This document contains the first volume of the proceedings of the 26th Annual Conference of the International Group for the Psychology of Mathematics Education. Conference presentations are centered around the theme "Learning from Learners". In total, 290 presentations were given ranging from the psychology of mathematics in the very early years to discussions on advanced mathematical concepts. This volume features nine plenary papers, papers from four groups of research forums, discussion groups, working sessions, and short oral communications. Plenary papers include: (1) "Little Children, Big Mathematics: Learning and Teaching in the Pre-School" (Herbert P. Ginsburg); (2) "Researching Primary Numeracy" (Margaret Brown); (3) "How Students Structure Their Own Investigations and Educate Us: What We've Learned from a 14 Year Study" (Carolyn A. Maher); (4) "Mathematical Epistemologies at Work" (Richard Noss); (5) "Taking the Modeling Perspective Seriously at the Elementary School Level: Promises and Pitfalls" (Lieven Verschaffel); (6) "Learning from Learners" (Joao Filipe Matos); (7) "Episode 1: How Karin Disturbed Her Teacher's Line of Reasoning" (Joop Van Dormolen); (8) "Episode 2: Marco and Anna--Each Following Their Own Path" (Rosetta Zan); and (9) "Episode 3: Calculators--The First Day" (Susie Groves). Welcome to PME 26

Welcome to PME 26! The School of Education and Professional Development at the University of East Anglia is delighted to be hosting the twenty-sixth annual meeting of the International Group for the Psychology of Mathematics Education. The theme for the conference this year is ‘Learning from Learners’ which, we are pleased to report, has captured the imagination of many of this year’s contributors. In total we have in the region of 290 presentations, ranging from the psychology of mathematics in the very early years to discussions on advanced mathematical concepts. We will also be offering you a variety of entertainment that will restore your energy levels amid the demands of such a busy scientific programme.

We very much hope you enjoy your stay in Norwich and that you will feel welcome to return in years to come. The city dates back to Anglo-Saxon times and offers a wealth of sights, including a Norman castle (1067), two magnificent cathedrals (1096 and 1894) and what the eighteenth century historian, Francis Bloomfield, described as the ‘grandest market in all England’. We recommend that you take the opportunity to wander around the city and discover its delights for yourself.

We hope that the conference will run smoothly with, apparently, very little effort on our part. If it doesn’t, I can only reassure you that we have done, and will do, our very best! If it does all go well it will be due to many months of preparation and commitment from numerous people. We thank them all, especially members of the Local and Programme Committees. Particular attention must go to Gilah Leder for her encouragement in the early days of our work and to Rina Hershkowitz for continuing such support. Thanks too to Janet Ainley who proved to be an excellent Chair for the Programme Committee. The invaluable help of Lucila Recart and Bella Radford was also much appreciated. Angela Hook’s and Claire Butler’s hard work should not go unmentioned either. Joop van Dormolen’s ceaseless labours in both creating and refining the computer programme we relied on and his endless patience and enthusiasm also deserve particular recognition. And finally, a special mention to Elena Nardi, without whom this venture would have been impossible.
More formally, we would like to thank the following sponsors:

- The Lord Mayor of Norwich for his most generous contribution on our arrival at the dinner dance;
- Jarrolds Department Store for heavily subsidising the Norwich guidebooks in your conference pack;
- Falmer Press for providing conference pens;
- Paul Chapman Publishers for donating conference notebooks;
- Colmans of Norwich for the savoury packs in your conference bag;
- The University of East Anglia for providing us with both time and space to host this conference.

Finally, should you have any questions/concerns during your stay, please do not hesitate to ask members of the conference team. We very much hope that you enjoy PME 26 and that you return home feeling refreshed and invigorated.

With very best wishes,

Anne Cockburn
on behalf of the PME 26 Conference Committees

Summer 2002
# TABLE OF CONTENTS

## VOLUME 1

Welcome to PME26 1-iii
Table of Contents 1-v

### Introduction

The International Group for the Psychology of Mathematics Education 1-xxxv
Proceedings of previous PME conferences 1-xxxviii
The review process of PME26 1-xl
List of PME26 reviewers 1-xli
Index of presentations by research domains 1-xliv
List of authors 1-li

### Plenary Lectures

**Ginsburg, Herbert P**

*Little children, big mathematics: learning and teaching in the pre-school*

1-003

**Brown, Margaret**

*Researching primary numeracy*

1-015

**Maher, Carolyn A**

*How students structure their own investigations and educate us: What we've learned from a 14 year study*

1-031

**Noss, Richard**

*Mathematical epistemologies at work*

1-047

**Verschaffel, Lieven**

*Taking the modeling perspective seriously at the elementary school level: Promises and pitfalls*

1-064
### Plenary Panel

**Learning from learners**
Matos, João Filipe 1-083

**Episode 1: How Karin disturbed her teacher’s line of reasoning**
Van Dormolen, Joop 1-084

**Episode 2: Marco and Anna – Each following their own path**
Zan, Rosetta 1-091

**Episode 3: Calculators – The first day**
Groves, Susie 1-098

### Research Forums

**RF1 Abstraction: Theories about the emergence of knowledge structures**
Coordinators: Dreyfus, Tommy & Gray, Eddie

Dreyfus, Tommy & Gray, Eddie 1-113
*Abstraction: Theories about the emergence of knowledge structures: Introductory remarks*

Gray, Eddie & Tall, David 1-115
*Abstraction as a natural process of mental compression*

Schwarz, Baruch & Hershkowitz, Rina & Dreyfus, Tommy 1-120
*Abstraction in context: Construction and consolidation of knowledge structures*

