought. A clear example of his aspect of flexibility occurred when sixth graders found a formula for the handshake problem for different numbers of people at a party. Michelin asked if they could find a formula when they know the number of handshakes and don’t know the number of people. Two further examples, one from a college level remedial algebra course, the other from a pre-service elementary methods course, also illustrate this aspect of flexibility. For the first example, consider the remedial college algebra student who wrote, as part of his final self evaluation:

I now have the skills to interpret and use mathematical notations appropriately, reflected in my work and ability to interpret a function machine; convert from one type of mathematical notation to another, convert a function machine to an equation/equation to function machine.... I have identified inputs and outputs, which was the key to answering the questions, appropriately and accurately in my tests on questions involving: recognizing the given slope to make a table, showing input/output; identification of a given notation and breaking it down by input/output; naming input/output from a given function machine or equation; finding output if given input/finding input if given output.... I am knowledgeable in understanding the difference between evaluating and solving: solving for X; evaluating for Y.

This student’s work indicated that he did indeed know the difference between evaluating an expression and solving an equation, a distinction he did not make at the beginning of his course.

Second, consider the example of an elementary teacher who, in a mathematics methods course, turned around a problem, utilizing a reverse association. The
problem was to begin with a sheet of paper in one person’s hands, to tear it into two and pass one piece to some one else. That procedure was repeated until everyone had a piece of paper. The problem was to figure how many pieces of paper there were after the last tear. The reverse problem, raised by a teacher on the course, was to count the number of people in the room and figure how many tears were needed so that everyone had a piece of paper.

CONCLUSIONS
Building on the work of Krutetskii (169b), Gray & Tall (1994) and other research in mathematics education we identify several major aspects of flexibility of mathematical thought:

1. Use of novel strategies to solve problems.
2. Ability to establish both direct and reverse associations.
3. Ambiguous use of notation.
4. Capacity to interpret someone else’s thinking.
5. Using an idea or strategy across different contexts or changing an existing strategy to fit a new context.
6. Using multiple representations for the same mathematical problem or using multiple representations to express the same idea.
7. Raising hypothetical problem situations based on existing problems.

These aspects of flexibility are, from our point of view, all manifestations of a fundamental ability to utilize what is stored in long-term memory in novel settings: of place, time, direction, representation, or person. This ability we hypothesize is related to the capacity of the hippocampus to establish long-term relational memories. A model of Davis, Hill & Smith (2000) suggests that a teacher can act as an external agent in taking students’ procedures, helping to make them explicit and emotionally colourful, and so assist in transferring those procedures into explicit long-term memory. The classroom practices of the first author are entirely in accord with that model. Whether, and to what extent, all students can increase their flexibility of mathematical thought is a question we are currently investigating.

REFERENCES

This paper examines young children's ability to solve sentences with unknowns. A semi-structured interview was conducted with 87 children who had just completed their first three years of formal schooling. The purpose of this interview was to ascertain their thinking when solving problems with unknowns and draw implications for early years algebra. The results of the interviews indicated that many children are experiencing difficulties in solving for unknowns.

INTRODUCTION

The transition from arithmetic to algebra has been a major focus of recent research into the learning and teaching of algebra (Boulton-Lewis, Cooper, Atweh, Pillay, & Wilss, 2000). A focus of this research is the gap between the knowledge required to solve arithmetical equations by arithmetical methods and the knowledge required to solve algebraic equations by operating on or with the unknown (Booth, 1988; Herscovics & Linchevski, 1994; Filloy & Rojano, 1989). Student's inability to operate with or on the unknown has been central to delineating arithmetic from algebra, where algebra traditionally follows arithmetic. Early algebra research is moving towards the integration of arithmetic and algebraic reasoning in the elementary grades. Thus the importance of how young children deal with unknowns is growing.

ARITHMETIC IN THE EARLY YEARS

A variety of addition and subtraction problems exist in the real world. Fuson (1992) identified four broad categories that addition and subtraction problems seem to fall into. For each, the use of the unknown varies. The first is referred to as Change-Add-To and Change-Take-Away. This involves beginning with a single collection and changing the initial collection either by adding or removing something from it. This category covers the majority of problems children solve in the elementary school (Baroody & Standifer, 1993). In this instance, the unknown is the outcome of the change. Its manifestation in algebra (e.g., \(4 + 3 = x\)) is trivial and represents limited challenges in developing meaning for unknowns.

The second category focuses on considering arithmetic situations as comprising three components, two parts and a whole and arithmetic operation as joining the parts or removing one part. In this understanding, in order to find the unknown it is simply a matter of working out which component is missing and applying an appropriate solution strategy. For example, if we have \(3 + ? = 7\) or \(7 - ? = 5\) then we have the whole and one of the parts. To reach a solution we need to work out the other part. For problems such as \(3 + 4 = ?\) or \(? - 4 = 7\) we have the two parts and need to work out the whole. This thinking not only assists in classifying problems but also
suggests ways of reaching appropriate solutions for number sentences that fit the *Part-Part-Whole* framework. It also represents many of the unknown situations covered on the way to algebra. However, its limitations lie in its inability to model equivalent situations with two or more terms on both sides (e.g., 2+5=1+?). Thus, while it serves an understanding of arithmetic processes, its usefulness for algebra is uncertain.

The third and fourth categories are similar. The third, *Equalize*, involves removing the difference between two collections, for example, Jill has 5 cars and John has 8 cars, how many more does Jill have to buy in order to have the same amount of cars as John? In this instance, the unknown is the difference. The last category, *Compare*, considers the difference between two numbers, and is similar to *Equalize*, but does not entail any action and the difference between the two numbers persists. For example, John has 8 cars, he has three more than Jill, how many cars does Jill have? In both these instances the unknown represents change or difference.

**EARLY ALGEBRA AND UNKNOWNS**

Early algebra is not about introducing formal algebra in the early years but is about developing arithmetic reasoning in conjunction with algebraic reasoning. Thus exploring problems with unknowns in the early years is important. Slavitt (1999) suggested that a key to early algebraic competence is the ability to abstract computation to more structural realms, commonly referred to as generalised arithmetic. In this generalising process it is the numbers that map to variables and the operations remain the same, although the meaning of the operations could change.

Recent research has begun to focus on the development of young children's algebraic thinking (Falkner, Levi, & Carpenter, 1999), with a focus on children's understanding of equals as equality. Most students do not have this understanding; rather they have a persistent idea that the equals sign is either a *syntactic indicator* (i.e., a symbol indicating where the answer should be written) or an *operator sign* (i.e., a stimulus to action or “to do something”) (Behr, Erlwanger & Nichols, 1980; Filloy & Rojano, 1989). Warren (2001) indicated that (i) young children are capable of reaching generalisations, (ii) classroom experiences can interfere with them reaching valid generalisations, (iii) in some instances teaching materials act as cognitive obstacles to abstracting the underlying mathematical structure, and (iv) new learning in mathematics can be incorrectly used to solve old problems. Incorporating 'real' world language can further complicate many situations. Priie and Martin (1997) claimed that language only serves problems where the equal sign appears just before the answer, thus reinforcing the equation as an action and privileging equations with the unknown occurring directly after the equal sign.

Several studies have investigated student's equation solving strategies. The various methods used by algebra students have been classified as follows; using
number facts, using counting techniques, cover-up, undoing (or working backwards), trial-and-error substitution, transposing from one side of the equation to the other, and performing the same operation on both sides (Kieran, 1992). Commonly, it is assumed that students bring with them from their experiences in arithmetic in the elementary school some understanding of the first two methods, number facts and counting techniques. Both these methods assist young children to find the 'missing addend' in number sentences. Counting techniques consist of counting on, counting up, or counting back (Fuson & Fuson, 1992). The questions are: do these techniques assist children in solving missing addend problems in a range of situations or are there problems that are beyond these techniques, how are the methods aligned with preparing young children for algebra, and are young children capable of using other strategies in meaningful ways in the early years?

The specific aims of this paper were to investigate young children's strategies for finding the unknown in first degree equations with one unknown, and to delineate the thinking that supports the development of algebraic understanding.

METHODS

The sample comprised of 84 children from four elementary schools in low to medium socio-economic areas. The children are all participants in a three year longitudinal study investigating early literacy and numeracy development. The average age of the sample was 8 years and 6 months and all had completed the first three years of formal education. In Queensland children spend 7 years in the elementary school. Five tasks were developed for the semi-structured interview. Two tasks were developed to probe young children's ability to ascertain the unknown in equations (see Figure 1).

![Figure 1 Tasks presented for the interview](image)

All children had completed their formal introduction to the concepts of addition and subtraction and could add and subtract numbers involving tens and ones. The two tasks chosen for this segment of the interview were believed to probe children's ability to operate with equations in differing formats and to understand the inverse relationship between addition and subtraction. The format reflected formatting commonly used in algebra, that is, the equations were represented horizontally, the unknown was on different sides of the equation, and more than one term followed the equal sign. Both tasks were presented in a symbolic format. Task 1 represented format commonly presented in most classrooms with the unknown on the left hand side and one number of the right hand side. Task 2 was atypical with the unknown on the right hand side of the equation and the equal sign followed by two terms. Two digit numbers were deliberately chosen for the two tasks. It was believed that...
this would force children to use equation solving strategies other than number facts and counting on. Throughout the interview students had access to a calculator and were encouraged to use it if they so wished.

The script for this segment of the interview was: *What is the card asking you to do? How can you find the missing numbers? What is the missing number? How did you find it?* The interviews were audio-taped and the scripts transcribed for analysis.

**RESULTS**

**Task 1**

An examination of the transcripts indicated that the responses to the first task \((16 + \square = 49)\) fell into four broad categories, namely, counting up, counting back, subtraction, and no response, each reflecting the general approach taken to reach a solution. Each category consisted of a number of differing solution paths. The next section describes each of the categories and includes some typical responses.

**Category 1 Counting up**

Counting up consisted of three strategies, counting up in ones, counting up in tens then ones, and using a trial and error method on a calculator. A typical response for counting in 1's was:

*What is the card asking you to do?* Well it doesn't have a number in there and it is not a turn around and it equals 49. I have to try and figure out the answer in there. *What are you thinking about?* I was just counting in my head 17, 18, 16, 17, 18, 19, 20 ... 33, 34, ... 41, ... 49. [While counting up the student kept track of the number of tens with her fingers.] That is 34.

A typical response for the trial and error strategy was:

*What is the card asking you to do?* 16 plus something equals 49. *How do you find the something?* You find it by well is should be something else so you can figure it out. *So can you work it out for me?* [Long silence] 16 + 16 equals [the child enters the two numbers into a calculator] No. 16+17. No. 16+29. No 16 +34. No. 16+33. It is 33.

**Category 2 Counting back**

A typical response for this category was:

*What is the card asking you to do?* Put the number in there. *How can you find the missing number?* You go from 49 and count back 16 and whatever you land on is your answer. 49, 48, 47, 46, 45, ....... 33 So you put 33 in the box.

**Category 3 Subtraction**

Subtraction consisted of two strategies, using a pen and paper algorithm (either 49-16 or 16-49), or reaching the answer by mental computation processes. A typical response for the pen and paper algorithm was:
What is the card asking you to do? Something plus 16 equals 49. How would you do it? Take 16 away from 49. [The child proceeded to write the sum 49 - 16 in the vertical format and obtained the answer of 33]

Each response was coded according to the four categories. Table 1 summarises the frequency of responses for each category.

</tbody>
</table>

The most commonly chosen strategy was counting up. Not surprisingly many of those who chose counting up in ones experienced difficulty in reaching the correct solution. They either included the starting number in their solution or simply lost track of where they where up to. Only 15 children (18%) used the inverse relationship between addition and subtraction to ascertain the unknown with all of those who chose the correct algorithm (49-16) reaching the correct solution.

Task 2

An examination of the transcripts indicated that the responses to the second (54 - □ = 12) fell into four broad categories, namely reformatting the original problem, interpreting '=' as 'the answer must follow' and thus the unknown must be 54, reaching the solution by addition, and no response.

Category 1 **Reformatting the problem**

Three different strategies were used for reformatting the original problem. Each resulted in a format where there was only one 'thing' after the equal sign, either the unknown or one of the numbers in the problem. The first simply entailed 'flipping the format over' (12 - □ = 54). The second involved swapping '=' and '-' (54 - □ = 12). and the last strategy placed the unknown after the equal sign (12 - 54 = □ or 54 - 12= □). Some typical responses were

What is the card asking you to do? 54 take something = 12 no 54 = something take 12. You have to put the missing number in the box...but it is going backwards. How would
you find the missing number? Count on. What way would you like to see the problem? 12 take something = 54. Can you work out the number? No you can't do it.

What is the card asking you to do? 54 minus something = 12. 54 equals something minus 12... I don't know what that means. So what is wrong with it? Because the = is before the 12 and it shouldn't be. What should it look like? Well 54 - 12 = something. The box is after the equals it should be at the end. How would you work that one out? I don't know how to .... I will try 26 [The child entered 54 - 26 into the calculator]. I'll try 35 Oh I am doing it wrong it is 42.

Category 2 Interpreting = as 'the answer'

What is the card asking you to do? 54 = something take away 12. What is that asking you to do? 54 equals 54. Why? Can you explain? The answer is 54 because it must be 0 plus 54 equals 54.

Category 3 Solving by addition

What is the card asking you to do? 12 take away.. is it going that way?... 66 goes in there. How did you work that out? Because the 12 needs a higher number... the 54 is the answer the 12 has to have a big even number and it was a 6 and then the other one needed a 6. Why did the 12 need a 6? To make that number and it was 66 and that takes away a 10 then it has to be 6 and then the 12 take away the two and it equals 54.

Each response was coded according to these categories. Table 2 summarises the frequency of response for each category.

Table 2 Frequency of response for each category of responses to 54 = □ - 12.

</tbody>
</table>

Over half the sample (58%) needed to reformat the problem before they could even attempt to reach a solution, with most insisting on placing the unknown after the = sign. As compared with Task 1, the number of children who reached a solution by using the inverse relationship increased from 15 to 21 children and all but one of these indicated that the unknown must be 66. Only 8 of these 21 children used the
inverse relationship to solve both tasks. The rest either solved Task 1 by counting on in ones (4 children) or counting on in tens then ones (9 children).

DISCUSSION AND CONCLUSIONS

As expected, most children found Task 1 easier than Task 2. Some conjectured reasons are that Task 1 meets student's understanding of equals and it can be easily represented in everyday language in all four categories (Change-Add-to, Part/Part/Whole, Compare & Equalise). By contrast, Task 2 seemed not to meet student's understanding of equals, and cannot easily be represented in everyday language in any of the categories. Arazello (1998) believed that natural language is crucial for developing an algebraic way of thinking. So how do young children deal with problems that cannot be easily translated into real world contexts? Does continually situating problems in real world contexts privilege some types of problems over others, as suggested by Pririe and Martin (1997)?

Early algebra involves a reconceptualisation of arithmetic in the elementary school. One expectation is that children will be able to solve for the unknown/unknowns in a wide variety of contexts and formats, including number sentences such as 12+?-1=23+5. As we move towards asking young children to be able to solve an array of problems with unknowns that are not commonly presented in our elementary schools, the role of natural language in developing an algebraic way of thinking takes on new meaning. Is it necessary condition to represents problems in real world contexts or is it sufficient for children to simply to be able to translate problems into spoken language?

The format of the tasks seemed to evoke differing solution strategies. For Task 1, the inclusion of addition seemed to suggest counting up rather than using the inverse relationship between addition and subtraction, whereas Task 2 did not suggest counting back but rather either reformatting the problem to an easily recognised form, or using addition, the inverse operation. This conjecture is supported by the increase in the number of children who chose to use the inverse relationship to solve Task 2. The use of the inverse algorithm for Task 2 could also reflect young children's unease with counting back (Fuson, 1992). The need to reformat the problem supports previous findings with regard to interpretation of equal as a syntactic indicator, that is, a symbol indicating where the answer should be written.

Young children are using a variety of strategies for finding the unknown. While the majority used counting strategies, some used an undoing strategy (recognising addition as undoing subtraction and vice versa). In fact, all the children who were successful in Task 2 used this strategy. The tasks did not seem to elicit an understanding of balance to reach the solution. This is reflected in their lack of success in rewriting Task 2, with all maintaining the '-' sign in their transformations.
Trial and error was also a strategy used by some. These children already have equation solving strategies beyond number facts and counting techniques.

As we broaden the exemplars involving unknowns in the early years, the nature of categories, the role of natural language and equation solving strategies need further investigation, as all seem to play some part in successfully reaching solutions.

This study of the learning of vectors is situated in the intersection of embodied theory relating to physical phenomena, and process-object encapsulation of actions as mathematical concepts. We consider the subtle effects of different contexts such as vector as displacement or force, and focus on the need to create a concept of vector that has greater flexibility. Our approach refocuses the development from ‘action to process’ as a shift of attention from ‘action to effect’ in a way that we hypothesise is more meaningful to students. At a general level we embed this development from enactive action to mental concept within a broad theoretical perspective and at the specific level of vector we report initial experimental data.

INTRODUCTION

This study is part of an ongoing enterprise to build a practical cognitive theory embracing human learning and the powerful use of symbolism in mathematics (Gray & Tall, 2001). As such, it stands at the conjunction of two major theories of cognitive development: the embodied cognition of Lakoff and others (Lakoff & Johnson, 1999, Lakoff & Nunez, 2000) and the development of symbolic mathematics through process-object encapsulation (Dubinsky, 1999, Tall et al, 2001). The current three-year study focuses on the concept of vector. This is particularly appropriate for the wider development of the theory as it encompasses embodied aspects in Physics—such displacement, force, velocity, acceleration—and a complementary approach in Mathematics that is based on a text with an implicit process-object approach (Pledger et al, 1996).