Gravemeijer, Koen 1-125
*Building new mathematical reality, or how emergent modeling may foster abstraction*

Sierpinska, Anna 1-129
*Reaction*

Boero, Paolo 1-133
*Abstraction: What theory do we need in mathematics education?
RF2  *The nature of mathematics as viewed from mathematics education research*

Coordinators: English, Lyn D & Goldin, Gerald A

English, Lyn D & Goldin, Gerald A

*The nature of mathematics as viewed from mathematics education research – introductory remarks*

Greer, Brian

*Complexity of mathematics in the real world*

Sfard, Anna

*Mathematics as a form of communication*

Edwards, Laurie D

*The nature of mathematics: A personal journey*

Vinner, Shlomo

*Boundaries, identities and mathematical objects – should we bother?*

Meissner, Hartwig

*Einstellung, vorstellung, darstellung*

Goldin, Gerald A

*Connecting understandings from mathematics and mathematics education research*

English, Lyn D

*Concluding points*

RF3  *Measuring mathematics learning and describing goals for systemic reform*

Coordinators: Sullivan, Peter & Siemon, Diane

Sullivan, Peter & Siemon, Diane

*Measuring mathematics learning and describing goals for systemic reform – introductory remarks*

Lerman, Stephen

*Measuring mathematics learning and describing goals for systemic reform: Some issues for consideration*
Brown, Margaret & Askew, Mike & Rhodes, Valerie & Denvir, Hazel

Measuring progress in numeracy learning

Ranson, Esther & William, Dylan

Measuring and describing learning: The early numeracy research project

Mevarech, Zemira R

Large-scale studies in mathematics education: A search for identity

van den Heuvel-Panheusen, Marja

From core goals to learning-teaching trajectories as a guide for teaching primary school mathematics in The Netherlands

Wright, Robert (Bob) & Gould, Peter

Using a learning framework to document students' progress in mathematics in a large school system

RF4 From number patterns to number theory: Issues in research and pedagogy

Coordinators: Zazkis, Rina & Campbell, Stephen R

Zazkis, Rina & Campbell, Stephen R

Making a case for number theory

Campbell, Stephen R

What is number theory?

Zazkis, Rina & Liljedahl, Peter

Repeating patterns as a gateway

Sinclair, Nathalie

For the beauty of number theory

Mason, John

What makes an example exemplary?: Pedagogical and research issues in transitions from numbers to number theory

Rowland, Tim

Proofs in number theory: History and heresy
Discussion Groups

DG01  *Imagery and affect in mathematical learning*  
Coordinators: English, Lyn D & Goldin, Gerald  
1-239

DG02  *Stochastical thinking, learning and teaching*  
Coordinators: Greer, Brian & Reading, Christine  
1-240

DG03  *Semiotics in mathematics education research*  
Coordinators: Sáenz-Ludlow, Adalira & Presmeg, Norma  
1-241

DG04  *Researching the social and political in mathematics education from a critical perspective: Dilemmas for researchers*  
Coordinators: Hardy, Tansy & Povey, Hilary  
1-242

DG05  *Facilitating the conceptual change in mathematics*  
Coordinators: Pehkonen, Erkki & Merenluoto, Kaarina & Tzekaki, Marianna  
1-243

DG06  *Examining theses discussion group*  
Coordinators: Hart, Kathleen & Sullivan, Peter  
1-244

DG07  *Symbolic cognition in advanced mathematics*  
Coordinators: Hegedus, Stephen J & Tall, David & Eisenberg, Theodore  
1-245

DG08  *Learning disabilities in mathematics*  
Coordinators: Scherer, Petra & Moser Opitz, Elisabeth  
1-246

Working Sessions

WS01  *The psychology of object construction*  
Coordinators: Mason, John & Watson, Anne  
1-249

WS02  *Learning from each other*  
Coordinators: Breen, Chris J. & Hannula, Markku  
1-250

WS03  *Composing trajectories*  
Coordinators: Nemirovsky, Ricardo & Barros, Apolinario  
1-251

WS04  *Gesture, metaphor and embodiment in mathematics*  
Coordinators: Edwards, Laurie & Bolite Frant, Janete & Draisma, Jan  
1-252

WS05  *Writing research papers for publication [with attention also to the review process]*  
Coordinators: Ainley, Janet & Jaworski, Barbara  
1-253
Short Oral Communications

Abdul Rahman, Roselainy & Mason, John & Yusof, Yudariah Mohd
   Changing engineering students attitudes to calculus

Alcock, Lara & Simpson, Adrian
   The effectiveness of a question-based first course in analysis

Al-Ghafri, Mohammed & Jones, Keith & Hirst, Keith
   Secondary trainee-teachers' knowledge of students' errors and
difficulties in algebra

Alsaadi, Aziza
   Comparing the classroom practice of teaching primary mathematics
   in England and Qatar

Alvarez, Jairo & Delgado, César
   The Tall-Vinner problem. An operative reformulation

Barash, Aviva
   Algorithmic mental models and metacognition

Benson, Carol
   Instructional strategies and tasks developed in a teaching experiment
   on probability modeling

Berenson, Sarah
   Lesson plan study and the growth of understanding of school
   mathematics among prospective high school teachers

Bershadsky, Irina & Shir, Karni & Zaslavsky, Orit
   Looking at a square through another lens: A square as a locus

Borba, Rute & Nunes, Terezinha
   Understanding number meanings and representations of directed
   numbers

Brinkmann, Astrid
   Mathematical networks and their transformation in teaching and
   learning processes

Brown, Laurinda & Coles, Alf
   It's not what you do, it's why you do it: Reflections on the role of
   teachers in research on algebra
Cavallaro, Maria Ines & Anaya, Marta
*Cognitive problems of university students with the concept of distribution*

Chang, Ching-Kuch
*Taiwanese inservice mathematics teachers' beliefs and values can change*

Chung, Jing & Chu, Tien-Chen
*The affective domain and the achievement of the school children under two different mathematics instruction*

Da Rocha-Falcão, Jorge Tarcisio & Leitão, Selma & Araújo, Cláudia Roberta & Lins Lessa, Mônica Maria & Oliveira Osório, Mônica
*Argumentation in the context of a didactic sequence in elementary algebra*

De Bock, Dirk & van Dooren, Wim & Janssens, Dirk & Verschaffel, Lieven
*Broadening the scope of the illusion of linearity: A conceptual reanalysis of probabilistic misconceptions*

Delice, Ali
*Recognising, recalling and doing in the 'simplification' of trigonometric expressions*

Fakir Mohammad, Razia
*A co-learning partnership in teaching development: Practicality and limitations*

Gadanidis, George & Hoogland, Cornelia & Hill, Bonilyn
*Mathematical romance: Elementary teachers' aesthetic online experiences*

Giraldo, Victor & Carvalho, Luiz Mariano
*Local magnification and theoretical-computational conflicts*

Gono, Ebert N & Hungwe, Godwin
*Mathematical language and pupils' performance*

Gonzáles-Martín, Alejandro & Camacho Machín, Matias
*Use of a competence model to describe students' understanding of concepts related to improper integration*
Gur, Hulya & Çömlekoðlu, Gözde & Ersoy, Yasar
Perceptions of a group of primary teacher trainees and mathematics teacher trainees on the use of calculators as a cognitive tool

Kabani-Potouridou, Elisabeth & Koleza, Eugenia
Imagery in geometrical problem solving

Kaufman Fainguelernt, Estela & Cohen Gottlieb, Franca
How the geometric constructions help the understanding of complex number?

Klein, Ronith & Bassan-Cincinatus, Ronit & Sheffet, Malka
A teacher empowerment program - a model of teaching

Koyama, Masataka
Research on the process of understanding concepts of triangle and quadrilateral in a classroom

Krupanandan, Daniel
Problem solving the challenge facing South African mathematics teachers

Kwak, Jeeyi & Reiss, Kristina M.
Different views of Korean and German teachers beliefs about mathematics

Lam, Eva Tsz Wai
Making and proving conjectures: Circles

Lann, Avital & Falk, Ruma
An average with unimaginative weights when the weights equal the values

Law, Huk-Yuen
The use of student questioning for assessing mathematical understanding

Le Roux, Amanda & Murray, Hanlie & Olivier, Alwyn
Analysis of children's argumentation while making sense of fractions

Lee, Sit Yuen
Teachers' thinking on incorporating graphing calculators into mathematics teaching

BEST COPY AVAILABLE
Lin, Fou-Lai & Yang, Kai-Lin
Defining a rectangle under a social and practical setting by two seventh graders

Mackay, Irene F.
A time of change

Mamede, Ema Paula
The calculator's role in problem solving: a case study in a fourth grade classroom

Mamona-Downs, Joanna & Downs, Martin
Promoting students' awareness in applying bijections in enumeration tasks

Markovits, Zvia
Have we done a good job? What do teachers think about their training to teach mathematics in elementary school?

Martins-Mourao, Antonio
An integrated view of children's number understanding: A multi-component analysis from early counting to place value

Mevarech, Zemira R & Kramarski, Bracha
Metacognitive discourse in mathematics classrooms

Misailidou, Christina & Williams, Julian
Diagnostic teaching and ratio: The effect of pictorial representations on strategies

Mok, Ida Ah-Chee & Tse, Betty Sui Wah
Students' appreciation of 3-dimensional solids: A study in Hong Kong

Monteiro, Cecilia & Serrazina, Lurdes & Barros, Elsa
Children's strategies to solve proportional problems in a real context

Moschkovich, Judit
"I went by twos, he went by ones" Multiple views of graphs

Mukhopadhyay, Swapna & Greer, Brian
Six characters in search of an answer

Nason, Rod & Woodruff, Earl & Lesh, Richard
Establishing and maintaining authentic mathematical activity in CSCL communities
Nasser, Lilian & Tinoco, Lucia
Argumentation and proofs in mathematical teaching

Ngoepe, Mapula
Explanations by mathematics teachers: An analysis

Papadopoulos, Ioannis & Dagdilelis, Vassilios
Using computers for didactic activities on areas: a case study

Parzysz, Bernard & Jore, Francoise
What is geometry for French pre-service elementary school teachers?

Pehkonen, Erkki & Merenluoto, Kaarina
Teacher students' mathematical understanding from the viewpoint of conceptual change

Perivolakis, Antonis & Koleza, Eugenia & Skordoulis, Constantine & Dellaportas, Dimitris
The effect of the socio-cultural factors during an interdisciplinary approach of teaching mathematics & technology

Perrusquia, Elvia & Rojano, Teresa
The role of representation devices in the conceptualization of change: A case study with 10 to 11-year old pupils

Pinel, Adrian
Catechetics observed in mathematics classrooms

Price, Alison
Analysis of young children's achievements in measuring 'time'

Rogalski, Janine & Rogalski, Marc
How do future mathematics teachers deal with different types of implications?