In the first year, (September 2000 – July 2001), the first author followed a strategy using full class plenaries to encourage students to construct their own coherent conceptions. As we shall see, this had positive effects in improving the flexibility of the students’ concept of vector. In the second year, which is now in progress, a new initial emphasis focuses on embodied activities in which the new students enact vectors as transformations moving a shape on a flat surface. The movement of any point on the shape can be represented by an arrow from start to finish, and all the arrows have the ‘same effect’. This idea (formulated by a student, Joshua) has proved to be a helpful bridge in translating the sophisticated theory of process-object construction to a practical idea of action-effect. In this article we discuss the findings of the exploratory study and data analysis of the first stages of implementation.
THE COMPLEXITY OF THE LEARNING SITUATION

Students meet the notion of vector in different contexts with subtle differences in embodiment. For instance, vectors may be encountered as displacements sensed as physical journeys from one place to another, or as forces acting at particular points. In the addition of displacements, one journey followed by another is naturally interpreted using the triangle law, but the addition of forces operating at a point is more naturally represented by the parallelogram rule. In the curriculum we are considering, the notion of vector is first introduced as a translation in the plane and dealt with as a column matrix in mathematics, or as the separate horizontal and vertical components in physics. Both versions are linked to a picture of the vector as the hypotenuse of a right-angled triangle with components as horizontal and vertical sides. In turn this links more easily to the triangle law than to the parallelogram law. Given a problem solvable by horizontal and vertical components such as figure 1a, 25 out of 26 students were able to solve it. However, given a more complex physical problem such as that in figure 1b, asking the student to mark the forces involved with an object on a rough sloping plane, only 4 out of 26 students were successful. In interviews, it transpired that several students, who used the triangle law to draw a picture as in figure 1c, used the triangle of forces to mark the components; because the force parallel to the plane is drawn well below the object, it did not seem to be acting on it and was ignored.

Fig 1b: describe & mark forces  
Fig 1c: forces as marked

The research project therefore focuses on two main objectives, the first is to analyse the cognitive development of the notion of vector in the curriculum, the second is to help students develop the notion of vector as a flexible cognitive unit that can be applied transparently in its various incarnations.

METHODOLOGY

The research method draws upon qualitative and quantitative data and includes lesson observations, standard class tests to assess progress, and a specially designed conceptual questionnaire coordinated with clinical interviews with students and Mathematics and Science teachers (Ginsburg, 1981; Swanson et al., 1981). The data was triangulated, by analysing the books used by students and teachers, by videoing and observing classes, by interviewing teachers on their preferences and their expectations of the students' knowledge about vectors, with particular emphasis on the questions used in the conceptual questionnaire.
The research is conducted at a Comprehensive School with a good academic reputation (for example, in 2001, 63% attained a grade C or above in mathematics in the GCSE examination taken at age 16, as compared with a national average of 54%). The research involved 23 Lower Sixth students (aged 16-17), 26 Upper Sixth students, (aged 17-18), 2 teachers of Physics, and 4 teachers of Mathematics (two covering the preliminary work on vectors at GCSE level, and two teaching the two-year ‘A’ level course in the Sixth Form).

THEORETICAL FRAMEWORK

The topic of vectors spans both mathematics education and science education. In science the ideas often begin from what we would now call a real-world embodied viewpoint. For instance, in dealing with vectors, Aguirre and Erikson write:

Teachers could [...] build upon students intuitions (developed through experience in everyday settings) by relating these intuitions to the more formal problem settings in the scientific domain.

(Aguirre & Erikson, 1984, p 440.)

They proceed by detailing networks of vector concepts to support this approach, however, their network shows no indication of the mathematical concept of vector. After many years of such developments, Rowlands, Graham and Berry observe:

... various attempts at classifying student conceptions has been by and large unsuccessful [...] . A taxonomy of students conceptions may be impossible because the considerations of ‘misconceptions’ require a specific regard for the framework from which the ‘misconception’ occur [...] and how misconception is linked to the other forms of reasoning.

(Rowlands, Graham & Berry, 1999, p 247.)

The recent development of embodied cognition, particularly in the formulation of Lakoff (eg. Lakoff & Johnson, 1999, Lakoff & Nunez, 2000) even formulate the idea that all thought is embodied. Here we are faced with a genuine quandary. If the attempts to classify the development of vector through intuitive student concepts is, by and large, unsuccessful, and the evidence is that the notion of vector has subtly different meanings in different contexts, how are we to progress in teaching the subject? One strategy that seems evident is to encourage students to reflect on the different aspects of different embodiments and to help them rationalise the various contexts to give an entry into the mathematical notion of vector wherein the ideas of the triangle law and parallelogram law are different aspects of the same theoretical idea, not distinct rules that each have their separate domain of meaning. To gain insight into this possibility, the first author began a programme of plenary discussions with the Upper Sixth based on the underlying unity of the idea of vector.

In linking various embodied ideas to the mathematical notion of vector, we were conscious of the large number of theories relating embodied experiences with mathematical symbolism: These include Piagetian stage theory developing through sensori-motor via concrete operational and formal operational, the Bruner (1966) theory of enactive-iconic-symbolic representations, the work of Krutetskii (1976) on...
geometric, harmonic and symbolic styles of thought, the van Hiele (1986) development in geometry, and the SOLO taxonomy (Structure of Observed Learning Outcomes) of Biggs & Collis (1991), not to mention the wide range of work in using visual and symbolic interfaces with computers. Amongst all of these we found most empathetic was the notion of how successive modes of thought arise in the SOLO taxonomy whereby each broadens to be included in the next and how physical action (in the sensori-motor mode) is broadened to the ikonic mode, then, through the introduction of symbols, to the symbolic mode and on to successive formal modes of operation. As each of these becomes available and is added to previous modes, we found ourselves dealing with students in a situation where the two main modes of operation are a combined sensori-motor/visual embodied mode of thought and a fundamentally concrete-symbolic mode.

ANALYSIS OF THE SCHOOL APPROACH TO VECTORS

The text-book (Pledger et al, 1996) used in the school for introducing vectors to the students in the previous year followed a pattern that is reminiscent of the encapsulation of processes as objects. In this approach, the processes are translations of objects in the plane and these lead to vector concepts, as follows:

1. translations are described using column vectors, \( \begin{pmatrix} x \\ y \end{pmatrix} \) with the column vector \( \begin{pmatrix} 6 \\ 1 \end{pmatrix} \) meaning 6 units in the positive x direction and 1 unit in the positive y direction.

2. an alternative notation which can be used to describe the translation is \( \overrightarrow{AB} \) representing where A is the starting point and B is the finishing point. [...] The lines with arrows are called directed line segments and show a unique length and direction.

3. a third way to describe a translation is to use single letters such as \( \mathbf{a} \). Translations are referred to simply as vectors. [...] [Each vector] has a unique length and direction...

4. Position Vectors. The column vector \( \begin{pmatrix} x \\ y \end{pmatrix} \) denotes a translation. There are an infinite number of points which are related by such a translation. ... The diagram shows several pairs of points linked by the same vector. The vector which translates \( O \) to \( P \), \( \overrightarrow{OP} \), is a special vector, the position vector of \( P \).
This pragmatic approach has some of the aspects of process-object encapsulation. Stage 1 sees a vector as an action on a physical object. The translation is already represented as an arrow. In stage 2 the object is omitted and the focus of attention is on the line segment as a journey from a point A to a point B. Stage 3 shifts the focus to the vector as a single entity drawn as an arrow and labelled with the single symbol a. This entity has both an enactive aspect (the movement from tail to nose of the arrow) and an embodied aspect (as the arrow itself). In stage 4 the column vector is used to denote an infinite family of arrows with the same length and direction, with one specific vector starting at the origin singled out as a position vector as a special representative of the whole family.

In practice, the Physics teachers preferred to ‘simplify’ the ideas by referring separately to horizontal and vertical components of vectors. For example, to add two vectors, they would consider each vector separately, calculate its horizontal and vertical components and add them together to get the components of the sum. In parallel, the students would often use the equivalent matrix method to add vectors in pure mathematics. Thus, although they had been taken through the spectrum of development in stages 1 to 4, to make any computations, they were encouraged to fall back to level 1.

**ACTIONS AND EFFECTS – THE INSIGHT OF A SPECIAL STUDENT**

In attempting to build a more flexible conception of the notion of vector that encapsulates the whole structure of embodiment and process-object encapsulation, we were struck by the interpretation formulated by one particular student whom we will call Joshua. He explained that different actions can have the same ‘effect’. For example, he saw the combination of one translation followed by another as having the same effect as the single translation corresponding to the sum of the two vectors.

By focusing on the effect, rather than the specific actions involved, we realised that it proves possible to get to the heart of several highly sophisticated concepts. For instance, in fractions, ‘divide into three equal parts and take two’ is a different action from ‘divide into six equal parts and take four’ but they have the same effect, giving rise to the central idea of equivalent fractions. The same idea occurs in algebra where 2(x + 4) and 2x + 8 involve different sequences of actions with the same effect, leading to the notion of equivalent expressions. We hypothesize that the notion of action-effect is a more approachable way of describing the theory of action-process (Dubinsky, 1991) or procedure-process (Gray & Tall, 1994).

In dealing with this approach, we encouraged students to participate actively by shifting a triangle placed on the table. Figures 2a and 2b have the same start and endpoint (and therefore the same effect, even though the journeys they take in between are different.) The arrows in figure 2b represent equivalent vectors (free vectors having the same effect) and figure 2c represents Joshua’s idea that the sum of two vectors has the s
Fig 2a: a translation  
Fig 2b: a translation  
Fig 2c: The sum of two vectors

Figures 2a, 2b ‘have the same effect’  
Two translations and their total effect

ame effect as the two vectors applied one after the other.

This approach implicitly encapsulates the notion of equivalent free vectors ‘having the same effect’ and encourages students to feel able to shift free vectors around in any appropriate manner. We would therefore expect students following this approach to be more flexible in handling free vectors.

**EMPIRICAL DATA ANALYSIS**

To investigate the reasons underlying the original problem in figure 1c, a question was given showing a body on an inclined plane, as in figure 3. Figures 3b and 3c represent the ways in which two students James and Chris split the weight W into components \( W_1 \) and \( W_2 \). Are either or both of James and Chris right?

The 23 students beginning the course in the lower 6th gave a variety of responses, 11 said both were right, 4 chose fig 3b, 1 chose fig 3c and 6 said neither. All of the students in the sixth form who had taken part in the reflective plenaries found the question trivial and saw the triangle and parallelogram as equivalent.

To test the student’s ability to deal with vectors graphically, we gave the question in figure 4. The first part is a natural triangle problem with the vector \( \vec{AB} \) followed by \( \vec{BC} \), the other two benefit from being able to see the vectors as free vectors to be able to move them so that they follow on end to end.

In the test, all the students were easily able to cope with the sum \( \vec{AB} + \vec{BC} \). However, parts (ii) and (iii) were more problematic. When we consider those...
students who were able to solve all three problems, we get the data in tables 1a and 1b.

![Diagram of vectors](image)

Show clearly a vector equivalent to:

(i) $\overrightarrow{AB} + \overrightarrow{BC}$
(ii) $\overrightarrow{AB} + \overrightarrow{AD}$
(iii) $\overrightarrow{AB} + \overrightarrow{CA}$

In table 1a those upper sixth students who participated in reflective plenaries were more successful than those following standard class lessons and in table 1b, those following an embodied approach also had more success.

Table 1b: effect of embodied approach in reflective plenaries

Interviews with six selected students in the lower sixth confirmed that students following a standard course had problems adding two vectors that did not follow on one after the other, especially in cases where they were joined head to head. In the latter case, two out of three students thought that two vectors pointing to the same point would have resultant zero, because they would cancel out.

REFLECTION

The study so far has revealed the complexity of the meaning of vectors as forces and as displacements and the subtle meanings that are inferred in differing contexts. Studies in science education have attempted to build a classification of misconceptions without clearly identifying the underlying problems. Our approach is to develop a pragmatic method that will work in the classroom. One aspect is the use of conceptual plenaries, which are already becoming part of the formally defined curriculum in England. The other is to continue to develop a theory that links physical embodiments to mathematical concepts via a strategy that focuses on the effects of actions. Our experience shows that such an approach can be beneficial in the short-term and we are continuing our practical and theoretical developments over the longer term.

Extending example spaces
as a learning/teaching strategy in mathematics

Anne Watson, University of Oxford and John Mason, Open University

Abstract This paper gives an illustrated theoretical account of some roles for student-generated examples in the teaching and learning of mathematics. We give instances which show that the development of example spaces contributes to conceptual engagement, and that such spaces are personal and situated.

Introduction

In this paper, learning is seen as growth and adaptation (extension) of personal, situated, example spaces; teaching involves providing situations in which this can take place. We find this metaphor useful in characterising many teaching strategies which promote active engagement with concepts, and also in characterising experiences of conceptual learning. This theoretical approach has been developed over a number of years through examination of our own mathematical work, through the responses of groups to mathematical tasks we have offered them, through our observations of teachers and their students, and through some of the literature on exemplification.

We recognise the importance of interaction, discourse, ethos and enculturation in the learning of mathematics, but we find ourselves unable to adopt a solely social constructivist or socio-culturalist position when thinking about learning and doing of mathematics. When we do mathematics for ourselves, we do not recognise our experience as anything other than internal struggle with the unknown to achieve what feels like a self-contained sense of understanding. As institutional learners, personal struggle for sense was supplemented by a need to satisfy an external authority (the teacher). We acknowledge that these descriptions, our behaviour and our judgements are subtly guided by social practices, of which we are a constituent part, but that has little bearing on our sense of relationship with the mathematical problem or concept once we have engaged with it. The questions which guide us are:

How can engagement in mathematics be encouraged?

How can construction of mathematics be supported?

We see mathematics as a structure of agreed quantitative and spatial conventions which can be extended in agreed ways into abstract worlds, about which we communicate in ways which imply agreements. Learning mathematics involves making personal sense of experiences of quantitative, spatial and abstract objects and relationships, and matching these senses to further experiences and conventions. The interactive aspects of these experiences are crucial, because language (verbal, non-verbal, symbolic) is the medium through which a teacher can construct situations in which learners meet abstract concepts and compare the implications of their constructions with the implications of conventions. Thus we are interested in 'good-
fit’ relationships between language and active construal, that is, relationships which are effective in leading learners to construe mathematics in useful ways.

Put more simply, we ask what tasks teachers can set to help students learn conventional mathematics, given that learning involves constructing meaning in the environment created predominantly by the teacher.

The role of examples in learning mathematics

It is has long been acknowledged that people learn mathematics principally through engagement with examples, rather than through formal definitions and techniques. Indeed, it is only through examples that definitions have any meaning, since the technical words of mathematics describe classes of objects or relations with which the learner has to become familiar.

We use ‘example’ to cover a broad range of mathematical genres, including examples of classes, examples illustrating concepts, worked examples demonstrating techniques, examples of problems and questions which can be resolved, examples of appropriate objects which satisfy certain conditions, examples of ways of answering questions, constructing proofs, and so on. Thus learning mathematics can be seen as a process of generalising from specific examples: learning to add involves generalising a process which works for given examples so that it can be applied to examples one has not met before; learning about quadrilaterals involves understanding what types are possible, and what their properties are. The broader the range of examples, the richer the possibilities for generalisations and connections to be made, so the extent of the set of familiar examples is influential in construction of conceptual understanding.

Most examples come to students from authorities (by whom we mean teachers, textbook and examination writers), but there is a contrast between a single example seen as paradigmatic, or generic, by the expert but as something merely to learn by a student (Mason and Pimm, 1984). For instance, a teacher might multiply some numbers by 0.3 to show, generically, that multipliers between 0 and 1 make ‘smaller’ products, but are students aware that this is an example of a range of numbers which act similarly, or do they perceive merely a set of practice exercises?

It is useful, then, for students to have several examples from which to get a general sense of what is being taught. Firstly, it is important to compare examples to see what features are common, and hence to appreciate generality. This helps avoid students’ fixations with figural concepts which have unhelpful features. Choice of examples is important in helping students develop generalisations of structures rather than surface features (Bills and Rowland, 1999). The process of comparing examples can also highlight the conceptual, semantic and structural similarities between problems rather than superficially seeking cues in syntax, habit or context (Reimann & Schult, 1996). Learners may however only use worked examples as templates to be followed using different inputs, rather than as demonstrations of how to manipulate
representations, to transform relationships, or to synthesise facts to achieve solution (Anthony 1994). For example, the processes of elimination and substitution essential to solving simultaneous equations may be lost in the detail of “multiplying and subtracting”.

There has been much debate about the usefulness of including counter-examples in students’ experience. In some studies, counter-examples appear to be helpful in focusing students on what is relevant and what is irrelevant; in other studies, the role of counter-examples appears to confuse students who do not understand how or what it refutes (Zaslavsky and Ron, 1998).

**The extent and extension of example spaces**

There is a special kind of counter-example, referred to by Askew and Wiliam (1995): ‘The ideal examples to use in teaching are those that are only just examples, and the ideal non-examples are those that are very nearly examples’ (p. iii). Our searches for such examples have led us to develop the more general notion of boundary examples. For example: if a general straight line is given as \( y = mx + b \), then lines of the form \( x = a \) may be excluded from students’ experience because they are not expressed in the general form; consequently teachers have to introduce these deliberately in some way. We call \( x = a \) a boundary example for straight lines expressed as \( y = ax + b \).

We use the word ‘boundary’ because we see students’ experiences of examples in terms of spaces: families of related objects which collectively satisfy a particular situation, or answer a particular mathematics question, or deserve the same label. Such spaces appear to cluster around dominant central images.

For example, some mathematics postgraduates all offered \( |x| \) as a function which is continuous but not everywhere differentiable but they needed considerable prompting to extend their images and provide other examples. When asked for a second example most translated \( |x| \); on being asked for a third example some commented (excitedly!) that a vast number could be generated from \( |x| \); others searched for very different examples and reported looking for other central images from which to work, such as an image of a curve becoming a straight line. None of them tried to construct anything solely from definitions. A group of mathematics graduate teacher trainees nearly all drew segments of circles when asked to give an example of an image for a quarter; a few gave sections of rectangles; one wrote \( 1/4 \); none gave a point on a number line. Only after coaxing, critique and discussion did other images arise.

**Student-generated examples**

Waywood (1992) encouraged a metacognitive shift by asking students to write journals which included collections of examples. He detected a range of responses from the inclusion of examples copied from other sources, through the use of examples to demonstrate an application or use or illustration, to the construction of annotated examples to summarise aspects of a topic or idea. Over time, his students progressed towards the personal construction of examples. In the two incidents
described just before this section, students worked on extending their example spaces by generating more examples for themselves. In the process, they had to think about the meaning of concepts and draw on experiences which had not readily come to mind.

There is a growing body of work in which the use of student-generated examples is advocated. Mainly these are for assessment purposes, to motivate interest in a topic, or to give students the opportunity to pose their own problems in the hope that this will make them better able to solve problems posed by authorities.