Sakonidis, Haralambos & Bliss, J
Mathematics teaching and learning practices in transition

Selva, Ana Coelho Vieira & Da Rocha-Falcão, Jorge Tarcísio
Understanding and using graphs: a didactic sequence for pre-school children

Shane, Ruth
Supporting mathematical literacy for kindergarten children at-risk
Spinillo, Alina & Lautert, Sintria  
Representations and solving procedures in word division problems: Comparing formal and informal knowledge in children  

Squire, Sarah  
Children's misunderstanding of an inverse relation  

Steward, Susan  
Ability grouping, sex and social class - effects on attitude towards and confidence in mathematics  

Stupp, Jonathan  
Equations as an example of a "procept"  

Swoboda, Ewa  
Relationship: Signs--object-concept in the process of the creation of the concept of similar figures (case study)  

Tortora, Roberto & Iannece, Donatella & Nazzaro, Pasqualina  
From naïve drawing to cartesian representation  

Tzekaki, Marianna  
Introducing reasoning in early childhood  

Ursini, Sonia & Sacristán, Ana Isabel  
Challenges in incorporating new technologies to the mathematics classroom  

Vamvakoussi, Xanthi & Vosniadou, Stella  
What mental models do students use regarding the structure of the domain of rational numbers?  

Watanabe, Tad & Ginshima, Fumi  
Japanese children's understanding of 10 as a unit  

Wilson, Kirsty & Briggs, Mary  
Able and gifted: a case study of year 6 children  

Winbourne, Peter  
Student teachers' experiences of becoming 'expert' within the practice of primary school mathematics teaching  

Yáñez, Gabriel  
Some challenges of the use of computer simulations in probability teaching
Poster Presentations

Applebaum, Mark & Samovol, Peter

Logical errors of students in the solution of mathematical problems

Ashleigh, Glenda

Individual differences in cognition and affect and secondary school students' multiplicative knowledge in basic arithmetical problems

Attorps, Iiris

Teachers' knowledge about the equation concept

Costa, Maria Conceição

Early experiences in dynamic visual reasoning in a computer environment

da Silva, Maria Solange & da Silva, Marco Antonio Costa

How does a teaching practice project influence the teacher-students' actions

De Bock, Dirk & van Dooren, Wim & Weyers, Dave & Verschaffel, Lieven

Do individual students consistently apply the same intuitive rule?

Fonseca, Lina

Preservice teachers, geometry and proof

Forrester, Ruth

Joined up thinking

Gazit, Avikam

Reflecting at the M.I.R.R.O.R. - teaching students with learning disabilities in mathematics

Gelfman, Emanuila & Kholodnaja, Marina

Forming cognitive schemes is one of the conditions of developing students' intellectual abilities

Hannula, Markku & Maijala, Hanna & Pehkonen, Erkki & Soro, Riitta

Three measures for confidence in mathematics

Hejný, Milan

Semantic types of an anchored addition and subtraction

Hoffmann, Ronit

Old tunes, new technology: how computers meet history in the math classroom
Hofmannová, Marie & Novotná, Jarmila

Implementation of content and language integrated learning (CLIL) in mathematics classroom

1-346

Hoyos, Verónica

Focus on mediation of activity to developing classroom discourse

1-347

Kaldrimidou, Maria & Pange, Jenny

Computer-based mathematical games for preschool children

1-348

Karaca, Denizhan & Gur, Hulya

Elementary mathematics teachers' beliefs about the use of technological mathematics teaching in rural and urban areas

1-349

Kaur, Berinderjeet

Supporting change through an in-service course: Activities to promote thinking in the mathematics classroom

1-350

Koirala, Hari

Opening the mathematical horizon using open-ended tasks

1-351

Kontozisis, Dimitros & Kaldrimidou, Maria

A teaching experiment on how children understand the meaning of \( \frac{1}{2} \) fraction

1-352

Krainer, Konrad

IMST\(^2\) - A nation-wide initiative for upper secondary schools in Austria

1-353

Kratochvilova, Jana

Difficulties arise with idea of complement

1-354

Kubínová, Marie

Levels of understanding of letters in the word problem solving processes

1-355

Le Roux, Amanda & Murray, Hanlie & Olivier, Alwyn

A web-based module on fractions for pre-service teachers

1-356

Linn, Marcia

Wise design of mathematics software

1-357

Littler, Graham H

Semantic types of number

1-358
Lucena, Ana Tiburtius & Noss, Richard
The design of a computational environment to explore children's development of place value

Mamede, Ema Paula
The calculator's role in problem solving: a case study in a fourth grade classroom

Maranhão, Cristina & Igliori, Sonia & Soares, Elizabeth
Relations for fifth to eighth graders

Millet, Shoshy & Patkin, Dorit & Ezer, Hanna
What is between Lafontein's quarter and the rational number quarter? or What is the difference between math justice and jungle justice

Mooney, Claire & Jones, Keith
Lost in space: primary trainee teachers' spatial subject knowledge and their classroom performance

Presmeg, Norma & Barret, Jeff
Concepts of operational symmetry in the thinking of four elementary school students

Rogalski, Marc & Rogalski, Janine
What do future mathematics teachers evaluating an implication when facing the case of premise falseness?

Safuanov, Ildar & Gusev, Valery
The structure of mathematical abilities

Saló Nevado, Laia
The Euro at school

Singer, Mihaela
New ways of developing mathematical abilities

Soro, Riitta & Pehkonen, Leila
Methodological considerations on gender stereotypes

van Dooren, Wim & De Bock, Dirk & Hessels, An & Janssens, Dirk & Verschaffel, Lieven
Remediing secondary school students' illusion of linearity: A developmental research
How to read a mathematical textbook

VOLUME 2

Research Reports

Acuña, Claudia

High school students' identification of equal slope and Y-intercept in different straight lines

Afantiti Lamprianou, Thekla & Williams, Julian

A developmental scale for assessing probabilistic thinking and the tendency to use a representativeness heuristic

Ainley, Janet & Pratt, David

Purpose and utility in pedagogic task design

Akkoc, Hatice & Tall, David

The simplicity, complexity and complication of the function concept

Alatorre, Silvia

A framework for the study of intuitive answers to ratio-comparison (probability) tasks

Amit, Miriam & Fried, Michael N

Authority in the mathematics classroom and its influence on students' ability to reflect

Anghileri, Julia

Scaffolding practices that enhance mathematics learning

Barkai, Ruth & Tsamir, Pessia & Tiresh, Dina & Dreyfus, Tommy

Proving or refuting arithmetic claims: The case of elementary school teachers

Baturo, Annette

Number sense, place value and the "odometer" principle in decimal numeration: Adding 1 tenth and 1 hundredth

Belfort, Elizabeth & Guimarães, Luiz Carlos

The influence of subject matter on teachers' practices: Two case studies
Ben-Chaim, David & Ilany, Bat-Sheva & Keret, Yaffa
Mathematical and pedagogical knowledge of pre- and in-service elementary teachers before and after experience in proportional reasoning activities

Bezerra, Francisco & Magina, Sandra & Spinillo, Alina
How to promote children's understanding of fractions? An exploratory study

Bills, Christopher
Linguistic pointers in young children's descriptions of mental calculation

Blanton, Maria & Kaput, James J.
Design principles for tasks that support algebraic thinking in elementary school classrooms

Boaler, Jo
The development of disciplinary relationships: knowledge, practice and identity in mathematics classrooms

Bobis, Janette & Aldridge, Sharne
Authentic learning contexts as an interface for theory and practice

Boero, Paolo
Geometric signs and students' verbal reports: The case of the geometric model of sun shadows

Bohl, Jeffrey & van Zoest, Laura
Learning through identity: A new unit of analysis for studying teacher development

Borthwick, Alison
What do the pupils think? Pupils' perceptions of their mathematics lessons

Boufi, Ada & Skaftourou, Frosso
Supporting students' reasoning with decimal numbers: A study of a classroom's mathematical development

Bulgar, Sylvia & Schörr, Roberta & Maher, Carolyn
Teachers' questions and their role in helping students build an understanding of division of fractions
Cabral, Tânia Christina Baptista & Baldino, Roberto

INTRODUCTION
History and aims of PME
PME came into existence at the Third International Congress on Mathematics Education (ICME3) held in Karlsruhe, Germany in 1976. Its past presidents have been Efraim Fischbein (Israel), Richard R. Skemp (UK), Gerard Vergnaud (France), Kevin F. Collis (Australia), Pearla Nesher (Israel), Nicolas Balacheff (France), Kathleen Hart (UK), Carolyn Kieran (Canada), Stephen Lerman (UK), and Gilah Leder (Australia).

The major goals of the Group are:

- To promote international contacts and the exchange of scientific information in psychology of mathematics education
- To promote and stimulate interdisciplinary research in the aforesaid area with the cooperation of psychologists, mathematicians and mathematics educators
- To further a deeper understanding into the psychological aspects of teaching and learning mathematics and the implications thereof.

PME membership and other information
Membership is open to people involved in active research consistent with the Group's goals, or professionally interested in the results of such research. Membership is on an annual basis and requires payment of the membership fees (US$40 or the equivalent in local currency) per year (January to December). For participants of PME26 Conference, the membership fee is included in the Conference Deposit. Others are requested to contact their Regional Contact, or the Executive Secretary. More information about PME as an association can be obtained through its home page at: http://igpme.tripod.com or contact the Executive Secretary.

Honorary Members of PME
Hans Freudenthal (The Netherlands, deceased)
Efraim Fischbein (Israel, deceased)

Present Officers of PME
President: Rina Hershkowitz (Israel)
Vice-president: Chris Breen (South Africa)
Secretary: Viki Zack (Canada)
Treasurer: Peter Sullivan (Australia)

Other Members of the International Committee
Luciana Bazzini (Italy)
Janete Bolite Frant (Brazil)
Anne Cockburn (UK)
Jorge Tarcisio Da Rocha-Falcão (Brazil)
Jan Draisma (Mozambique)
Ruhama Even (Israel)
Peter Gates (UK)
Masataka Koyama (Japan)
Ricardo Nemirovsky (USA)
Andrea Peter-Koop (Germany)
Catherine Sackur (France)
Marja van den Heuvel-Panhuizen (The Netherlands)
Tad Watanabe (USA)

Executive Secretary
Joop van Dormolen
Rehov Harofeh 48A/10
Haifa 34367, Israel
Phone: +972-4-8246239
Fax:+972-4-8258071

PME26 Programme Committee

Janet Ainley (University of Warwick)
Alan Bell (Nottingham University)
Anne Cockburn (UEA)
Ruhama Even (Weizmann Institute of Science, Israel)
Derek Haylock (UEA)
Rina Hershkowitz (President PME, Weizmann Institute of Science, Israel)
Marja van den Heuvel-Panhuizen (Utrecht University, The Netherlands)
Barbara Jaworski (University of Oxford)
Stephen Lerman (South Bank University)
Elena Nardi (UEA)
Tim Rowland (University of Cambridge)
Catherine Sackur (University of Nice, France)
Johannes Siemons (UEA)

PME26 Local Organising Committee

Anne Cockburn (UEA)
Elena Nardi (UEA)
Derek Haylock (UEA)
Sue Cramp (UEA)
Ralph Manning (UEA)
Johannes Siemons (UEA)
Tim Rowland (University of Cambridge)
Stephen Lerman (South Bank University)

Members of the Communication, Conference and Catering Services at UEA

Secretarial staff: Lucila Recart, Bella Radford and other very welcome occasional helpers.