Contextual questions created by students are motivating for the producer and also likely to relate more closely to the experience of other students. Shifting the responsibility for test construction and problem posing from teachers to students can have clear affective gains, and necessarily involves some review of material used. Ellerton (1988) comments that the questions and examples produced by students generally reflect what they are used to from their teachers’ styles. Further, experience of problem-posing enabled some students to ‘reason by analogy’ when presented with similar questions (English, 1999).

But the ability of students to create and answer questions which are dissimilar from those previously experienced would be a more powerful indicator of mathematical learning. Silver and Cai (1996) working in urban middle schools with ethnically and linguistically diverse populations in economically disadvantaged communities, found that their students could indeed create complex problems involving several relationships or challenging given constraints if they had appropriate support. In their study, active extension of the example space of possible questions took place, moving students away from the centrality of the teacher’s example as dominant template.

**Use of SGEs for concept development**

A few writers use SGEs to promote conceptual development of new mathematics rather than primarily for motivation or assessment. For example, Sadovsky (1999) challenges her students to exemplify division operations which give a dividend of 32 and a remainder of 27. She asks ‘How many are there? If you think there are less than three write them all down, and explain why there are no other ones. If you think there are more than three write down at least four of them and explain how other solutions can be found’ (p. 4-147). One outcome of her study, whose main aim was to explore algebraic shifts, was her conclusion that ‘... these problems are simultaneously a chance to find the limits of arithmetic practices and to enrich the conception of Euclidean division’. But concept development through exemplification need not be an incidental effect; it can be an explicit pedagogic aim. Sowder (1980) reports using the prompt ‘Give me an example, if possible, of ........’, with the teacher taking responsibility for guiding students towards peculiar examples as an integral component of concept construal. Dyrszlag (1984) suggests asking learners to give
examples as a way of expressing their own understanding of a concept, and thus affecting future learning. Zaslavsky (1995) asked students to ‘find an equation of a straight line that has two intersection points with the parabola y = x² + 4x + 5.’ Attention was thus directed to features of a parabola and a straight line, rather than to algebraic or trial-and-error techniques for finding intersections. Each strategy led to further questions such as ‘find an equation of a straight line which does not intersect twice with the parabola….’ Students encountered most of the analytical geometric syllabus, engaging with the structures and equations of straight lines and parabolae through their own examples.

A particularly interesting account of the use of exemplification for conceptual understanding is given by Dahlberg and Housman (1997). They asked their tertiary students to give examples and counter-examples of analytical concepts as well as their own explanations, having previously been given only formal definitions. Students who consistently employed example generation as an integral part of their learning strategy, even when not specifically prompted to do so, underwent more shifts of concept image, could give better explanations, developed broader example-spaces and hence had a more complete understanding of the taught concept. “Example usage, particularly example generation and verification, is crucial for understanding a new concept.” (p. 284). These reports fall far short of the practices described by Brown and Coles in several accounts (e.g. 2000) in which students raise mathematical questions and examples as a natural part of their classroom discussions.

Is it realistic to expect all students to be able to generate examples of newly-met concepts? Students in a low-attaining year 9 class were nearly all able to produce examples of a variety of mathematical ideas when asked, having become used to being asked for these by a teacher during only three lessons. Sometimes, unexpected examples would be produced which had been constructed rather than recalled from previous lessons. On one occasion, a student responded to the question ‘do you know what a prime number is?’ by offering a non-example with its factors and saying ‘you can’t do that with prime numbers’.

For a few years we have been working on ways to characterise teaching actions which engage students in active reorganisation of knowledge structures or creation of mathematical objects. The purpose of such characterisation would be to give teachers access to a range of strategies which they may adapt and develop, while recognising that every individual teacher’s practice is particular to them (Watson and Mason, 1998). Many of the teaching approaches we have observed can be described as offering opportunities for extending personal example spaces.

---

1 A translation of Dyrszlag’s suggestions, provided for us by Anna Sierpinska, can be found in Watson and Mason (1998 p31)
The individuality and situatedness of example spaces

When we consider a concept, a paradigmatic image might come to mind and, as we have already suggested, this image might have special features which make it rather less general than we would hope. For instance, a rectangle with sides parallel to the edges of the paper appears when someone says "quadrilateral", a unit fraction appears when someone says "fraction", a decimal number including lots of 9s appears when someone asks for a number very close to 1. Some of these dominate because they have been presented frequently to learners through texts, others because of recent exposure. For some learners, central images have an affective dimension: they might be associated with a favourite teacher, or a particular memory of a page of a textbook. Hence, although a significant number of a group of teachers drew 'page-parallel' rectangles with sides roughly 2:1 when we asked them to draw a quadrilateral, because it is a dominant image in (and outside of) mathematics texts, not everyone did. For some, other influences were brought to bear. Their experience of mathematics, and of us, led them to be more creative or devious in what they drew. Some drew a square, because their interpretation of the task was that something very special is required; some felt too insecure to draw anything because they did not know the success criteria. We then asked them to draw further quadrilaterals which satisfied more ands more constraints, structuring our request so that eventually they had to abandon their rectangles and construct shapes from properties, rather than just searching through their existing categorisations and figural examples.

What comes to mind for individual learners when working on known concepts, or when asked for examples of mathematical objects, can relate to dominant or figural images in the topic, but can also be influenced by past experience, preferences, interpretations of what is required and what is valued. The teacher trainees who drew segments of circles as fractions may have been interpreting the task as about offering images to their students; or believing that an image had to be a picture. The postgraduates offering \(|x!|\) were giving it as a starting point for whatever was to come, not as an illustration of their total knowledge.

Similarly, how dominant images provide access to other examples and images varies from person to person. We asked a group to find families of quadratics which have the same 'inter-rootial' distance. One, a secondary mathematics educator, imagined a family of quadratic curves, all the same 'shape', related to each other by lateral translation and then paused, hoping to find something else as well. Another, who worked much of the time with dynamic images, saw these as essentially the same curve. For him, the family of translations was one example, not infinitely many. His focus was on generating curves which were different shapes but were all 'pinned' at two fixed points on a notional x-axis. Both of these knowledgeable mathematicians knew about all the curves that would have this property, but their senses of what

---

2 We define 'inter-rootial distance' as the distance between the roots along the x-axis
could be varied and how to vary it were different because of their different ways of working in that moment. Their examples were the same, but they were in differently structured spaces in terms of relations between examples.

These stories from our experiences of working with others illustrate the potential for variety in the examples, and their structuring, which are evoked in response to teachers' prompts. From these and many similar experiences we deduce that example spaces come into being in response to prompts, and are differently structured, with different contents, for different learners, at different times and in different contexts.

**Extending example spaces**

Individual spaces, situated by time, place, people and prompt, provide the starting point for students' work. Even with a new topic, there are connections with previous knowledge which will bring images and examples to mind. Whatever the teacher says, students will work with their own example spaces, and they will try to fit what is said into them. Sometimes learning involves restructuring the contents of such a space; sometimes learning involves extending the space to include new items. Consider this prompt: *Find two numbers such that the square of the smaller is larger than the square of the larger.*

For some students this may well be a mystery, because their example spaces of numbers only include positive integers; in order to answer this they are going to have to begin extending it to include some other numbers – but what other numbers? Responding to this prompt might lead to positive numbers between 0 and 1, but it might also raise the question of what is meant by 'smaller' and 'larger' when negative numbers are considered. The search for two appropriate numbers, probably aided with a calculator and number line or graph, encourages an extension of the example space which may be lasting for some students, or ephemeral for others.

The prompt to find functions with the same inter-rootal distance can lead people to try to restructure their example spaces, some wishing to remove the limitations of fixed axes from their spaces, others wishing to see curves as representing an infinite number of translated versions of themselves from now on.

**Conclusion**

We have illustrated how seeing teaching/learning mathematics as creation and extension of personal example spaces can inform the construction of tasks in which students can work directly on their own mathematical structures and relationships. Achieving competence in mathematics can be seen as the development of complex, interconnected, accessible example spaces.

This report focuses on one aspect of a larger study of school students' understanding of statistical variation. Although the study included students in grades 3, 5, 7, and 9, this paper will focus on grade 5 students only. Students experienced a unit of 10 lessons on the chance and data part of the mathematics curriculum conducted over an eight-week period. Lessons included a particular emphasis on variation and its role in statistical understanding. Pre- and post-tests were administered and improvements were found in overall performance and for variables reflecting appreciation of variation in chance, variation in data, and variation in sampling. Some comparisons are made with grade 3 students' performance.

INTRODUCTION

Variation is an important element in the basic understanding of statistics (Moore, 1990), yet many middle school students have little understanding of what constitutes appropriate variation. Partly because of the complex formula traditionally used to measure variation, educators and curriculum developers tend to avoid it at this level. As a result, students usually do not encounter the concept of variation or its applications until senior level mathematics in school or university statistics courses. Until this time there is a tendency to focus on centers with little regard for spread or variation within data sets. It is possible, however, to help primary school students reach a broader appreciation of variation without the computation of complex formulas. In a related investigation by the same researchers (Watson & Kelly, 2001) it was shown that students as young as grade 3 could develop a foundation for the understanding of some aspects of statistical variation. Although this understanding was limited, it was hypothesized that slightly older students, with the same instruction and materials, could gain a firmer grasp of the concepts involved.

The data used in this study were part of a larger project designed to model development of, and monitor change in, students' understanding of statistical variation in grades 3, 5, 7, and 9. This report will focus on the change in understanding following instruction for grade 5 students, comparing improvements with grade 3 students in the same study (Watson & Kelly, 2001). Similar patterns of improvement and an understanding at a slightly higher level were expected.

SAMPLE AND TEACHING UNIT

The sample of grade 5 students in the present study consisted of 82 children from three primary schools in the Australian state of Tasmania (n = 35, 31, and 16). Students were taught 10 lessons covering aspects of the chance and data curriculum with a special emphasis on variation. All lessons were taught by the same experienced teacher, provided by the research project.
The first lesson was an investigation of a small packet of coloured chocolates called Smarties™. Students were asked to investigate the contents of the packets in pairs or groups and develop column graphs to show the number of different colours in each box. Whole-class stacked dot plots were created from the individual graphs and these were compared against the data collected in individual pairs. Lesson 2 was about “People in a Family” (Russell & Corwin, 1989), and students recorded the number of people in their families. Once again, different types of graphs were created; people graphs, linked blocks, and paper-and-pencil graphs were used to display the information. The types of information that can be obtained from such representations, the general shape of the graphs, and the existence of outliers were discussed during this session. The third and fourth lessons dealt with equiprobable events using spinners and dice, and non-equiprobable events using two dice. The activities allowed students to compare class graphs and discuss the shapes of graphs generated from one die with graphs generated from two dice (Edwards & Hensein, 2000). Variation was a strong theme during these sessions, linked with discussions of the theoretically expected outcomes. Lessons 5 and 6 were related to sampling and the first was introduced with a discussion of what constitutes a sample. Activities included selecting randomly drawn samples from the classroom and predicting to the wider classroom population. The issue of fairness and the idea of predicting from a sample were the most difficult concepts for students to grasp.

The final four lessons were designed to introduce students to experimental methods. In lessons 7 and 8 students investigated how long they could stand on each foot with their eyes closed (Rubin & Mokros, 1990). The two data sets (for left and right feet) were then represented on a whole-class-generated stacked dot plot for discussion and analysis. Students focused on clumps, outliers, common scores, range, and the differences between the two sets of data. The final lessons followed on from this and gave an opportunity for students to plan and conduct their own experiments. All students were told they would be given a pencil, measuring equipment, and a recording sheet, and would be asked how far the pencil could be blown across a flat surface. Each class then had to decide on a question and develop a hypothesis. Most classes focused on possible differences between boys and girls, sports players and non-sports players, and so on. Even though the analysis of the data required a great deal of teacher direction, the students conducted their experiments efficiently. Once again, discussions focusing on differences, common scores, outliers, and the shapes of the graphs reinforced the notion of variability in the data sets.

**SURVEY INSTRUMENTS AND ANALYSIS**

The pre- and post-tests consisted of the same 29 items, covering four aspects of the curriculum as emphasised in the teaching unit: Basic Chance and Data, Chance Variation, Data Variation, and Sampling Variation. The items on Basic Chance and Data were adapted from the studies of Watson, Collis, and Moritz (1997) involving dice and coloured marbles, of Torok (2000) involving spinners, of Watson (1998) involving basic table reading, and of Watson and Pereira-Mendoza (1996) involving
reading pictographs. For Chance Variation there were items involving spinners over many trials developed by Torok (2000), as well as a question concerning the prediction of outcomes for 60 tosses of a die. Data Variation was assessed through pictograph items adapted from Watson and Pereira-Mendoza (1996), as well as three items asking for comparison of two differently scaled stacked dot plots representing the same data on how long students in a class had lived in town (Konold & Higgins, in press; see Figure 1). The items asked students what they could tell from each of the plots and then asked for a decision as to which stacked dot plot told the story better. Sampling Variation items included giving a definition of “sample”; suggesting a method of sampling, and evaluating the bias in four sampling methods, for the “raffle scenario” of Jacobs (1999); and suggesting a fair way to select students to lead a parade in the context of the table reading items of Watson (1998). For a more detailed description of the items and their contribution to the four variables (Basic Chance and Data, Chance Variation, Data Variation, and Sampling Variation), refer to Watson and Kelly (2001).

Figure 1. Stacked dot plot problem from Konold and Higgins (in press).

The post-test was administered approximately seven weeks after the completion of the teaching units. Five variables were defined, representing the four aspects of the curriculum covered in the subscales described above, and the total score for the test. The scoring for each item ranged from 0-1 to 0-5 depending on the potential sophistication or complexity of the response. Of interest in this study is the change, potentially the improvement, in scores from the pre- to the post-test and the improvement of performance as compared to the grade 3 students. Paired t-tests were performed for the five variables (n = 82). The tests for grade 3 were the same as for grade 5 except that they did not include the three items on stacked dot plots (Konold & Higgins, in press) or one of the biased sampling items (Jacobs, 1999).

RESULTS

Pre- and post-test means and standard deviations for the five variables defined for the grade 5 students are given in Table 1. As can be seen, there is a statistically significant improvement for the three themes of variation and on the overall total. The paired t-test for pre- and post-tests for the Basic Chance and Data variable was not significant. The maximum possible score on this variable was 16 and as can be seen, the grade 5 mean pre-test understanding of Basic Chance and Data was relatively high. The non-significant change may have been due to a ceiling effect.

For the Chance Variation variable students improved on 3 out of the 4 spinner items. Two items showing significant differences required a prediction of how many times the spinner would land on the shaded part out of 10 spins and asked how many spins landing on the shaded part out of 10 would be surprising. In response to the first, a student in the pre-test wrote, “6 times, [because] you spin and hope it will come up”, whereas in the post-test she used a more theoretical prediction, “5 times, because they have an equal chance.” A few grade 5 students on the post-test were able to expand on this and acknowledge the role of variation. An optimal response was “4, 5, or 6, because it would land on the shaded part approximately half the time.” On the spinner item that asked for a prediction of a shaded outcome for a 50-50 spinner spun 10 times on six different occasions, one initial response indicated a strict probabilistic view (“5,5,5,5,5,5”), whereas the corresponding response on the post-test acknowledged the potential for variation over the six trials (“5,3,6,4,7,5”).

For the Data Variation variable, all three items comparing the two differently scaled stacked dot plots in Figure 1 revealed a significant improvement from pre- to post-test. One student, for example, in the pre-test responded by reading the data on the first stacked dot plot incorrectly; she wrote, “Most people have lived here one year, and the person who has been here the most has been here for four years.” This student mistakenly read the X’s on the stacked dot plot to be the years (instead of people) and the numbers on the horizontal axes to be individual people (instead of years) even though it was labelled. The same student responded in the post-test by stating “3 years has the most; and, 0, 1, 4, 5, 6, 10, 10 have one X on them.” Although this student did not put the data into the full context, she read and interpreted the horizontal axis correctly, an improvement over the earlier response.

The pictograph items, part of the Data Variation variable, showed no improvement on the post-test. Of interest was the item about the gender of a new student if the new student arrived by car, which required students to make an inference based on the data presented in a pictograph. Statistical reasoning based on the observed majority (girls), accompanied with an element of uncertainty, for example, “Girl, I don’t know [why], I’m having a guess … because there is more chance of it being a girl,” was shown by only 1.2% of grade 5 students on the post-test. None answered like this on the pre-test and the majority of students both times responded by
focussing on patterns in the data, with no emphasis on uncertainty or observed majorities. The possible reasons for this are discussed later.

For Sampling Variation, there was a significant improvement in performance on five of the eight items: judging two of the survey methods presented in the ‘raffle scenario’, choosing the best survey method out of the four presented, defining a sample, and suggesting fair selection methods for students to lead a parade. Overall, students demonstrated a better post-test understanding of what a sample is and applied this knowledge to examine critically the survey methods presented and suggest methods of selection on their own.

Table 2 shows the means and standard deviations for grades 3 and 5 for the variables defined from the subset of the 25 common items completed by both grades. As can be seen, the grade 3 students improved significantly on the Basic Chance and Data variable, whereas the grade 5 students improved very little. The grade 5 pre-test mean, however, was significantly higher than the grade 3 post-test mean (p<0.001) and as noted there may have been a ceiling effect for grade 5. Similarly, for the common items in the Data Variation variable, grade 3 students improved significantly whereas the grade 5 students showed no improvement. Again the grade 5 pre-test mean was higher than the grade 3 post-test mean (p<0.05), but this difference was not considered meaningful given the small number of common items.

*Data from Watson & Kelly (2001)

The Chance Variation variable showed a significant improvement for both grades 3 and 5. The grade 5s performed at a higher level than the grade 3s in both the pre- and post-tests but the post-test mean for the grade 3 students was equivalent to the pre-test mean of the grade 5 students. The analysis of the Sampling Variation common items showed a significant improvement from the pre-test to the post-test for both grades 3 and 5, with greater improvement for the grade 5 students.

DISCUSSION

Two aspects of the outcomes of the research with grade 5 students will be covered in this section: the overall improvement in their performance following instruction and their performance relative to that of grade 3 students. Finally some suggestions will be made for future research.
The improvements observed for the variables reflecting the three themes of variation are almost certainly a result of exposure to experiences reflecting variation in the chance and data lessons taught. The Data Variation variable showed a significant improvement only when the three items from Konold and Higgins (in press) were part of the variable. The improvement on all three items provides evidence of the emphasis on collecting and displaying data in stacked dot plots within the teaching unit presented. Lessons 7 to 10 dealt explicitly with gathering data and generating stacked dot plots from the data. In relation to this, Konold and Higgins state that it is important for students not only to be able to read and interpret data from graphs but also to be able to refer the data back to the context in which they are set. An integrated and optimal response to this item would thus include the context of the question (i.e., how long students have lived in town). In response to the second stacked dot plot, one student, after incorrectly reading the plot in the pre-test, responded in the post-test by saying, “A lot of people have lived in the town between 0 and 5 years.” This post-test response not only summarizes the data correctly, but also refers the data back to the context within which the task is embedded, as is recommended by Konold and Higgins.

The greatest improvement occurred in the variable measuring Sampling Variation. Lessons 5 and 6 of the teaching unit focused specifically on sampling. In the first session the students demonstrated pre-instructional knowledge of sample through giving examples encountered in everyday life. Anecdotal evidence from videos of the lessons indicates most students had a good intuitive basis on which to build an understanding of sample (e.g., “a lady giving out food in a supermarket”; “a doctor takes a sample of your blood”). Jacobs (1999) in her study of students in grades 4 and 5 found a similar occurrence, stating that her students had a sound knowledge of sampling before instruction began and were using examples containing elements of statistical samples when asked for a definition. The objective of the formal work with students in this study was to improve on the developing understanding of sample by putting it into different contexts and highlighting its potential for description and prediction. The results in Table 1 highlight the significant improvement in the understanding of sampling after the teaching unit.

In comparison to the grade 3 students, the grade 5 students performed at a higher level on the Basic Chance and Data variable and on the common items in the Data Variation variable, even though they did not improve significantly after instruction (Table 2). Anecdotal evidence from preliminary analysis of grade 7 and 9 data shows that the pre and post means for these grades were equivalent to or slightly lower than those reported for the grade 5s, supporting the idea of a ceiling effect for these items. The lack of improvement on the common items for Data Variation for grade 5, however, may be related to mathematical experiences in the classroom outside of this study. On the tests the items used were based on interpreting a pictograph, whereas during teaching stacked dot plots were used more frequently. Patterns of various types (e.g., girl, girl, boy, girl, girl, boy) were present in the pictograph data and recognising such patterns as significant is part of most primary
school mathematics programs. Responses to the pictograph items often reflected pattern recognition and whereas for grade 5s this was consistent across the pre- and post-tests, for grade 3 it occurred more in the post-test indicating an "improvement" from not being able to interpret the graph at all. The lack of specific discussion of pattern and pictographs during the lessons meant that students were not specifically encouraged to move beyond this level in either grade. For the grade 3 students—who were just starting graph reading and interpretation—any experience during the lessons was helpful in improving their performance. Grade 5 students had previous experience and began at a slightly higher level on the pictograph interpretation tasks. The lack of discussion of pictographs meant their performance did not change on these items (Table 2) but they reacted well to stacked dot plots, and hence improved on the Data Variation variable with more items (Table 1).

In relation to the Sampling Variation subscale, grade 5 students made a larger absolute gain in this area than the grade 3 students. Students in grade 3 had good out-of-school experiences (e.g., were able to give reasonable examples of a sample) but struggled with making inferences from samples to populations (Watson & Kelly, 2001). This made it particularly difficult for the grade 3 students to choose which of the survey methods was the best in the "raffle scenario". Perhaps the greater initial understanding demonstrated by the grade 5 students led to adopting the concepts and applying them to an unfamiliar context with greater ease and to an improvement in the ability to judge the more appropriate survey methods.

Overall, the difference in average levels of performance favouring grade 5 students over grade 3s would be expected due to their greater time in school and experience in everyday life, as well as their potentially greater levels of cognition and better ability to comprehend the objectives of the lessons. Although the teacher made every effort to conduct each lesson on the same topic in a similar fashion, student input sometimes influenced the direction of the lessons. In grade 3 this sometimes resulted in the reinforcement of ideas already presented, and for the grade 5 students it sometimes led to an extension of the original ideas. All in all, what was encouraging was that within the expectations for the grade levels, both groups improved in their understanding of aspects of variation with chance and data.

Three directions for future research are suggested by the outcomes of this study. First is an analysis of how much transfer is to be expected between the content of the lessons taught and the content of the pre- and post-tests. Obviously, using identical content in the tests and lessons is likely to lead to statistically significant but educationally less useful results. On the other hand if the differences are too great, as perhaps was the case with pictographs and stacked dot plots, then some alterations need to be made after clarifying objectives. Second, research into the performance of other groups after instruction would increase the depth of understanding of how elementary and middle school children understand variation. Are there differences in the impact of instruction between private and public schools in pre and post understanding? Do samples from other countries that perceive chance and data to be
important behave similarly to this Australian sample? Is there a universal developmental pattern emerging for a concrete understanding of variation in chance and data concepts? Third, there is the issue of using classroom teachers as the conveyors of the lessons in future research. In this study, classroom teachers were reluctant to organise and teach lessons themselves. Since teachers’ own competencies and understanding of the topic are important determinants of the successful teaching of that topic, professional development is strongly advised for those taking part. Teacher attitude, enthusiasm, and topic knowledge, may affect pre-post results.

REFERENCES

This paper draws together the findings of a series of probability studies with students aged 11 to 14 years and incorporates new data not previously reported. The collective data emphasises the fragility of probability notions and the strong effect of confirmation or refutation of outcome 'predictions' on probabilistic reasoning. Although some evidence of development of probabilistic reasoning with age was found, instruction appears to have a positive effect. The studies confirm the usefulness of videos of seemingly random experiments as research tools.

INTRODUCTION

Probability remains a pedagogically problematic topic in mathematics education at both primary and secondary levels. While the topic is recognised as being important in some countries (for example; USA, National Council of Teachers of Mathematics, 2000), there is enough concern about the efficacy of teaching the topic that it has been downgraded or even omitted in other curricula (UK, Department for Education and Employment, 1999; New South Wales Department of Education, 1998 respectively).

Much work in several avenues of inquiry is still needed:

1. Information about specific probability concepts and decision-making strategies and their relationship to other mathematical concepts and processes.

2. A coherent framework of the development of probabilistic thinking, which will support assessment procedures.

3. Development and evaluation of instruction programmes for the classroom.

In recent years, work in each of these three areas has begun to overlap productively (e.g. Fischbein and Schnarch, 1997; Jones, Langrall, Thornton & Mogill, 1996, 1997, 1999; Watson, Collis & Moritz, 1997). The ultimate goal of most educational research is to inform classroom practice, and research in this third area is long overdue. However, we are far from achieving a complete model for the development of probabilistic thinking, and researchers are still discovering new information about children's perceptions of probability situations and their patterns of thinking.

Understanding of probability involves the integration of several concepts, including randomness, ratio and proportion (the structure of the sample space) and likelihood of particular events. In children, the connections between these concepts, when made, remain tenuous and can be adversely effected by occurrences that challenge their thinking (Jones, Langrall, Thornton & Mogill, 1997, 1999). For example, a child might appropriately state the most likely outcome of drawing a specified object from a box, based on either knowledge of the sample space or on a known set of previous
outcomes, only to have their 'prediction' refuted by the next draw producing the least likely outcome. While the expectation that the long-term distribution of outcomes would be representative of the sample space is appropriate, believing that a small set of outcomes should be representative is inappropriate. This notion of representativeness has received much attention (Amir, Linchevski & Shefet, 1999; Fischbein & Schnarch, 1997; Shaughnessy, 1981), yet the quite commonly occurring scenario described above has not. The dramatic effect it can have on children's fragile probabilistic thinking is just being realised (Proposed by Truran, 1996) and confirmed by Ayres & Way, 1999, 2000).

A major hindrance to probability research with children is, ironically, randomness itself. In other areas of mathematics the concrete experiences needed to support children's learning can be prepared and predetermined. However, when engaging children in probability experiments and games, the outcomes naturally remain unpredictable. With adults and adolescents this difficulty is overcome by providing hypothetical situations and lists of outcomes, but a less abstract approach is generally desirable for children. A surprisingly little used solution is to create videos of seemingly random experiments. This enables researchers and educators to present predetermined and consistent experiences to different groups of children at different times.

This paper reports on a number of linked studies that have utilised this technology. A series of studies has been conducted by Ayres and Way (1999, 2000, 2001) with Australian students aged 11 to 14 years to investigate particular aspects of their understandings of probability. Although each of these three studies contained a new element of investigation, all of them included a common experience in the form of a pair of pre-recorded videos depicting a series of apparently random draws from a box of balls. From 1999-2001 we reported the results of these studies at various stages of completion. However, in each case, additional data was collected which was not previously reported. Consequently, the new data has enabled us to conduct further analysis, as well as more consistent statistical testing, on a larger sample size. This paper focuses on the new and consolidated findings.

**Video recordings as a research instrument**

The major research tools used in the studies were video-recordings. Two videos were made which featured a presenter making thirty selections of coloured balls from a box, with replacement. In each video, 19 whites (63% of the total selections), 7 blues (23%) and 4 yellows (13%) were drawn from the box. For each group of five selections, the total number of whites, blues and yellows balls that occurred were identical for both videos. Consequently after each set of five selections the progressive experimental probabilities of each colour occurring were identical. However, for the 6th, 11th, 16th, 21st and 26th selections, the colours varied according to the video. For one video, which we called the *typical sequence video*, a white was selected in four of these five positions. For the second video, called the *non-typical sequence video*, one of the less likely colours (blue or yellow) occurred in place of a white four times out of five. As students were required to predict the most-likely colour for the next draw after
observing the five previous selections, these differences were highly significant. Students who consistently chose the most frequently occurring colour (white) would be successful in their predictions if they viewed the typical sequence, but unsuccessful if they viewed the non-typical sequence. As a result of this design we were able to investigate how confirmation or refutation of success affected student choice.

Although the outcomes of these videos were manipulated and not random, it was expected that students observing these videos would believe that they were genuine random experiments. This was tested (see Ayres & Way, 1998a, 1998b) and found to be the case. Furthermore, over the whole series of experiments completed so far, no evidence has ever emerged that students doubted the validity of the videos. By controlling the colour sequences we were able to not only compare how students reacted differently to the two videos, but also see how different groups of students reacted to the same videos. Consequently, it was possible to make meaningful comparisons across studies, as the instruments are identical. A major empirical difficulty in conducting probability experiments of this nature is that random generators produce random outcomes. Video-recording techniques, such as the one described here, can overcome this problem.

RESULTS

Prediction analysis

For each study, students observed one of the videos and were asked to make six predictions. Students were told that the prediction tasks were a game and they should try to predict as many correct colours as possible. Because the selection of white (the most frequent colour) was considered an important statistic, as it indicated probabilistic reasoning, the number of whites chosen was reported in each study. Furthermore, as students often changed their strategies over the course of the trial, prediction trends were noted by recording the number of whites chosen in the first and last three predictions. It should be noted that none of the participants in these studies had any formal classes in understanding likelihood, as probability was not part of the syllabus for these students.

1999 Study

The main goal of the 1999 study was to investigate how students were influenced in their probability judgements by confirmation or refutation of their predictions. Students from the same school participated from two grades (Grade 6, aged 12 and Grade 7, aged 13). Half the student from each grade observed one of the two videos. The mean number of white balls by group and location selected are reported in Table 1. The inclusion of the Grade 7 data, previously not reported, doubles the sample size and allows a 2x2 (grade x typicality) ANOVA to be conducted on the total number of white balls selected. A significant main effect for typicality was found; F (1,116) = 4.3, p < 0.05; indicating that the students who viewed the typical video selected white more times than those who viewed the non-typical video. No main effect was found for grade: F (1,116) = 2.5, p = 0.12.

*Data not previously reported

A notable feature of this study was how prediction strategies changed over the course of the task. For the typical group (Grades 6 and 7 combined), students chose significantly more whites in the second half of the task (final three predictions) than on the first (first three predictions) under a paired t-test: t (61) = 3.6, p < 0.01. In contrast, the non-typical group chose significantly less white balls for the second half compared with the first half under the same test: t (57) = 3.3, p < 0.01. These comparisons indicated that students who were being rewarded for choosing the most likely colour (typical group) continued more frequently with this strategy, whereas students who were not being rewarded (non-typical group), reduced their selections of the most likely colour.

2000 Study

In the 1999 study, students were not told about the sample space (ratio of the coloured balls in the box) prior to starting the trial. However, in 2000, the effect of knowing or not-knowing the sample space was investigated. The experimental design of the previous study was extended by subdividing further each of two groups who received either a typical or non-typical video into two subgroups, one of which knew the sample space and the other did not. In addition to the previously reported data on Grade 8 students, a cohort of Grade 7 students participated from the same school. This data is reported in Table 2. A 2 x 2 x 2 ANOVA (grade x typicality x sample space) was conducted. A significant main effect was found for grade: F (1, 100) = 15.5, p < 0.01; indicating that the older group of students selected more whites than the younger group. There was also a significant main effect for typicality: F (1, 100) = 12.6, p < 0.01; indicating that students who observed the typical video predicted more whites than those who viewed the non-typical video. However, there was no main effect for sample space: F (1, 100) = 0.2, p = 0.64; indicating that knowing or not-knowing the sample space made no difference to student predictions. No significant interactions were found.

Analysis of the prediction trends revealed that students who viewed the typical video had no significant difference in their choice of whites between the first and second three predictions under a paired t-test: t (53) = 0.2, p = 0.82. However, students who
viewed the non-typical video predicted significantly less whites during the second half of their predictions than the first half: $t(53) = 3.5, p < 0.01$.

**Interview data**

Twenty-four (three chosen at random from each cell in the study) of the 108 participating students were asked to give reasons for each prediction made. The four most frequent reasons given were: a) more white balls in the box (42%), b) the colours formed a pattern (22%), c) guessed (15%), and d) a particular colours turn to come up (15%). Students who stated that they chose white because there were more whites in the box were demonstrating probabilistic reasoning. However, the frequency of this response varied according to which video was viewed. By recording group means for the number of times this "more whites" reason was given a 2 x 2 (typicality x sample space) ANOVA could be conducted (grades combined). There was a significant main effect for typicality: $F(1, 20) = 6.5, p < 0.05$; indicating that students who viewed the typical video gave more reasons consistent with probabilistic reasoning than those who viewed the non-typical video. No significant main effect was found on knowing the sample space or not. By further analysing the “more whites” reason over the first and second three predictions made, a further difference was found. Students who viewed the typical video, gave the “more whites” reason significantly more times during the second three predictions (2.1) than the first three (1.1): $t(11) = 3.4, p < 0.1$; indicating that they became more convinced as the trial progressed. However, for those who viewed the non-typical video, no significant difference was found between the two phases: $t(11) = 1.1, p =0.31$. Although, "more whites" was offered as the reason more on the first 3 predictions (mean = 1.1) than the second 3 (mean = 0.8). Overall, the trends for the reasons given, consistently matched the predictions made.

**2001 Study**

The main aim of this study was to investigate the effect of instruction (small-group practical activities) on predictions. As reported previously (Ayres & Way, 2001), the
different instructional experiences and group dynamics affected student predictions when individuals responded to the *non-typical* video. In addition to this data, students were asked to give reasons why they made each prediction. The mean number of times the "more whites" response was given is recorded in Table 3. Although, knowing or not-knowing the sample space failed to reach significance, knowing the sample space produced higher means for both the number of whites chosen and the "more whites" reason, and suggested there may be a real effect for a larger sample. Furthermore, consistent with the other studies, there was a significant decrease in the number of whites chosen; $t(21) = 2.7$, $p < 0.05$, and the "more whites" reason; $t(21) = 3.5$, $p < 0.01$; from the first 3 predictions to the last 3.

**CONCLUSIONS**

The inclusion of new data and its analysis has strengthened and extended the findings of the 1999-2001 studies. Overall, the findings fall into three main categories. Firstly, it is clear that students in this age range appear to develop an understanding of likelihood with age, even without instruction. By choosing a high percentage of the most-likely colour throughout these studies, students have demonstrated some understanding of basic probability. Interview data, collected on students' reasons for particular predictions, have reinforced this conclusion. However, many misconceptions have also been observed. Notably, many students believe that colours that have not occurred for a while are then more likely to occur- "it's that colour's turn to come up". This **negative recency** effect has been observed in other studies (see Fischbein and Schnarch, 1997). Of particular interest has been the discovery that students often look for patterns. This finding, which is easily explained considering the emphasis placed on patterns in modern curricula, may make understanding randomness for students of this age, more difficult, especially if outcomes are displayed in pattern-like sequences found in these studies.

Secondly, students in this age group have a fragile commitment to using probabilistic reasoning consistently. The differing responses to the two videos have demonstrated this effect conclusively. Students, who viewed the *non-typical* video, switched from choosing the most-likely colour into strategies based around various misconceptions. In contrast, students who viewed the *typical* video tended to choose the more-likely
colour more often, as the trial progressed. Refutation or confirmation of 'prediction' is an important factor in this type of task.

Thirdly, instruction appears to have a positive effect. Students presented with the non-typical video after instruction, extensively chose the most frequently colour and argued that they did so because it was more likely. Nevertheless, this strategy still decreased for many students as a result of their predictions being refuted. However, of particular note, was the high number of whites chosen by the Grade 6 students compared with all other students in these studies, many of whom were older. In particular, students who were aware of the sample space had a mean score of 4.5 out of 6 - the highest score for any group in all three studies. Although, knowing the sample space or not, did not produce a significant difference when directly tested, it was done so only on students who received no instruction. It is feasible that following instruction, knowledge of the sample space may become more meaningful.

Further research directions follow directly from these studies. The previous studies were deliberately limited to one type of random generator, a particular sample space structure and two specified sequences of outcomes. However, future research could expand to include a wider variety of random generators, such as dice and spinners; a range of sample space ratios; and various sets of frequency data. The value of using video-recorded probability trials in such research has been established. Therefore, to enable the use of videos as instructional aids and/or assessment tools a range of videos could be developed. Using such videos, the effectiveness of instruction can be directly tested, as well as the types of instruction, and the influence of knowledge of the sample space.

Finally, in reference to the debate about inclusion of chance into school curriculum, it should be acknowledged that it is a difficult concept for young children to understand; nevertheless, our research suggests that students as young as eleven can benefit from instruction.