IT staff at UEA: Rob Barnes, Peter Saward, Elena Nardi, Angela Hook, Dave Knock, and members of the Audio Visual Services.
PROCEEDINGS OF PREVIOUS PME CONFERENCES

Copies of some previous PME Conference Proceedings are still available for sale. For information, see the PME home page at http://igpme.tripod.com, or contact the Executive Secretary Dr. Joop van Dormolen, Rehov Harofeh 48A, Haifa 34367, Israel; fax: +972 4 8258071; email: joop@tx.technion.ac.il.

All proceedings, except PME1, are included in ERIC. Below is a list of the proceedings with their corresponding ERIC code.

Abstracts from articles can be inspected on the ERIC web site (http://www.accesseric.org) and on the web site of ZDM/MATHDI (http://www.emis.de/MATH/DI.html).

Micro fiche with the content of the proceedings might be available for inspection at university libraries or can be bought from: ERIC/CSMEE, 1929 Kenny Road, Columbus, OH 43210-1080, Tel: (614) 292-6717, Fax: (614) 292-0263, e-mail:ericse@osu.edu

MATHDI is the web version of the Zentralblatt für Didaktik der Mathematik (ZDM, English subtitle: International Reviews on Mathematical Education). For more information on ZDM/MATHDI and its prices or assistance regarding consortia contact Gerhard König, managing director, fax: +49 7247 808 461, email: gk@fiz-karlsruhe.de.
THE REVIEW PROCESS OF PME26

Research Forums
Four Research Forums were suggested by the International Committee and the Programme Committee for PME26: RF1 Abstraction: Theories about the Emergence of Knowledge Structures; RF2 The Nature of Mathematics as Viewed From Mathematics Education Research; RF3 Measuring Mathematics Learning and Describing Goals for Systemic Reform; RF4 From Number Patterns to Number Theory: Issues in Research and Pedagogy. For each Research Forum the proposed structure, the contents, the contributors and their role were reviewed and agreed by the Programme Committee.

Discussion Groups and Working Sessions
Eleven DG proposals, of which all but two were accepted, and four WS proposals were received, of which all were accepted. After consultation with the PC one DG agreed to become a WS. Overall there are 8 DG and 5 WS in the programme.

Research Reports
The Programme Committee received 237 Research Report proposals. Each proposal was sent for blind review to three reviewers. As a rule, proposals with at least two recommendations for acceptance were accepted. The reviews of proposals with only one recommendation for acceptance were carefully read by at least two members of the Programme Committee. When necessary, the Programme Committee members read the full proposal and formally reviewed it. Proposals with three recommendations for rejection were not considered for presentation as research reports. Altogether, 165 research report proposals were accepted. When appropriate, authors of proposals that were not accepted as Research Reports were invited to re-submit their work — some in the form of a Short Oral Communication and some as a Poster Presentation.

Short Oral Communications and Poster Presentations
The Programme Committee received 91 Short Oral Communication proposals and 18 Poster Presentation proposals. Each proposal was reviewed by at least two Programme Committee members. From these proposals 59 Short Oral Communications and all Poster Presentations were accepted. Of the rejected Short Oral Communication proposals, 12 were recommended as Posters.
LIST OF PME26 REVIEWERS

The PME26 Programme Committee thanks the following people for their help in the review process:

Adler, Jill (South Africa)  
Aharoni, Dan (Israel)  
Ainley, Janet (United Kingdom)  
Arnon, Ilana (Israel)  
Artigue, Michèle (France)  
Ayres, Paul (Australia)  
Azcárate, Carmen (Spain)  
Bakker, Arthur (The Netherlands)  
Balacheff, Nicolas (France)  
Baldino, Roberto (Brazil)  
Bartolini Bussi, Mariolina (Italy)  
Batanero, Carmen (Spain)  
Bazzini, Luciana (Italy)  
Becker, Joanne Rossi (USA)  
Bednarz, Nadine (Canada)  
Bell, Alan (United Kingdom)  
Ben-Chaim, David (Israel)  
Ben-Zvi, Dani (Israel)  
Berenson, Sarah (USA)  
Bills, Elizabeth (United Kingdom)  
Bishop, Alan (Australia)  
Björkqvist, Ole (Finland)  
Boavida, Ana Maria (Portugal)  
Boero, Paolo (Italy)  
Boite Frant, Janete (Brazil)  
Booke, George (Australia)  
Boulton-Lewis, Gillian (Australia)  
Bowers, Janet (USA)  
Breen, Chris J. (South Africa)  
Brecke, Gard (Norway)  
Brito, Márcia Regina F. de (Brazil)  
Brodie, Karin (USA)  
Brown, Laurinda (United Kingdom)  
Brown, Roger (United Kingdom)  
Campbell, Stephen (USA)  
Cannizzaro, Lucilla (Italy)  
Carrillo Yafiez, Jose (Spain)  
Chapman, Olive (Canada)  
Chazan, Daniel (USA)  
Chinnappan, Mohan (Australia)  
Christou, Constantinos (Cyprus)  
Cifarelli, Victor (USA)  
Civit, Marta (USA)  
Clarkson, Philip (Australia)  
Coady, Carmel (Australia)  
Cobb, Paul (USA)  
Cockburn, Anne (United Kingdom)  
Cooney, Thomas (USA)  
Cooper, Tom J. (Australia)  
Crowley, Lillie (USA)  
Csikos, Csaba (Hungary)  
Da Rocha-Façã, Jorge Tarcísio (Brazil)  
Davis, Gary (USA)

Three-, 4-, and 5-year-old children (in the U.S., we call them pre-schoolers) are little. They are short. They do not know as much as adults. As Piaget suggested, their thought may be different from adults'. Mathematics is big. It is one of the crowning intellectual achievements of humanity. It is abstract, symbolic, and difficult. Many believe that mathematics is too big to teach to little children because they cannot understand it a meaningful way.