REFERENCES

Associations between mathematically insightful behaviour and student affect are studied. A tool is developed to identify this behaviour and study its association with positive affect. Mathematically insightful behaviour displayed by a collaborative pair of senior secondary calculus students is used to illustrate this tool and discuss a situation in which student autonomy, spontaneity and creativity accompanied positive affect. The tool builds upon the ideas of Dreyfus, Hershkowitz, and Schwarz (2001), the concept of 'flow' (Csikszentmihalyi & Csikszentmihalyi, 1992), and the identification of student engagement as they discover complexities (Williams, 2000).

INTRODUCTION

This paper illustrates associations that can exist between positive affect in students and the creative development of a new cognitive structure (a mathematically insightful process of abstraction). An analytical tool that simultaneously displays student cognition, social interaction patterns (Dreyfus, Hershkowitz et al., 2001) and affective indicators (Csikszentmihalyi & Csikszentmihalyi, 1992; Williams, 2000) was used. Attention to whether the dialectic interaction occurred in response to earlier dialogue within the interaction under study facilitated identification and analysis of student spontaneity and student autonomy. An interaction was seen to be more autonomous and spontaneous where the students within the pair responded to interaction from within rather than outside the pair. Where autonomous and spontaneous behaviours were exhibited, further analysis was undertaken to find evidence of creativity. The simultaneous display of affective indicators 'made visible' associations between engagement with the task and students' autonomy and spontaneity in the process of 'abstraction' (Dreyfus, Hershkowitz et al., 2001). It is recognised that the cognitive artefacts students assemble during the creative process could include strategies, ideas and concepts that relied upon contributions from individuals external to the group prior to this interaction. In relation to the interaction under study, these previous influences contribute to the cognitive artefacts students assemble (Dreyfus, Hershkowitz, et al., 2001). The extent to which an interaction is seen as creative in this study depends partly on the spontaneity with which students assemble these artefacts and the students' prior knowledge of their relevance.

David Clarke’s comments on an earlier version of this paper led to my further clarification of some ideas.
Student alienation with school is an issue of current concern (Marks, 2000) and one solution is to create enhanced learning situations where positive affect is linked with new learning (Csikszentmihalyi & Csikszentmihalyi, 1992). The presence of positive affect associated with mathematics learning has been identified in Nicholls' (1983) task-centred rather than ego-centred learning. The characteristics of students undertaking task-centred learning can be seen in instances of learning through 'discovered complexity' as identified by Williams (2000). Discovered complexity occurs during task completion where a group of problem solvers perceive intellectual and conceptual complexities not evident at the commencement of the task. When a complexity is discovered, the group spontaneously formulate a question that leads to higher level thinking (analysis, analytical-synthesis, synthesis, and evaluative-synthesis) in the domain of mathematics. The resolution of the question leads to an abstraction associated with this complexity. Both Nicholls (1983) and Williams (2000) linked student learning accompanied by positive affect to 'flow' (Csikszentmihalyi & Csikszentmihalyi, 1992). Flow is an optimal learning condition that may occur when a person works just above their present skill level on a challenge almost out of reach. Individuals or groups in flow become so engrossed with the task at hand that they lose awareness of self, time and the world.

![Diagram](https://example.com/diagram.png)

**Figure 1. Representation of associations between discovered complexity and flow**

Williams (2000) illustrated the fit between discovered complexity and the conditions for flow by modifying the schematic representation (Figure 1) developed by (Csikszentmihalyi & Csikszentmihalyi, 1992). A student's perceived level of skills and concepts and perceived challenge comfortably overcome are represented by A and M respectively. Students in flow are seen as working to achieve a goal represented by a point within the shaded region of flow (B, N). This goal is just above their perceived skills and concepts level and involves a challenge perceived to be almost out of reach (flow). Once this goal is achieved, each student’s perceived skills and concepts level is B and they can comfortably achieve a challenge of N. The shaded region representing flow is now located to the right of B above N between the parallel lines. To sustain flow would require a discovered complexity that led to a goal represented by a point like (C, P).
By definition (Williams, 2000), the mathematical ideas in a discovered complexity are new to all students in the group and the teacher does not contribute new mathematical ideas during the interaction. Before the present interaction, other class members, the teacher, or another source may have contributed to the cognitive artefacts the students chose to assemble. In such situations where the student group develops new concepts through discovered complexity, the type of student response described is seen to be partially attributable to the task and the implicit pedagogical approach (Williams, 2000). The process students enact when working with discovered complexity is an insightful process of autonomous, spontaneous, and creative abstraction similar to the activity described by a research mathematician (Chick, 1998). Dreyfus, Hershkowitz and Schwarz (2001) are interested in ‘abstraction’—an activity of vertical reorganisation of ‘previously constructed mathematical knowledge into a new structure’ (p. 377). (Vertical refers to a new mathematical structure as opposed to strengthened connection between a mathematical structure and a context (‘horizontal’)). They have diagrammatically represented a simultaneous display of cognitive activity and social interaction present during the abstraction process. Six categories of dialogue were used in the analysis of social interaction—control, elaboration, explanation, query, agreement and attention. Through analysis of the dialogue of participants as they undertake the social process of critical inquiry, the cognitive elements of the process of abstraction were made more visible. These nested elements of the process of abstraction as identified were: (a) ‘recognising’—seeing a previously known mathematical structure within a new context or realising a previously known mathematical structure fits a new context; (b) ‘building-with’—using a combination of previously generated abstracted entities in a new context; and (c) ‘constructing’—use of assembled resources to vertically re-organise a mathematical structure.

Figure 2: Relationship between nested elements of abstraction and discovered complexity

Figure 2 illustrates the relationship between discovered complexity, the activities of a research mathematician (Chick, 1998), and the epistemic elements in the abstraction process. In examining the process of creation of mathematical concepts,
Chick (1998) reported the presence of positive affect as strategies, ideas and concepts were synthesised to produce a novel mathematical insight about the complexities in a mathematical structure. This is consistent with Krutetskii's (1976) description of the mental activity of combining concepts to create a new idea.

Engagement in a task was monitored by Williams (2000) through observation of video data to identify indicators of positive affect: (a) eyes on the task; (b) pens on the task page or bodies leaning in towards the task; (c) unaware of the world around; (d) participating in the interaction; (e) students building on each others' ideas (latching comments); (f) exclamations of pleasure.

Analysis of what triggered each part of the dialectic interaction and the nature and source of the conceptual artefacts upon which students draw will facilitate the identification of insightful mathematical behaviour.

BACKGROUND ORIENTATION FOR THE ILLUSTRATIVE TRANSCRIPT

Three students, William, Talei and Gerard were videotaped working as a collaborative group to solve the unfamiliar challenging problem 'Understanding the Double Derivative'. The teacher selected the groups, provided the task sheet and stated that \( f''(x) \) meant the derivative of \( f'(x) \). Students followed a familiar classroom-working pattern; they worked in groups for twelve minutes then made their first brief report to the class as a whole. The interaction reported occurred eleven and a half minutes into group-work and continued for one and a half minutes.

In the previous twelve months, all three students had worked briefly with sign diagrams and extensively with gradients of curves in individual and group settings through investigation and exercises. The students had not previously encountered second derivatives. Gerard had not been exposed to the term 'curvature' in a mathematical context. Talei and William were working to mathematically formulate 'curvature' in another mathematics subject studied simultaneously (with another teacher). At the time of this research, they had not achieved their goal. The teacher made no reference to the idea of curvature or to the other subject.

![Graph of y = f(x)](image)

Figure 3: The shape of \( y = f(x) \) in the 'Understanding the Double Derivative Task'

The task ‘Understanding the Double Derivative’ required students to use the graph (Figure 3) as a starting point. By sketching the graphs of \( f'(x) \) and \( f''(x) \) and the sign diagrams to the three graphs and generating other information if they chose to do so, students were required to investigate links between \( f''(x) \) and \( f(x) \). The task sheet contained general suggestions and questions about possible ideas to explore but these were not prescriptive and did not provide hints or directions about specific ideas to explore, strategies to use or pathways to follow. They included questions...
and statements like: ‘What happens to key features on one graph in another graph?’ ‘Search for patterns and reasons why these patterns exist’. ‘Predict’. ‘Check’. ‘Is the f’(x) graph sufficient information to be able to generate the f(x) graph? Explain’.

Key to transcript: ‘1’ one individual completed or extended the previous statement (latch); ‘/’ one individual cuts across the statement of another (cut).

1 William: The shape. [Time 11 min. 30 secs.]
2 Talei: Uh hu.
3 William: To there.
4 Buzzer: [Denotes the end of collaboration time].
5 Teacher: [Begins to organise the reporting phase. No mathematical talk, just organisational. Continues simultaneously with interaction to Line 24]
6 William: Well if you look between there and there it is curving}
7 Talei: {Yes.
8 William: The curve is getting less and less}
9 Talei: {Yes ... it’s the gradient yes it’s}
10 William: {'till there which means it’s negative ... it’s steep}
11 Talei: {Yes}
12 William: {'till there when it starts to get more}
13 Talei: {So when the curvature is
14 William: and more}
15 Talei: {smaller but that’s
16 William: but what about between there and there ... what happens? Why is that?/
17 Gerard: /What are we going to talk about? Do you want/
18 William: /Why is that ... a positive?/
19 Gerard: /to talk?
20 Talei: It’s sort of ... that is ... that’s true .../
21 Gerard: /Do you want to talk?/
22 William: /It turns there but it doesn’t turn and go the other way ... it always turns the same way- THAT’S IT! [Moves his hand in the shape of a minimum turning point and watches his hand move]
23 Talei: Yes} [Smaller hand movement in the shape of a minimum turning point without appearing to see William’s hand movement]
24 William: {It’s positively turning that way. [Time 13 mins.]

By the eleventh minute, the group had found several patterns through the discovery of six successive complexities (Williams, 2001). William then commented ‘there must be something more’. William’s focus of attention on a level beyond searching for patterns and towards finding an over-arching reason for why these patterns occurred produced the implicit spontaneous focus question to another discovered complexity. It appears the pair were responding to an implicit question like ‘why do the patterns we have found exist?’ Gerard did not participate in this final collaboration because his attention was drawn back to the class task (and away from
the spontaneous question explored by William and Talei) by the buzzer (signalling the end of group-work) and the organisational comments of the teacher preparing students for the reporting session. For this reason, in this paper Talei and William have been described as a collaborating pair and Gerard as an outsider for this final one and a half minute interaction where ‘constructing’ occurred between Talei and William. William and Talei gave no indication that they were aware of the activity around them; they did not respond to the external attempts to focus their attention on the reporting process (buzzer, teacher, or Gerard).

Figure 4. Tool to aid identification of student autonomy, spontaneity, and creativity in the abstraction process (from Dreyfus, Hershkowitz & Schwarz; 2001; Williams, 2000)
DISCUSSION AND CONCLUSIONS

The analysis tool (Figure 4) used to explore associations between student affect and the creative process of abstraction is a diagrammatic representation displaying the cognitive, social, and affective features of the interaction. Numbers down the left hand side of the diagram represent the line of transcript. The shaded squares in the first column indicate the inferred presence of epistemic cognitive elements in the process of abstraction for the individual speaking in that line of transcript. The centre column contains a vertical line that separates the small circles representing those within the collaborating pair from those outside the collaborating pair. The numbered arrows indicate the individuals to whom the speaker appears to attend and the social interaction category to which those prior statements belong. The number of ticks in the grids on the right hand side provides an indication of task engagement. Arrows that cross the separating line in the centre column suggest less spontaneity and autonomy than when the arrows from members of the collaborating pair are directed to dialogue within the pair. By considering cognitive activity in conjunction with social interactions, inferences can be drawn about student creative behaviour. Where students are constructing and the social interaction pattern indicates students are responding only to sources internal to the group, the students display autonomous, spontaneous behaviour that may be creative. The pattern shown by the directions of the arrows from William and Talei (Figure 4, centre column) indicate the pair responded only to each during the interaction. William’s first statement is in response to the overall task and the pair’s discovered complexity within it (Q in Figure 4). They displayed numerous indicators of positive affect (Figure 4, right column) as this autonomous, spontaneous pair employed mathematically insightful behaviour whilst constructing a new mathematical insight. Evidence of creative behaviour exists and requires further exploration.

William explored the complexity by directing attention to a feature of a segment of the graph using common language to elaborate ideas (Transcript Lines 1, 3, 6 and 8 categorised as attention in Figure 4). The use of common language rather than precise mathematical language indicated the presence of an amorphous idea rather than a well-structured mathematical idea. Talei recognised the mathematical significance of William’s comment (Transcript Line 9); she synthesised the amorphous structure of ‘curvature’ she recognised as applicable and built-with this as she elaborated further (Transcript Line 13 & 15). Talei and William now moved their pen along the curve undertaking evaluative-synthesis between the f(x) graph (Figure 3) and f’(x) graph. Almost simultaneously they found the minimum point in f(x) (Figure 3) appeared to contradict their theory (the ‘but’ in Line 15 and 16). Their subsequent behaviour suggested they explored ‘Why doesn’t the minimum point on f(x) show as a key feature on f’(x)?’ William’s exclamation and comment framed partially in common language (Line 22) and Talei and William’s hand movements (Line 23, 24) provide evidence of vertical cognitive reorganisation.
A more detailed characterisation of the factors that contributed this student interaction would require exploration of factors such as classroom culture, task characteristics, and the teacher's introduction to the task. This brief illustrative example shows how this tool can be applied to distinguish between the processes of 'abstraction' in general and a subset of that process where student behaviour is spontaneous and creative. Further work is required to extend the tool to examine the nature of dialectic intervention from an 'outsider' who stimulates rather than inhibits spontaneity and creativity. The tool presents possibilities for examining such incidents and has been designed for use with the video and interview data in the Learners' Perspective Study of Year 8 Mathematics classrooms being conducted in ten countries.

REFERENCES

This paper presents a semiotic analysis of the (often claimed) potential of computer algebra systems (CAS) for enabling mathematical activity on a higher conceptual level than usual. Theoretical points are illustrated by an example from a development project in the context of a first-year university course on calculus. We also discuss how they may be used in 'a posteriori' didactical analysis.

DREYFUS’ POTENTIAL.

Broadly speaking, there are two main types of issues relating to the use of standard CAS, such as Maple or Mathcad, in undergraduate mathematics teaching:

- **Pragmatic issues**, concerning the competencies that students need in present and future mathematics-related practice, where CAS is or could be a relevant tool,

- **Didactical issues**, concerning the actual or potential impact of CAS-use on the students’ learning of mathematics.

In the first case, we are talking about needs for actual practice, such as solving concrete mathematical problems, while in the second case, CAS is viewed as a vehicle for learning.

We shall discuss, in this paper, the didactical aspects of Dreyfus’ potential, defined as the possibility that CAS may serve as follows:

The idea is for students to operate at a high conceptual level; in other words, they can concentrate on the operations that are intended to be the focus of attention and leave the lower-level operations to the computer. [Dreyfus (1994) p. 205]

The didactical interest of Dreyfus’ potential is rather obvious, in particular it is likely to reflect the ideal of most CAS-using university teachers. However, as it stands, it is exactly ‘an idea’ that may or may not ‘appeal’ to their colleagues, depending on their experience and personal preferences. In order to rationally discuss, plan, implement and document realisations of this idea, we need to formulate it in terms of a clear theoretical framework. In particular we need to clarify the notion of a ‘high conceptual level’ in its (potential) relation to CAS use in university education. This is where the analytic tools of semiotics come in; specifically, we draw mainly on Duval’s semiotic analysis of mathematical cognition (cf. the next section). Of course, we must also relate the theoretical model with actual practice; at the end of this paper, we give examples of how it may be used in didactical analysis and design based on semiotic variables.
SEMIOTICS AS AN ANALYTIC TOOL FOR DIDACTICS.

Duval (2000) points out three major cognitive functions related to the semiotic registers used in mathematics: representation (e.g. a graph representing a function), processing (e.g. computation with number symbols) and conversion (change of register of representation). Even though students do not acquire mastery of these functions separately, their separate analysis proves useful for our purposes.

Semiotic representations in mathematics do not 'represent' in the naïve sense: the entire discourse refers to...nothing other than its own signs (Rotman, 1988). Mathematical objects are created and invoked through semiotic representations (Sfard, 1999). Yet in many (if not all) mathematical contexts it is crucial not to confuse an object with a particular representation (Duval, 2000), e.g. not to identify a 'triangle' with a concrete drawing. In fact, particular representations are less important than the changes (processing, conversion) of such representations that might be effected, while retaining a representation of the object. A simple semiotic description of an individuals' conceptual image of an object can thus be said to be a class of representations invariant under some class of transformations (processing, conversion). These classes will typically be implicit for the learner, and will develop gradually through actual instances of representing, processing and converting, briefly, through semiotic activity. This provides a theoretical basis for the need that students engage in such activity using a wide range of relevant registers and transformations. It may, in particular, challenge the modern contempt of 'training exercises' to the extent these exhibit such variation – even if variation pertains only to processing. However, as pointed out by Duval (1995, pp. 45-59), many of the most interesting and persistent learning difficulties arise in the context of conversion. Hence the 'degree of freedom' of the individual with respect to conversion (coordination of registers pertaining to the same conceptual object) is essential for the individual's conceptual development (opus cit., p. 69).

In university level mathematics, patterns of relations among different conceptual objects are at the heart of the learning enterprise. To establish and develop such relations coherently, very specific forms of discourse – involving more or less formal uses of natural language in coordination with 'simple' semiotic registers – are needed. These forms may be classified as apophantic, expansive and reflective functions of discourse (opus cit., chap. II). While a 'high conceptual level' may be indicated in semantic terms, it is usually accompanied by (at least implicit) semiotic and discursive complexity, and so its realisation in undergraduate mathematics education is intrinsically linked to developing the students' degree of semiotic freedom within this larger discursive framework. This implies the need for a careful design of learning situations centred on specific discursive and semiotic functions, where the latter includes pertinent forms of processing and conversion. It points to semiotic activity and discursive functions as crucial variables in didactical engineering (Artigue, 1989 and Brousseau, 1997, pp. 24f) at the undergraduate level.

The semiotic activity of students serves pragmatic as well as didactic purposes.
Pragmatic, because mathematical competencies are articulated – and can only be observed and evaluated – through discursive and semiotic performance (e.g. Sfard, 1999). Didactic, because an individual’s conceptual development depends on his effective range of semiotic activity, as explained above. Notice that this is by no means a denial of the social nature of the learning enterprise, as semiotic activity to a large extent derives its meaning from a social context (interchange with other agents). Moreover, semiotic activity is influenced by the social context in the forms of agents, media and codes (the latter being a matter of consensus but also a condition for semiotic activity). Only codes may be independent of the context, that is, they belong to a large extent to a global context of mathematical discourse (Duval, 1995, p.225). The shared perception – largely implicit – of codes among participating agents is, on other hand, decisive for their potential for engaging in shared semiotic activity.

**SEMIOTIC VIEW OF DREYFUS’ POTENTIAL.**

In a semiotic interpretation, the basis of Dreyfus’ potential is that a CAS may provide a higher degree of semiotic freedom, primarily by facilitating processing, and – in a few cases, such as plotting – conversion. To ‘operate on a high conceptual level’ implies, in functional terms: to engage in discourse involving complex semiotic activity. The ‘lower level operations’ – carried out by the CAS – consist mainly of the processing parts of this activity. Typically, the explicit complexity of semiotic activity is reduced by the use of CAS, as the CAS tends to leave out several intermediate steps that may, or may not, be made explicit at wish. In fact, the ‘black box issue’ (Dreyfus, 1994) arises to the extent this is the case.

It follows from the above interpretation that the use of a CAS – at least, a priori – facilitates neither coordination of registers nor the main discursive functions. The simple representation of objects and transformations is not simplified, either. On the contrary, we have an extra medium (the computer), an additional special code (depending on the CAS) for semiotic activity, and a kind of ‘automatic semiotic agent’ with a potential influence on discourse (Winsløw, 2000). These additions may be particularly disturbing for novice users of CAS, but their influence remains important even in a context with experienced CAS-users.

**An example.**

Our key example is an event observed during a development project (Solovej et al., 2001) in the context of a freshman calculus unit. It occurred towards the end of a two-hour class session, in which students had presented and discussed a number of exercises on linear differential equations. In this unit, Maple was generally used by students in their homework, and it was demonstrated and used as illustrating device during lectures. In class, the computer was mainly used as a medium for presenting homework (students bring floppy disks to the class) and, occasionally – but with increasing frequency – as a semiotic agent in ‘whole-class’ exploring. There was one PC in the classroom, connected to a screen projector; both students and teacher used
this PC to present their work and ideas. At the point we shall consider, all exercises set for that day have been treated. Then a student – let us call him Peter – raises a question. He has been working on an exercise from the book (in the same section, but not among those given as homework), concerning the initial value problem

\[ u''(t) + u(t) = \sin vt, \ u(0) = 1, \ u'(0) = 0 \]

where \( v \) is an undefined parameter. Using Maple’s routine \( \text{dsolve} \) for solving ordinary differential equations, he had obtained the output [copied from Maple]:

\[
\begin{align*}
\frac{v \sin(t)}{1 + v^2} - \frac{\sin(v t)}{-1 + v^2} = \cos(t) + \frac{1}{1 + v^2} \\
\end{align*}
\]

and then wondered how this should be interpreted in the case \( v = 1 \). The teacher asks Peter to show his solution, as outlined above, to the class (which he does). The teacher then proposes to let Maple solve the problem (*) with \( v \) substituted by 1. Peter copies the first input to a separate input line, and makes the proposed change. This results in the following new output:

\[
\begin{align*}
\frac{1}{2} \sin(t) - \frac{1}{2} \cos(t) t + \cos(t) \\
\end{align*}
\]

which, on the face of it, seems quite different from the first answer. The students are confused. Peter comments: ‘That looks strange’. The teacher says: ‘Clearly, one cannot simply substitute \( v \) by 1 here [points to the first output, then hesitates for a while]. But how about taking a limit of it as \( v \) tends to 1?’ The student at the PC copies (1) to a new command line and ads the said limit. This gives the second output (2). The teacher says a few words about the possibility of studying the ‘continuity of solutions’ with respect to a parameter before the lesson is over.

This appears to be a fairly clear-cut example of how the processing powers of CAS may be used to realise Dreyfus’ potential. The teacher suggests the coordination of the (for the students at this level) separate registers of ‘ODE solving operations’ and ‘limit operations’, in order to enrich the concept of ‘solution’ with a relation to ‘continuity’; the didactic intention of the teacher is served by CAS as ‘processing agent’. While the students had some hands-on experience with using the standard procedure for solving inhomogeneous ODE’s, the discussion – that occurred during the last 5 minutes of a lesson – can be ‘lifted’ to a higher conceptual level (discussion of solutions in terms of a parameter) only because semiotic processing is left to the CAS.

**THE ROLE OF TEACHER CONTENT KNOWLEDGE.**

In the classroom example outlined above, the discussion (discourse beyond simple semiotic activity) is entirely governed by the teacher. However, Dreyfus’ potential talks about students operating on a higher conceptual level, while in the situation just described, these operations are only formally performed by the student (assisted by
The students do not actively participate in the ‘higher level’ discourse about ‘continuity of solutions’, and it is not clear to what extent they are informed by attending it. In a pessimistic evaluation, we may thus have a CAS version of the Jourdain effect (Brousseau, 1997, p. 26): students are led to perform certain CAS-assisted semiotic actions, and are then told ‘what they have done’ in terms of a higher-level discourse that is essentially beyond their reach.

In the example, this does not quite seem to be a fair evaluation of the situation. The discourse was indeed initiated by the student’s question on the special case $v = 1$ of the solution. The students understand the solution of the special case, but Peter’s comment (‘That looks strange’) certainly calls for an explanation; one input (ODE) is a special case of the other, yet the two outputs (solutions) look different. Given the impending end of the class, the teachers’ choice of a quick explanation cannot surprise, except perhaps that it is both improvised and correct. However, in retrospect, the question could be made useful in many different ways, and this might be a starting point for CAS-based didactical engineering.

In another class, Maple was only used by the teacher as an alternative way of processing (within one register, except for standard plots of functions), usually demonstrated just after ‘blackboard presentation’ of the same problem. Discussions of an abstract nature never involved use of CAS. Students in this class primarily saw CAS as a quicker and easier means of reaching a pragmatic goal (processing), and their expressed motivation for trying to use it was almost exclusively the advantage they supposed to achieve for the upcoming written exam. Their conceptual understanding was most likely not enriched by the repetitive demonstration that a CAS can do in seconds what they had struggled to do on paper. One may say that, in this case, CAS was allowed as a semiotic agent only in cases where it ‘echoed’ other agents. The teacher repetitively used expressions like ‘finally, it’s nice to see these calculations in reality’ (meaning, on the blackboard rather than on the screen).

While the teacher of the first class happens to be an eminent researcher of mathematics with a deep and flexible knowledge of mathematics, the teacher of this second class was a TA with his main occupation in high school teaching, and a strong focus on formal aspects (procedures, ‘official’ definitions etc.) of the topics taught. Throughout the project, he maintained a pessimistic view of the effect of CAS use on students’ performance and understanding. The importance of teacher content knowledge – and its flexibility – is often found to be a main determinant for the development of CAS-based pedagogy (see Kendal et al., 2001). It may, in our framework, be interpreted as the importance of the teachers’ own freedom of semiotic action within the discourse that he should help students to engage in.

**TOWARDS CAS-BASED DIDACTICAL ENGINEERING.**

We now return to the key example from the first class in order to sketch how this didactical situation could be improved by didactical engineering based on semiotic
and discursive variables, in order to more fully realise Dreyfus' potential. This discussion is partially based on a conversation with the teacher, a few days after. It is important that in this *a posteriori* analysis, the situation must be conceived in its total discursive context, which we can only describe here to the extent it enters our discussion. It must also be stressed that this kind of analysis and design depends crucially on collaboration with teachers who, based on their own agency in mathematical discourse, are aware of the importance of the variables mentioned. This awareness is, initially, likely to be mainly non-explicit, but it is an important part of collaboration to change that.

**Processing and the ‘black box’ issue**

In order to achieve an inclusive mode of discourse, where students participate actively, it is clearly desirable to maintain *coherence* with previous (not too distant) elements of discourse that included the students. In the class situation considered, the previous discourse focused on the problem of *solving* linear differential equations with constant coefficients (in the sequel, abbreviated LODE). In particular, the focus had been on: the solution of *homogeneous* LODE, partial solutions to *inhomogeneous* LODE (obtained by ‘informed guessing’), and the principle for finding the complete solution to inhomogeneous LODE (sum of two previous). The black box issue was partially mitigated in the case of homogeneous LODE’s, by reading off the characteristic polynomial from the coefficients of the equation, and then use the *solve* routine to find its roots. This way, the form of the solution of the LODE could be related to intermediate steps of the solution process. After identifying the ‘homogenous part’ of the general solution of an inhomogeneous LODE, the partial solution could be motivated as the result of an appropriate ‘guess’ based on the form of the right hand side. A strategy for dealing with Peter’s question might thus be to suggest a comparison between the two problems that result from (*) in the special cases v = 1 and (for example) v = 2, rather than between the two solutions (1) and (2), directly. Using the same patterns of analysis as previously, the students would find the crucial difference between the problems: in case v = 1, the right hand side, sin vt, is a homogenous solution, while it is not in case v = 2. Then the different forms of (1) and (2) may be explained by differences in the ‘good guess’ for a partial solution. And this might bring forward the *point of knowing (in principle, and perhaps a choice of) the intermediate steps of processing* involved in the solution process — *and* their function in discourse — for the task of evaluating and comparing solutions, and otherwise reflect on their status. Notice that while this does not prevent usage of *Maple* as a semiotic agent, it requires a more flexible and informed usage than simply asking for final solutions.

One might also proceed with the original suggestion of taking a limit, and then use the reaction of Peter (‘That looks strange’) to bring out the point above, by asking the question: *how could one proceed to justify this limit?* Incidentally, the students learned about l’Hospital’s rule 6 weeks before this event, and about partial derivatives just 3 weeks ago. This might, for instance, lead to a discussion involving the following two events of *Maple* processing:
> diff(nu*sin(t) - sin(nu*t),nu)/diff(-1+nu^2,nu);

\[
\frac{1}{2} \frac{\sin(t) - \cos(v t) t}{v}
\]

> limit(%, nu=1);

\[
\frac{1}{2} \sin(t) - \frac{1}{2} \cos(t) t
\]

(Here, the first line is Maple input code for: \( \frac{\partial (v \sin t - \sin vt)}{\partial v} \).)

**Conversion and coordination**

Continuing with the idea of simply exploring the relation between (1) and (2), one might profit from the fact that the students had studied functions of several variables 4 weeks before, in particular they were familiar with the conversion of algebraic to graphical representations of functions of two variables. In order to connect with this idea, one might suggest that the right hand side of (1) be regarded as the algebraic representation of a function of the two variables \( t \) and \( v \), and see if one might use the corresponding graph to relate it with (2). After a little experimentation with the settings, one might then produce the following two graphs of (1) and (2), respectively, understood as above, and with the domains \([-3, 3]\) for \( t \) and \([-1,1]\) for \( v \):

In *Maple* (not here!) the left image may be rotated in space, but even in the above 'static' form, it is not difficult to see the similarity between the 'upper edge' (corresponding to fixing \( v = 1 \)) and the graph to the left. The discussion that could evolve from this would have, as its main point, to provide an exercise in the (difficult) coordination of algebraic and graphical registers that is motivated by a concrete problem. It is facilitated by CAS as an agent of *conversion*.

**Expansive and reflective discursive functions**

In order to avoid the Jourdain effect described in the previous section, the students must be acquainted with – and ideally control – the discursive contexts of the proposed semiotic activities. Notice that the actual *devolutions* have yet to be devised (for an example, see Brousseau, 1997, 33-35). Typically, students must be in the presence of (or have access to) a number of discursive units (apophantic sequences of phrases, including semiotic elements) on which they will, in the adidactical situation, have to expand discursively, using their observation of similarity (semantic or semiotic) among these elements, or to produce reflective discourse concerning the status (logical, semantic) of these elements. In the case of the example discussed above, the units present *a priori* may not suffice for the
students to expand on (1) and (2) in order to relate them, and we have only outlined possible extensions of this fragment of the ‘given’ discursive inventory. The talk will present results (in terms of realised discursive expansion) from planned classroom experiments with more concrete extensions of this discursive basis of evolution.

But, in terms of discursive functions, the above expansions do not quite cover what the teacher, in the example, had in mind. Namely, once it has been established that (2) may be seen as the limit of (1) – and one has done similar investigations with other LODEs as well – one might try to help students proceed to a new kind of expansion: to develop (perhaps also prove) hypotheses in terms of more general forms of the problem (*) and its solutions. We then approach the professional mathematicians’ (pragmatic!) version of Dreyfus’ potential: studying ‘concrete’ examples using CAS as a ‘semiotic slave’ in order to generate hypotheses at a ‘high conceptual level’.

REFERENCES.

This study is based on a systemic, school-focused initiative and uses data from a very large number of children (23 121) who ages range from 4.5 to 9.9 years. Each child was assessed by their class teacher using an interview-based approach and a schedule of tasks. The study examines the use of Siegler’s overlapping wave theory to map the range of levels of strategies used by children to solve addition and subtraction tasks. The levels of strategies are derived from psychological models developed by Steffe, and links are made to Gray’s notion of preferential hierarchies. The results indicate that the overlapping wave theory is useful to demonstrate progression with age, of levels of strategy use.

A child provided with a pile of counters and asked to determine 6 + 3 could count out 6, then count out 3, and then count all nine items from one. This strategy which we call “counting from one three times” could be applied to a range of problems. Alternatively, the child might count-on from 7 to 9 and keep track of 3 counts. Strategies differ in the amounts of time their execution requires, in their processing demands, and in the range of problems to which they apply. On a problem-by-problem basis, children of the same age often use a wide variety of strategies (Geary & Burlingham-Dubree, 1989; Goldman et al., 1988; Gould, 2000; Siegler, 1988; Steffe et al., 1983). In a similar vein Carpenter et al. (1999) suggest that there is “a great deal of variability in the ages at which children use different strategies” (p. 26).

BACKGROUND

The Cognitively Guided Instruction (CGI) professional development program (eg Carpenter, Fennema & Franke, 1996) draws on word-problem research (eg Carpenter, 1985), and focuses on the ways teachers use knowledge of student's thinking in making instructional decisions. In New South Wales, a systemic professional development program, Count Me In Too (CMIT), has been developed to improve students' learning outcomes through a school-focused method of teacher learning (Bobis, 1997; Bobis & Gould, 1998), drawing on a research-based learning framework (see below). The learning framework used in the CMIT program is a synthesis of multiple research studies (Wright & Gould, 2000). CMIT emphasises the advancement of children's arithmetical solution strategies — a recognised need in teacher development:

The research on addition and subtraction has identified a progression of concepts and skills that is generally not reflected in instruction. Most instruction jumps directly from the characterization of addition and subtraction using simple physical models to the
memorisation of number facts, not acknowledging that there is an extended period during which children count on and count back to solve addition and subtraction problems (Romberg & Carpenter 1986, p. 856).

Beyond recognising that children can use multiple strategies to solve arithmetic problems, the question arises: How do they construct such strategies in the first place? This question has been investigated from a range of theoretical viewpoints (Carpenter & Moser, 1984; Steffe & Cobb, 1988; Steffe, 1992). The research methods employed include longitudinal studies, constructivist teaching experiments and microgenetic studies — small-scale studies of the development of a concept (Siegler & Crowley, 1991; Kuhn, 1995). This paper reports a study involving a large population of children and uses the theory of overlapping waves of strategy use arising from the microgenetic approach (Siegler, 1996; Siegler & Jenkins, 1989). The overlapping wave theory is based on three assumptions: (a) children typically use a variety of strategies and ways of thinking to solve a given problem; (b) the diverse strategies and ways of thinking coexist over prolonged periods of time; and (c) experience brings changes in relative reliance on existing strategies and ways of thinking, as well as introduction of more advanced approaches.

**Stages in number development.** According to Fuson, “children in the United States display a progression of successively more complex, abstract, efficient, and general conceptual structures for addition and subtraction. Each successive level demonstrates cognitive advances and requires new conceptual understandings” (1992, p. 250). The CMIT program uses a research-based Learning Framework in Number (LFIN) (Wright, 1998; Wright & Gould, 2000; Wright, Martland & Stafford, 2000) which has as one of its key components, a progression of conceptual structures which we refer to as the Stages of Early Arithmetical Strategies, and which is based on psychological models developed by Steffe et al. (eg Steffe, 1992):

**Emergent:** A child who is an emergent counter may have some number knowledge but it is generally made up of discrete pieces of information. For example, a child may know some of the sequence of number words and be able to identify some numerals while still being an emergent counter.

**Perceptual:** A child at the perceptual stage can count perceived items, matching the number word sequence to the items.

**Figurative:** A child at the figurative stage can determine the total in two concealed collections of items but typically counts from one to do so.

**Counting-on-and-back:** A child at the counting on stage uses advanced count-by-one strategies to solve a range of addition and subtraction tasks. A number takes the place of a completed count and a child can count on or back to solve problems.

**Facile:** A child at the facile number sequence stage can use a range of strategies other than counting by one. This includes a part-whole knowledge of numbers that enables children to draw on doubles or known combinations to five or ten.
Emphasised in the LFIN is that children frequently use strategies that are less sophisticated than those of which they are capable. This may happen for one or more reasons. A child may use a basic strategy because it is easier and although it may take more time this may not be of concern to the child. Alternatively, some feature of the child's thinking immediately prior to solving the current task may focus the child's attention on a less sophisticated strategy than the child is capable of. The emphasis in LFIN just described accords with the first two listed assumptions of Seigler's overlapping wave theory (see above).

**Preferential hierarchies.** Gray (1991) investigated the strategies used by 72 children to solve addition and subtraction tasks. The children were equally spread across the six age ranges of 7+, 8+, ... 12+ at each of three teacher-defined ability levels - below average, average and above average. Addition strategies were classified as known fact, derived fact, count-on, or count-all; and subtraction strategies were classified as known fact, derived fact, count-up or count-back, or take-away. Gray describes these four-level classifications of addition and subtraction strategies as preferential hierarchies. If unable to solve a task by immediate recall (ie known fact) the child reverted to what might be regarded as a preferred level. Gray identifies “two distinct approaches to the regression” (p. 569-70):

The first makes use of other known knowledge, the deductive approach [used mostly by above average and average children]. The second is dominated by the use of counting, the procedural approach [used mostly by below average children]....What has become fairly clear ... is that the below average ability child is neither successful at learning the number bonds nor in making use of the ones that they do know .... [For younger below average children] memory is abandoned for a procedure that involves the use of physical or quasi-physical objects. The bits they do know do not appear to be held together, with the result that this change in strategy may involve the child in long sequences of counting....In contrast, condensing the long sequences appears to be almost intuitive to the above average child. This eventually becomes the cornerstone to their higher level of attainment; they can take short cuts and operate with increasing levels of abstraction.