I strongly disagree, and in this talk will present a different view of early mathematics education. I will show that little children are more competent than we usually think they are. They have a great interest in mathematical ideas and even in mathematical symbolism. They can learn mathematics and can benefit from teaching. I will also describe how research can both stimulate and be stimulated by the development of a rich program of early childhood mathematics education.

COUNTING AND EVERYDAY MATHEMATICS

In this talk, I will focus on one small area of young children's mathematical knowledge, namely their acquisition of counting words, the language of counting—not enumeration, not understanding of cardinality, not any of the other important topics on which researchers have focused.

Why place so much emphasis on counting words? At first, the topic appears to be relatively uninteresting. Counting is often seen as a mechanical process; it is not considered to entail genuine mathematical thinking. Children seem to acquire counting through a process of rote learning. In this view, although children clearly need to learn to count, mathematics educators and researchers should devote attention to deeper mathematical topics.

I think these views are wrong. First, counting is not simply a matter of rote memory; it is an interesting cognitive activity. And second, counting can present young children with opportunities for rich mathematical learning. It is worth thinking about how children learn to count and how it can be taught. Moreover, the example of counting suggests some general lessons about research on the psychology of mathematics education and on curriculum development.

We know several things about counting language. First, young children like to count, even to high numbers. Walkerdine (1988) reports that “... children initiate a counting sequence and often count spontaneously” (p. 105). Irwin and Burgham (1992) describe how children at 5 years of age enjoy counting up to relatively large
numbers, like 100. Similarly, Gelman (1980) observes that some children exhibit a spontaneous interest in large numbers. "I remember a five-year-old who told me that she had been trying to count to a million, had been at it for two days and said it would still take her a long time to reach her goal!" (p. 65).

I have observed similar phenomena.

One day during "free play" Kasheef, a 5-year-old African-American boy, was sitting at a table alone. He poured a large number of small beads from his hand onto the table. "Oh, man! I got one hundred," he proclaimed. Then, he began to count the beads as he picked them up one by one, although grasping them was difficult because they were so small. When he reached "ten," Barbara joined the activity. She said the numbers but did not actually count out the beads. As he progressed through the twenties, Kasheef made a mistake. He dropped the bead as he said "twenty-six," but ignored it and continued counting. Barbara kept pace with him. When he got to "thirty," Kasheef dropped the bead again. He paused for a second and said, "Wait! I made a mistake."

So here is a child who spontaneously decided to enumerate a large collection of objects, estimated their number, said the numbers correctly through 30, and performed a 1-1 matching of the spoken numbers to the objects. No one told him to undertake these activities. He made two mistakes, but recognised the second. He was highly motivated, persisting over a period of time despite the physical difficulty of the task. And he was joined by a peer who also found the activity of some interest.

Kasheef began to count the beads again. "One, two, three...." When he counted "three," Barbara picked out one bead, showed it to him, and said, "I have one." But Kasheef ignored her and continued to count. Barbara joined him at "five." When he counted "ten," Barbara again showed her beads to Kasheef, "I got, look...." Kasheef again ignored her and continued counting. Barbara kept pace with him, uttering the same number words. When he counted "twelve," Barbara shouted in his ear, as if she wanted to distract his attention. Kasheef ignored her again. When Kasheef reached "forty-seven," another girl came over and asked, "What do you count?" Again, he ignored the distraction. After the "forty-nine", Kasheef paused, apparently not knowing what came next. Barbara said, "fifty" and Kasheef followed her with "fifty-one, fifty-two...."

Kasheef had clearly decided to count the whole collection of beads and was not about to be distracted from the task. He persisted despite several interruptions. He counted very well, making almost no mistakes until he reached "forty-nine." At this point, he needed and benefited from Barbara's help. But once given "fifty," he knew what to do with it: he knew the rule for constructing numbers from decades and units.

When they reached "fifty-two," Ruthie came to the table, picked out one bead, and joined their counting, "fifty-two, fifty-three...." Madonna also joined the counting, "fifty-six, fifty-seven...." The female chorus said the counting words but sometimes picked out
several beads at once or sometimes didn’t pick out a single bead. After “seventy-nine,” Kasheef again paused. After the girls said, “eighty,” Kasheef continued, “eighty-one, eighty-two...” When they reached “eighty-five,” the girls fought with one another to grab beads, which then scattered on the table, dropped on the floor and rolled in every direction. Despite the disturbance, Kasheef continued, “eighty-six, eighty-seven... ninety-four.”

Kasheef’s counting drew a crowd of girls who found the activity of interest. They were competent in saying the counting numbers, but were not careful in enumerating the objects. They were disruptive. Kasheef largely ignored them, except when they provided him with the numbers he did not know. Kasheef showed remarkable persistence in his attempt to count each bead and to say the numbers correctly. He was almost always accurate, getting help on only two occasions.

After he picked out the ninety-fourth bead, there were no more on the table. He picked up some beads from those on the floor, and continued, “ninety-five, ninety-six, ninety-seven...” What he said next was inaudible. Madonna shouted, “One hundred!” raising her arm. Kasheef, Barbara, and Ruthie said, “One-hundred!” right after her. And Kasheef concluded, “We all got one hundred.” In the course of the celebration, the girls got down under the table and began to squabble over picking up the beads. Kasheef joined the fight. At this point the teacher came over and yelled at the children for their misbehaviour.