Gray's preferential hierarchies suggest that students might use strategies that are less sophisticated than those of which they are capable.

**Mapping strategy use.** Carpenter and Moser (1984) identified inconsistency of strategy use as an issue. “When children have several strategies available, they often use them interchangeably rather than exclusively using the most efficient one. Even when a more efficient strategy like counting-on from larger has been acquired, children often revert to a less efficient strategy like counting all” (p. 189). In the CMIT program, strategy use is documented using an interview-based assessment which we call the Schedule for Early Number Assessment (SENA) (NSW Department of Education and Training, 2000) and the subsequent analysis of children's responses. Each child's performance is recorded as the highest level of strategy use demonstrated during the interview. Thus the child's highest level of
strategy is taken to indicate the child’s level of conceptual development in number in terms of the model of stages of early arithmetical strategies.

**Research question.** This report addresses the following research question: Is the overlapping wave theory useful to demonstrate progression with age, of levels of strategy use?

**METHOD**

The data reported here is derived from analyses of individual interviews (using SENA) of 23,121 children, across 327 schools in New South Wales. The children were in classes from Kindergarten to Year 4 and ranged in age from 4 years 6 months to 9 years 11 months. Each child was interviewed by their classroom teacher at the start and end of the CMIT classroom project. In each school the team of participating teachers was assisted by a district-based mathematics consultant trained in CMIT. In each class, the assessment interviews of at least three students were videotaped. These tapes were used in consultant-led, professional development meetings focusing on children's solution strategies. The meetings constituted a forum for collaborative planning of instruction aimed at advancing children’s strategies. As well, the consultants assisted the classroom teachers with assessing, analysing and planning for teaching. Analyses of the assessment interviews enabled determination of each child’s stage of early arithmetical strategy, and levels of facility with number words and numerals (e.g., Wright, Martland, Stafford, 2000). This report focuses only on the children’s stages of early arithmetical strategy, as determined in the first assessment interview, that is, the initial interview. Any child whose data set was incomplete was excluded from the analysis.

**RESULTS AND DISCUSSION**

Table 1 shows the numbers of students in each age group, determined to be at each stage of early arithmetical strategy use, at the time of their initial interview. These numbers are consistent with the notion that children’s highest level of strategy use tends to increase with age.

**Table 1.**

Figure 1 is obtained from the grouped frequency distribution data in Table 1 as follows. For each stage of early arithmetical strategy a line graph is plotted across the six age ranges using the cell numbers from Table 1 expressed as percentages. Each cell number is expressed as a percentage of the total number in the corresponding age range. Curve smoothing is then applied to the resulting line graphs. The overlapping wave theory suggests that children in a given age range have access to more than one level of strategy. Figure 1 gives an indication for each age range, of the proportion of children for whom a given strategy level is their most advanced.

**Figure 1.**

**Strategy use by age**

The data in Table 1 and the resultant overlapping waves in Figure 1 indicate that the overlapping waves theory is useful to demonstrate progression with age, of levels of strategy use. All of the levels of strategy use are present in the population at any given age range with the exception of the facile level at the lowest age range (4.5-4.9), but there is significant variation in the degree to which levels of strategy use occur. Perceptual counting appears to peak between 5 to 6 years of age and counting-on appears as the dominant strategy used between 8 to 9 years of age. A
significant range and change of strategy use appears to occur between 6 to 7 years of age. A positive feature of this approach to mapping children’s levels of early arithmetical strategy use against age is that it incorporates both a sense of directionality in children’s learning and a sense of children’s movement among the levels. At the same time, applying overlapping wave theory in this way does not capture the insidious nature of inefficient strategies. Inefficient arithmetical strategies continue to be used by some students long after they need to, simply because they work. Thus inefficient strategies can be very persistent. A child asked to find $8 + 3$ could count out 8, then count out 3 and finally count all the objects to obtain an answer. If this strategy persists in later years, the amount of mental effort needed to obtain the answer can make it difficult to achieve a necessary cognitive reorganisation.

Overlapping waves theory specifies four dimensions along which learning occurs: (a) acquisition of novel ways of thinking; (b) more frequent use of the more effective ways of thinking from among the existing possibilities; (c) increasingly adaptive choices among alternative ways of thinking; and (d) increasingly efficient execution of the alternative approaches (Siegler, 2000). Clearly, Gray’s (1991) notion of preferential hierarchy has implications for the second and third mentioned dimensions. In reviewing video-taped assessment interviews we have seen that occasionally, children become quicker at using inefficient strategies. As well, children do not necessarily spontaneously progress to higher levels of strategy use. Thus it seems that instruction should focus directly on the development of higher levels of strategy use.

**CONCLUSION**

One of the features of assessment in the CMIT project is explicit acknowledgement that children are not always consistent in their choice of strategy. Consequently, the assessment tasks have been designed to elicit the most advanced strategy that children can demonstrate. Although a child might be able to count on or use non-count-by-one strategies, it does not mean that he or she will always do this. Competent adults might revert to perceptual counting for comfort when placed under stress or if materials are present. In our view, any approach to mapping children's solution strategies needs to take account of changes of strategy use. This study shows that an overlapping wave model of strategy use is can be applied to a large cross-sectional sample of children. Mapping individual strategy use as a function of age is a useful graphic organiser for capturing students' arithmetical strategies. The overlapping wave model constitutes a broad response map for displaying children's solution processes, describes the flow of development as observed in the population and suggests movement between the various strategies is possible at a range of ages. Thus a model arising from a microgenetic approach can be applied in a macrogenetic cross-sectional study of arithmetical solution strategies. This is consistent with the view that “the most important aspect of a research study is the constructs and
theories used to interpret the data” (Kilpatrick, 1981, p. 27). Changing the theoretical lens need not distort the view.

SEVEN YEAR OLDS NEGOTIATING SPATIAL CONCEPTS AND REPRESENTATIONS TO CONSTRUCT A MAP

Chronis Kynigos and Nikoleta Yiannoutsou
University of Athens and Computer Technology Institute
University of Athens

We report on-going research on the spatial – geometrical meanings generated by two groups of seven-year olds collaborating to construct a map of the area surrounding their school. The learning environment involved the use of a G.P.S. device dynamically linked to cartography software and was designed so that each group worked in a different external representations environment and was reliant only on verbal communication with the other in order to co-construct meanings which would enable them to make the map. Results showed student negotiations about concepts of motion, location and orientation to include instances where they dissociated from the software representations and made choices from a variety of geometrical reference systems.

FRAMEWORK

We report on-going research on the spatial – geometrical meanings generated by two groups of seven year olds collaborating to construct a map of the area surrounding their school. The learning environment was designed so that each group worked in a different external representations environment and was only able to communicate with the other group verbally in order to co-construct meanings which would enable them to make the map. One group physically roamed the area carrying a Global Positioning System device. The other worked indoors using cartography software where they could see an icon of the G.P.S. carrier on the screen dynamically moving and turning in the corresponding direction in synchrony to the carriers’ movement. Both groups could communicate verbally with walkie-talkies. We studied their actions and talk while they made discriminations between their different environments (screen representation and actual space) and attempted to develop some joint understanding about position and orientation in order to construct the map in the context of making a treasure hunt game.

Related research has highlighted the dual nature of the map as representational medium and as embodiment of spatial concepts i.e. scale and absolute (Cartesian, polar) and relative (Euclidean) orientation, position and motion (Liben & Yekel 1996). In that context, map construction may provide an environment for creating and understanding representations of such spatial concepts in order to use them for negotiating about the concepts themselves. As Kaput et al (2001) put it:

`People need to represent for themselves how things work, what makes systems fail and what would be needed to correct them. This kind of knowledge is increasingly important;`
This research draws from two perspectives in analyzing the problematic in students’ understandings of spatial concepts and representations. One has to do with the symbol–referent relationship and specifically what we could refer to as the distance between the two, i.e. the level of abstraction needed to relate surface structure (signifier) and deep structure (signified). In discussing algebraic notation, Kaput (1987) stressed the importance of students’ abilities in choosing, building and interpreting mathematical representations and their difficulty in relating these to the represented concepts, rather than merely focusing on the surface rules of the representations themselves. Research with younger children involved attempts to narrow the distance between symbol and referent by means of using tangible objects to represent real objects in space (e.g. a model of a classroom and the objects inside it, Lieben and Yekel, 1996). DeLoache et al, (1999), however, found that the children have difficulty dissociating from the tangible properties of the representational objects in order to relate them to the represented ones and displayed better understanding of iconic representations which were more distant to the referent space. DiSessa studied primary students’ bottom-up methods of building abstract representations (graphs) in order to negotiate and explain experiences with physical phenomena (diSessa, 2000). On the other hand, however, Nemirovsky et al (1998) suggested that fusion between signified and signifier can be a source of intuition for understanding representations, in environments designed to encourage linking kinesthetic experiences with their immediate iconic representation on a computer screen. In our study we had two groups of students negotiating to understand and build on representations of space by providing one group with tools to interpret and create iconic representations and by placing the other in an environment constituting the referent space itself.

The other research perspective relevant to our study has to do with the spatial – geometrical concepts embedded in map construction and students’ related intuitions. Even though Papert coined the term body-syntonicity (1980) in describing students’ use of their intuitions about their own movement in order to understand motion and orientation on the plane, subsequent studies revealed different sets of intuitions employed in settings involving a different system of reference to the plane, such as the Cartesian (Lawler, 1985). Students find it particularly difficult to relate their intuitions about Topological, Cartesian and Intrinsic systems of reference (Kynigos, 1992). Most research, however, is based on learning environments focusing on the use of one system at a time and on its use for the understanding of geometrical figures and properties, rather than studying the ways in and the reasons for which students choose between systems to understand concepts related to location, and orientation. In this research, we focused on the students’ respective choices in a setting where these reference systems were simultaneously available since they could
choose to refer to external objects, to bodily movements and to relative positioning of external objects.

**SETTING**

**The activities**

Two pairs of seven year-old pupils collaborated for the joint construction of a map. One pair was the "base team", situated indoors in front of the computer screen. The other was the "roamers", following the teacher who carried the bulky G.P.S. Whole group discussions took place before and after each research session, involving setting out goals and experience exchanges. The two groups exchanged roles when a part of the activity was completed. The activity involved creating a map of the area around the school and then using it to play a treasure hunt game. That area had a number of identifiable objects, such as trees, water taps, waste bins, lamp - posts, the flag. The two groups had to communicate about the objects in the area so that the base team could place ready made or child - created icons on the corresponding locations on the screen. The rationale underlying the deliberate differentiation of pupils’ perspectives while working on the same task was to pivot the activities around language exchanges (Nemirovsky et al, 1998). Before the map construction activity, the students engaged in two dot-to-dot type tasks. The first involved rubber cones placed on the playground and numbered icons of these on corresponding positions on the screen. The base team had to drive the roamer team from cone to cone in the right sequence (the roamers could not see the numbers) to form a star shape. The second involved the base team instructing the roamer team to place the cones in the corresponding positions to form the shape of a fish.

**The computer environment**

From a technical point of view, the environment was based on synergy between high accuracy G.P.S. (around 1 meter) and corresponding cartography software. The G.P.S. continually fed data to the computer via mobile phone so that the effect would be a dynamic synchronous correspondence between G.P.S. motion and orientation change and the respective changes of the roamer icon on the screen. The software involved a combination of a G.P.S. receiver component with a map and an icon editor component ('E-slate' software, see endnote). It was thus designed to embody a scalable representation of physical motion on the plane (the roamer icon moved leaving a linear trace and turned in the direction of the motion) in combination with the students placing pictures or self – constructed icons of objects in positions and orientations decided after negotiation with the roamers (see picture next to excerpt 1). The teachers or authors of the software configured the scale and orientation of the simulated plane so that it matched the base teams’ experience of the physical space outside the classroom.
RESEARCH METHOD

The study lasted for 16 hourly sessions with the same seven year-old students, 3 girls and 1 boy. They were selected in collaboration with their teachers so that they ranked at the middle of their class with respect to their classroom general abilities, knowledge and willingness to collaborate and communicate. We adopted a generative methodological stance, attempting to gain some detailed insight into student-generated meanings. Both groups were videotaped simultaneously throughout all the sessions of the research. For the data collection we engaged in participant observation intending to stimulate students to make their thinking explicit as well as to challenge their actions and explanations. During the observations we focused on a) the verbal exchanges between groups and among the members of each group separately b) students’ motions and gestures and c) the data captured on the screen. In our analysis we consider the exchanges between the groups in relation to the exchanges within each group. The discourse analysis focused on our subjective interpretation of the students’ communicational intent and meanings rather than on some pre-defined ‘objective’ methodological construct.

USING THE REPRESENTATION AND ACTUAL SPACE AS RESOURCE

One of the key features of the learning environment requiring rigour in the children’s exchanges was that one group used representation on the computer screen as resource for these exchanges while the other used their direct experience of the area in question. During the activity, neither team had access to the others’ experience apart from being able to talk about it. The base team could also “see” the roamers’ position and heading represented on the software. In accordance with our theoretical framework, it’s not surprising that at the beginning, the base team seemed bound to the representations on the screen, not being able to discriminate which of these were dependent on its orientation and which could be directly associated with the roamers’ physical experience. This was manifested in the language they used in their attempts to communicate as shown in the following excerpt. S1, S2 are the base team, S3, S4 are the roamers, and wt stands for talk into the walkie-talkie. S2 used the word “downwards” signifying the literal orientation of the screen. S1 asks S2 to clarify some end point as direction finder, in effect requesting for an external reference point (line 2). The roamers’ also take S2’s comment literally thinking she’s asking them to sit on the ground. However, since this request did not seem reasonable, the need to re-negotiate words and meanings arose. S1 tries a different idea, linking the requested heading change to the roamers’ present one, in effect, using an intrinsic frame of reference by taking the roamers’ point of view (line 7). From a mathematical point of view, this is correct. S2 cannot see that, bound to the upright orientation of the screen. S1 tries to mediate between the two parties by eliminating the word “downwards” which was explicitly causing confusion. However, she uses the word “diagonally” indicating that she too is bound to the screen representation,
even though in her previous comment she seemed to have disentangled from the screen addressing the roamers’ heading alone.

1. S2wt: As you are [means keep the heading you have] move downwards a bit.
2. S1: Where to?
3. S4: Should we sit on the ground?
4. S3: What did she say?
5. S4: As you are move down a bit.
7. S1: Move a bit towards the direction you are looking at.
8. S2wt: Move left, diagonally down.
9. S4wt: What do you mean move down?
10. S1wt: Move left diagonally.

Excerpt 1

At another session, this issue arose again, provoking more articulate language in the children’s attempt to negotiate a request for a roamer move (excerpt 2). S3 indicated the roamers’ position in space in terms of her perspective (line 11). S2 appears to try to relate the referent space with the next target point on the screen and to make an inference on what the change of heading should be (line 13). S1, on the other hand seemed to prefer to use external points of reference (using the word “towards” and pointing, line 12) but with no indication that she was thinking about the external space and not just the screen. However, her adamant comment that “down” was not communicable (line 16), brought S2’s comment on the walkie-talkie, requesting a change in direction and position using intrinsic terms of reference associated with the roamers’ perspective (line 19).

11. S3wt: We are looking towards the flag
12. S1 They should go towards there [indicates the point on the screen with her finger]
13. S2: So if they are heading to the flag they should move with their left hand [he means towards their left hand side] down
14. S1: Yes
15. S2: What?
16. S1: Down, they won’t understand
17. S2: So, turn on your left
18. S1: And move a bit
The specific episodes we presented here along with the body of our data indicate that there were instances where students attempted to relate symbols and referents and vice versa even though they initially referred to spatial concepts with expressions bound to the specific resources (line 4). Even though the students had to grapple with a set of representations with varying distances between symbol and referent, the dynamic link between physical motion and its representation and the continual negotiations to relate symbol and referent provided them with rich opportunity to develop rigorous communication and generate corresponding meanings.

**USING MULTIPLE REFERENCE SYSTEMS**

As mentioned before, the environment was set up so that the children would have opportunities to use concepts which we may assign to three different representational systems, the projective or intrinsic, the Euclidean and the topological. In line with previous research, we were expecting the children to use concepts from all three, but were interested to investigate whether they might show preference in using one system over the others and in the case where a child would use concepts from more than one, what was it that triggered their choice. Furthermore, we were interested to study the ways in which they made relations between concepts belonging to different systems, having in mind that the previously mentioned research has shown this to be particularly difficult. Our data indicates that children consistently used concepts from all three systems. The excerpts we present here illustrate this use. In the following excerpt for example, S2 seems to employ a combination of intrinsic and Euclidean concepts, since she uses the term “left” and the term “diagonally”. With respect to the latter, however, the dialogue indicates that it was the tangible size of the screen representation which enabled some logical connection between the two concepts. It may have well been that her intention was to find words for the concept of a 45 degree angle turn, and since the children did not know about degrees or angle size yet, it was the next best way to convey that meaning. S3 seems to consider the terms “left” and “diagonally” as contradictory, having a notion of left as a right angle turn and not being able to see himself walking on the edge of an area so that its diagonal would have meaning. However, that specific moment would have been an opportunity to help the children focus on the meaning of turn size and of the scale of the area they were mapping. It important to consider this, since the whole activity was replete with such events.

20. S2: Go left diagonally. Over
22. S3: Left. Diagonally. I didn’t understand a thing.

**Excerpt 3**
So, this use of concepts from different systems in an ad hoc fashion brought about
the need for rigour in the children’s communication, since the result of what they
jointly understood was immediately visible on the screen. In amongst the occasions
where a combination of concepts were used, there were instances of expression of
the respective mathematical meaning. The following excerpt is such an example. In
excerpt 4, S3 used a combination of an intrinsic (“move left”) and a Topological
(“not the first but the second cone”) notion. He does not use some screen – bound
representation and addresses the cones (which a mathematician would perceive as
standing for points on the Euclidean plane) as a means to specify the direction he
wanted S2 to turn towards. In doing that he makes a relative use of two cones.

23. S3:wt: Move left towards not the first but the second cone
24. S2: Left, which means this way [shows left hand]

Excerpt 4

Finally, during the map construction activities, there were many instances where
topological relations between objects came into play (Excerpt 5).

25. S3 wt: What is next?
26. S1: What did we tell them before?
27. S2: About the water taps…
28. S1: They have to put the trash can and the lamp post
29. S2:wt: … In front of the water-taps there is a trash-can and further ahead there is a lamp
-post.

Excerpt 5

In fact, S2’s comment is quite difficult to disentangle, since she uses the water –taps
as a central reference point to place the other two objects taking for granted that her
own position and heading are clear and that the base group can associate her
comment with that. This may mean that it was hard for S2 to conceptualise the
topological relation between the objects she could see in conjunction to her own
intrinsic position and heading. The excerpts in this section, however, indicate that the
environment provided rich opportunity for the use of concepts from all three
reference systems and in this way invited appropriate didactical engineering for the
children to create relations amongst these.

CONCLUSION

The learning environment seemed to provide rich opportunity for the children to
negotiate spatial concepts during the co-construction of the map. With respect to the
kinds of intuitions employed for referring to position and orientation changes and to
objects and the relative positions, we did not detect some preference with respect to
system of reference. It would be interesting, however, to study over more time
perhaps what kinds of strategies and connections children might make amongst
concepts associated with the three systems. The interdependency between symbols
and referents inherent in the learning environment played an important role in students' understandings of relationships between the two. In this sense, relating symbol and referent in meaningful settings with carefully designed dynamic representational tools may play an equally if not more important role in understanding and creating representations to the distance between these and the corresponding concepts. This may provide some explanation of the seemingly disparate views of di Sessa and Nemirovsky et al described earlier.

NOTES

C Cube: Children in Choros and Chronos, European Commission, Esprit LTR, Experimental School Environments, #29346, 1999-2000. The cartography software was co-developed by the authors with the E-slate software (http://e-slate.cti.gr). In a version for high school students, the object icons can be linked to information on a student created database and scaling of building perimeters can be implemented through variable Logo procedures dynamically manipulated with a variation tool.

LEARNING FROM LEARNERS: ROBUST COUNTERARGUMENTS IN FIFTH GRADERS' TALK ABOUT REASONING AND PROVING

Vicki Zack

St. George's Elementary School, Montreal, Quebec

I, a teacher-researcher, presented my fifth graders with an interesting but incorrect student-constructed proposal first seen in 1996 (Zack, 1997). The students used the patterns they had detected while solving the chessboard task to formulate counterarguments. The five types of counterarguments which emerged offer insights into the children's understanding of the mathematics. The children's perspectives, in turn, changed my understanding in substantive ways.

For the past ten years, as a teacher and researcher in a fifth grade classroom, I have been studying the problem-solving work and talk of ten to eleven year-old learners, with a particular interest in recent years in the children's notions of proving. This study is a follow-up to a study reported previously at PME (Zack, 1997). In that paper I showed how, in solving a variant of the chessboard problem, one team is convinced that their patterns work, and they use what they know of their patterns to refute an interesting but incorrect proposal put forth by the other two group members, Ted and Ross. I subsequently decided to offer the Ted-Ross idea to all of my fifth grade students for consideration (1999-2000, 2000-2001). My aim was to see whether, and if yes, when and how the fifth graders would refute this idea. It has been noted that "'wrong' ideas can be opportunities for important mathematical discussions and discoveries" (NCTM, 2000, p. 191). The authors of the recent NCTM (2000) Principles and standards for school mathematics envision children constructing valid arguments and evaluating arguments of others, detecting fallacies and critiquing others' thinking, and reasoning about mathematical relationships, such as the structure of a pattern (p. 188). I will describe the diverse counterarguments which emerged, and dwell on one in particular, the "array strategy" counterargument, which surprised and intrigued me. I have shown elsewhere (Zack, 1996, 1997, in press) and will also point out here in regard to the children's "array strategy," that the children's ways of seeing have changed my understanding in fundamental ways.

THE SCHOOL COMMUNITY AND CLASSROOM SETTING, AND ASSIGNED TASKS

St. George's is a private, non-denominational school, with a middle class population of mixed ethnic, religious, and linguistic backgrounds; the population is predominately English-speaking. The homeroom class size in the 1999-2000 year was 27, in the 2000-2001 year was 26; the work, however, is always done in half-groups (13/14 children in each group) of heterogeneous ability. Problem-solving is at the
core of the mathematics curriculum in this classroom. The school and classroom is one in which the children are expected to publicly express their thinking, and engage in conjecture, argument, and justification. The groundwork laid during the year by the teacher included an expectation that the children would be looking for patterns, and that they could be nudged to think about the mathematical structure underlying the pattern (Zack, 1997).

Mathematics class periods are 45 minutes, and twice a week are extended to 90 minutes. In addition to the in-class problem-solving sessions, each week the children also work on one challenging problem for which they are expected to record their work and reflect on their strategies. They write in a Math Log which serves as the initial basis of their group discussions in class. In class much of the session is conducted by the children as they discuss the problem first with a partner, then in a group of four or five, and finally with the entire group of thirteen students.

The children are videotaped throughout the school year as they work in their groups. In addition to the videotape records, data sources include focused observations, student artifacts (Math Logs), teacher-composed questions eliciting opinions (written responses), and retrospective interviews.

The mathematical context of the problem/discussion

The task is a variant of the 'Chessboard' problem (see Mason, Burton & Stacey, 1982). The work was assigned as follows:

Task 1: Find all the squares [in a four by four grid given as a figure]. Can you prove you have found them all?

Task 2: What if... this was a 5 by 5 square? How many squares would you have? Extensions were subsequently posed.

Task 3: What if this was a 10 by 10 square? What if this was a 60 by 60 square? How many squares would there be?

Interesting talk about proving arose with the ‘What if it was a 60 by 60 square?’ task. The proposal that 2310 would be the answer for the sum of squares for a 60 by 60, what I have called the Ted-Ross strategy, was first seen in 1996 (Zack, 1997), and then came up again in subsequent years. In the 1999-2000 and 2000-2001 school years, I distributed to all the students in the class the proposal which Ted and Ross made in 1996, and asked the students to respond. It was presented to each pair in late April after they had completed their discussion about their work done independently in their Math Log on the task, ‘How many squares would there be if it were a 60 by 60 square?’ The ‘Ted-Ross question’ was posed as follows:

Imagine that two of your classmates, Ted and Ross, came up with the following solution for the 60by60: The answer for the 10by10 grid is 385 squares. So take the answer for the 10by10 square (385) and 10 x 6 = 60 so multiply 385 x 6 = 2310 and you have the answer for the 60by60. What would you say?
I will speak first about the different kinds of counterarguments, and what the ten to eleven year-old students draw upon to shape their counterarguments.

FIVE COUNTERARGUMENTS

In the first study (Zack, 1997) Will, Lew, and Gord, in 1996, constructed three counterarguments (CA), namely CA #2A, #2B, and #1, in that order, in their quest to refute their partners', Ted's and Ross's, idea. A number of other counterarguments emerged in subsequent years, and all are described below using categories outlined in late 2001.

CA #1: 60 by 60 gives you 3600 squares of the smallest size, the 1by1 squares (not counting the others) and 3600 is already larger than 2310.

CA #2: The growth pattern is one in which the pattern of differences between the numbers grows as the numbers get bigger. There were a number of counterarguments which dealt in some way with the idea that the numbers increase in size, and are numbered 2A through 2D below.

(2A) The answer for the [number of squares in the] 10by10 (which is 385) is not double the answer for the [number of squares in the] 5by5 (which is 55). If you could just double the answer for the 5by5 to get the answer for the 10by10, the answer for the 10by10 would be 110, and it is not. (There were variants on this as the children chose different pairs to present their arguments, e.g. the 4by4 and the 8by8, the 3by3 and 6by6, but the reasoning was the same.) This counterargument proved hard to express. A few of the students (5, and 2 in the respective years) could not understand Ted and Ross's method. The majority however did understand Ted and Ross's method, and understood as well the connection between Ted and Ross multiplying by 6, and the presenters of the counterargument choosing to show that when one multiplied by two it did not work.

(2B) The pattern does not stop at 385 and then 'restart' itself. It keeps growing.

(2C) Look at the string of numbers (1x1, + 2x2, + 3x3 ...). By the time one reaches a certain point, for example, the 20by20 square, the answer for the total number of squares in the 20by20 was a number already greater than 2310.

(2D) Refer back to a task previously done in class, one which had a similar growth pattern. For example, in the task 'What is the number of diagonals in an n-sided polygon?' one could not take the answer for the number of diagonals in a 10-sided polygon, multiply that number by 2 and get the answer for the number of diagonals in a 20-sided polygon.

CA #3: If one takes a 10by10 grid and lays six of them side by side, representing what Ted and Ross are suggesting, one omits counting all the different-
size squares within each grid, and the squares which overlap the (10by10) grids. (This counterargument was offered only twice, by Jake in 2000, and by Dora, in 2001)

CA #4: There are 51 times 51 10by10's in a 60by60. This statement was offered once only as a counterargument, by Jake in May 2000, immediately after he presented CA #3. This counter argument will be elaborated below.

CA #5 If theirs (Ted and Ross) works, you should be able to take the answer for the 6by6 (91) and multiply it by 10 and it should give you 2310, but it does not. One student, Theo, presented this argument, in 2001.

The distribution of the different kinds of arguments is presented in Table 1. At times a student constructed more than one counterargument. In most cases it was 2 counterarguments, and in one case 4 (May, 2000), in the years 1999-2001. There is therefore a discrepancy between the total of counterarguments, that is, 20 and 23, and the total number of students who offered them, that is, 13 and 18, in 2000, and 2001. The total class size each year was 27 and 26 children respectively.

Table 1: Distribution of the five counterarguments

There was potential seen for a sixth counterargument, but the presentation of that counterargument did not materialise. In this case, the child, Kate, used inductive reasoning, appeal to empirical evidence, and reference to authority to support her way of arriving at her answer for the 60by60. She stated that "Leo's way", that of adding 1x1 plus 2x2 plus 3x3 and so on, as used by her classmate Leo, had been tried and tested for many examples by many of the students and it had proven true. She rejected the Ted-Ross strategy, giving the following reasons: "They didn’t prove it and they didn’t check it. They can’t prove it’s right." However, she did not then proceed to offer a counterargument to disprove their method. Had she made the move, she might have pointed out that using Leo’s way and with the help of the calculator, she had arrived at a sum far larger than 2310. (In fact, Kate had arrived at the correct answer, 73 810, one of only three students to have the correct sum.) Although she could not be certain that her answer was correct, she might have insisted that the discrepancy in size deserved attention and deliberation. The point
she might have made was both that the Ted-Ross method does not work, as the answer must be a far larger number, and that the Ted-Ross method is not needed because they are convinced that Leo’s way works and will result in the correct answer (provided that the calculator work is done without error).

The benefit of having diverse counter-arguments

Some might say that one counter-example is all one needs. Others might suggest that one should consider in the main the most elegant one. However, having a diverse assortment of counterarguments is beneficial. The counter-arguments tell us different things about the mathematics in the task. A look at the counterargument helps me as a teacher to come to a better understanding both of the mathematics, and of the children’s understanding of the mathematics. CA #1, that 3600 is already bigger than 2310, is the ‘simplest’ and some of the children voice their appreciation of it as the most powerful. Mark, who had used the Ted-Ross strategy in his independent work, states that he was quickly convinced by his partner Chris’s refutation: “I did what the person did on the sheet and he [Chris] proved me wrong. . . . [Chris] ended up showing me in like one rather small sentence that it was wrong, that sixty times sixty is three thousand six hundred.” CA #2 and the talk about growth rates reveals an understanding of the mathematics pattern which is at work here. The children at times themselves refer to the fact that CA #2A is difficult to articulate. However, those who propose and those can understand CA #2A -- and try to show for example that the answer for the 10by10 is not ‘double of ‘the answer for the 5by5 -- reveal an understanding of the method proposed by Ted and Ross, and its underlying structure.

The students “learn to describe relationships that hold across many instances and to develop and defend arguments about why those relationships can be generalised and to what cases they apply” (NCTM, 2000, p. 190). Lew, for example, builds upon what he knows of the number of little squares in the 5by5 square, and applies it to the 60by 60. This constitutes the foundation of CA #1. Lew explains the connection and justifies how he and his partners arrived at the number 3600 (of the littlest size square); while gesturing to both Gord's and Will's Math Logs, he points out: "Because here you would do five times five to see how many little squares there are, so we did sixty times sixty . . .” The students also push for reasons. When Adele keeps saying that the Ted-Ross strategy sounds good, stating: "I think it's right but I don't know how it works," Maggie (who has just finished presenting CA #1 to her group of five) insists: "Then you have no reason to think it's right." Soon after she repeats again: "But Adele, really, I think you should have a reason to think it's right."

The students who have generalised a rule after testing it, use what they know and trust it. Reid (in press) has shown for example how Will (from the Zack 1997 study) formulates a conjecture about one of the patterns he has seen, tests it, and once he feels sure that the pattern works, he is prepared to generalise it as a rule. Tom Kieren
spoke recently about a "truth box" in relation to cases in which the children are secure with the knowledge, and do not feel they have to continue to test (Gordon Calvert, Zack, & Mura, in press). I hear them predict with confidence, and state that 'it will always work like this'. There are a number of patterns which are pivotal, all of which the children introduced to me. One, the 1, 4, 9, 16 'criss-cross' pattern (see Zack, 1997); two, adding $1 + 4 + 9 + 16$ without having to worry about the number of squares (see Reid, in press); three, the pattern of differences between the above numbers a difference which increases by 2, i.e., 3, 5, 7 (Zack, 1997); and the "array strategy," a means whereby the children see that they can determine the number of squares there are of each particular size, which will be described below.

The "array" strategy

The counterarguments are robust in that they are deeply rooted in the children's grasp of various aspects of the mathematics of the task. I have seen how the students formulate generalisations about observed regularities in regard to diverse patterns which they have detected (NCTM, 2000, p. 262). I will use as an example a counterargument which startled me, namely CA #4, when Jake said that there are 51 times 51 10by10s in a 60by60.

Jake's second counter-argument came swiftly upon the heels of his presentation of CA #3 without any overt deliberation or elaboration with his partner or small group members. This took me by surprise, and I had to sit down and figure out by working down from 60 times 60 1by1's, to 59 times 59 2by2's, etc., to 51 times 51 10by10's that it was indeed so. In the follow-up interview (May 23, 2000), when asked how he had come to that answer, Jake said at first that he could not recall, and two of his peers were asked what they thought, and how was it that they knew he was correct. Dexter said: "I visualised (the) others would be off the grid." Another clue to Jake's approach might be found in his partner Ari's explanation of his/their way. In answer to the question “Why does it go down by one?” (i.e., from 60 x 60, to 59 x 59 etc.), Ari said: “The size goes up by one row of squares so there's one fewer.” Ari's reasoning introduced to me a new perspective: First there are 60 x 60 little 1by1 squares with none going off the grid. The next size square, the 2by2, is one square larger than the 1by1 going up and across, and therefore only 59 x 59 2by2's fit on the grid. Jake quickly dropped 9 squares down to get 51 x 51 10by10's, while I had to work it out one step at a time.

Jake may possibly have worked out yet another generalisation. He says the following during the interview as part of his response to how he arrived at the 51 x 51 10by10’s:

I remember Jennine showed there are four 2by2's [in a 5by5]. The one itself plus 3. There are 50 rows plus the one at the bottom that's 51.
Jake may have made the following connections, building upon Jennine’s idea: In the 5by5, 5 minus 2 (the size of the square) gives you three more 2by2 squares which you can fit; three plus the first one gives you four 2by2’s (along one dimension) in a 5by5. Hence there would be 4 times 4, or 16, 2by2’s. In a 60by60, it would be 60 minus 10 (the size of the square) which gives you fifty more squares which you can fit on the grid; fifty plus the first one gives you fifty-one 10by10’s in a 60by60. Hence there would be 51 times 51 10by10’s in a 60by60 (David Reid, personal communication, January 5, 2002). Jake found it difficult to articulate how he had arrived at his counter-argument of 51times51 10by10’s. Doubtless, articulation of the idea is challenging because the procedure itself is complex.

For the past three years a number of students have 'seen' and have attempted to explain in writing and in talk their strategy of how to figure out how many squares of different sizes are contained within a large square, the “array strategy.” These students are seen to develop and test conjectures about mathematical relationships. They work with generalisations they have made while doing their first tasks; they apply to the larger square, the 10by10, the generalisations about how many squares one can fit along two dimensions, that is both vertically and horizontally. For example, Clare in discussing the 10by10 showed how she arrived at 64, or 8 times 8, squares of the 3by3 size, saying: “It would only be 8 [3by3’s], cause you would go off the grid otherwise.” I saw this “array strategy” for the first time in 1999 in one child, Walt’s, work. In the past two years, seven and two students respectively have independently or with partners constructed and used this 'rule' about the array to arrive at their answer for how many there are of each size square. However, Jake was the only student seen to use this 'rule' to counter and refute.

As a result of the children's work I am constantly developing my own knowledge of children's thinking and my understanding of the mathematics in the task. My learning trajectory of the "array strategy" had its genesis in Lew's sliding of each size square across each row, from left to right (proof by cases) in 1996; was extended by students seeing the array as a way to arrive at the answer for the number of each-size square (Walt, 1999); and was further extended by Ari and Jake's knowing why it works that way (2000). This informs my work with future cohorts of children, in a continuing cycle of generative growth (Franke, Carpenter, Levi & Fennema, 2001).

The teacher’s role

The children who invented the “array” procedure have a tacit but not conscious awareness, and work ahead of formal instruction; indeed, in this case they were teaching me. One of my enduring questions is in regard to the role the teacher should play in making more explicit what some of the children are doing naturally. Richard Pallascio suggested recently that the teacher is instrumental in making certain aspects visible (Gordon Calvert, et al., in press). The students use
sophisticated reasoning, but may well not see the power in the reasoning they are doing. The teacher can bring to the surface some of the implicit items. She can point out the mathematical concepts the students have used perhaps without being conscious of them, and the types of arguments they have used. The teacher can come back to look at what the students have said, and to connect their talk with the ways in which a mathematician would express those ideas. My personal goal as teacher lies in encouraging the children to keep in touch with their personally meaningful ways of seeing, while valuing and learning the conventions of their culture. As I have elaborated elsewhere, the challenges inherent in that endeavor are substantial (Zack, 1999). Most important is to encourage the students to stay connected to the meaning they make personally.