We see then that Kasheef continued to count very well, at least to “ninety-seven,” and like the other children was very proud to reach the goal, “one-hundred.” What the teacher observed was a group of children squabbling under the table.

Many features of this example stand out. Kasheef and the other children were able to count, making only a few errors, to 100. They showed great interest both in the counting numbers themselves and in counting as a means to determine a quantity. Also, Kasheef persisted, despite frequent distraction; he was excited, interested, enthusiastic, hard-working.

Kasheef’s behaviour was not unique. In a large naturalistic study—which I will not describe in detail here—we found that during free play, 4- and 5-year old American children from various social class and ethnic groups spontaneously and frequently engaged in “everyday mathematics” (Ginsburg, Pappas, & Seo, 2001). This refers to the mathematical skills and competencies children employ in the ordinary environment. Young children’s everyday mathematics is usually intuitive (like the idea that adding makes more), (Brush, 1978); it is informal (not acquired through formal instruction); and it is free of written symbolism. In our study, children exhibited everyday mathematics in a little more than 40 percent of the minutes during which we observed them. Further, we failed to uncover statistically significant social class differences in the overall frequency of everyday mathematics. For example, the average percentages of minutes in which lower-, middle-, and
upper-SES children engaged in everyday mathematical behaviour were 44, 43, and 40 respectively.

We also found that three types of everyday mathematics occurred most frequently in children’s free play: enumeration, magnitude, and pattern. Enumeration included saying the counting words, enumerating objects (like Kasheef), and observing the quantity of a set of objects (e.g., “There are five here”). Magnitude involved such activities as judging that one set had more than another or that a quantity was very large. And pattern was shown when, for example, children devised elaborate symmetries, in three dimensions, during block play. Again, we failed to uncover statistically significant social class differences in the frequency or complexity of these three types of everyday mathematics.

In brief, our research clearly reveals that children frequently and spontaneously engage in an everyday mathematics that includes not only counting but also work with magnitudes and patterns. The research also shows that teachers were almost never involved in these mathematical activities.

We also know something about the cognitive processes underlying counting (Miller & Parades, 1996). To count successfully, learners (children or adults) must first memorise a relatively small set of meaningless sounds in an arbitrary sequence. In English, these sounds—a kind of meaningless “number song” (Ginsburg, 1989)—include “one, two... ten.” Second, learners must induce and then use rules for generating subsequent number words. In English, the rules for generating 21 through 99 are reasonably clear: take the decade word (twenty, thirty, and the like) and add to it the memorised sequence “one... nine” and then go to the next decade word. Use of rules like these was evident in the fact that once given a decade word he did not know, Kasheef easily attached to it the unit numbers.

Unfortunately, English presents learners with several difficulties. One is that a few number words above “ten,” namely “eleven” and “twelve,” appear to be arbitrary. A second is that generating the decade words is not so simple. “Seventy” bears a clear relation to “seven” whereas the relation between “twenty” and “two” is not entirely transparent. A third difficulty is really serious. The number words from “thirteen” to “nineteen” put the units (e.g., “thir”) first and the tens (“teen”) second, whereas all number words after 20 do the reverse, as in the case of “twenty-three.”

Counting need not be as odd as occurs in English. East Asian languages based on the Chinese are perfectly regular. To be sure, their learners must memorise the equivalent of “one” through “ten,” but after that they can benefit from a consistent set of rules. After “ten,” comes “ten-one... ten-nine,” and after that, with perfect regularity, come “two-ten, two-ten-one, ... nine-ten-nine.” Perhaps the coherent design of Chinese counting contributes to its speakers’ mathematical understanding.
In brief, learning the language of counting is a key aspect of everyday mathematics. Children enjoy counting and often try to count to large numbers. Counting requires more than memorisation; like other aspects of language, it is based on a system of rules.

Consider next how counting can be taught and what the teaching of mathematics teaches us.

A MATHEMATICS CURRICULUM

For many years, the message taken from Piagetian research was that young children are egocentric and cannot understand important mathematical ideas. Certainly young children’s thought suffers from various limitations. At the same time, the recent research literature on everyday mathematics paints a different portrait, namely that young children possess greater competence and interest in mathematics than we ordinarily recognise.

Given this view of young children’s abilities, I decided to develop a comprehensive mathematics curriculum for 4- and 5-year-olds. Why is it useful to do so? One might argue that a better policy would be to let young children enjoy and grow their everyday mathematics. In this view, young children learn from play and cannot profit from formal instruction; indeed, early lessons will only have the effect of turning them against mathematics at an earlier age than usual.

My answer to this argument is that play is not enough for several reasons. First, in the American context at least, many children, particularly poor children, are at risk of school failure and failing schools. They need a kind of mathematical head start to succeed in school. Second, mastering challenging tasks fosters children’s feelings of confidence and competence (Stipek, 1997). Third, many teachers are not aware of young children’s mathematical competence. Pre-schoolers’ successful learning of formal mathematics may help teachers appreciate the children’s competence and raise expectations of how much they should be learning in school in the later grades. And most importantly, our observations show that in their everyday play, the children already engage in and enjoy significant mathematical learning. It is great fun for them and of great intellectual significance.

As John Dewey (1976) advised: “Abandon the notion of subject-matter [like mathematics] as something fixed and ready-made in itself, outside the child's experience...” (p. 278). As we have seen, the child’s experience includes an everyday mathematics that is more substantial and enjoyable than much of what is typically taught in school. Given this fact, as Dewey puts it, “Guidance is not external imposition. It is freeing the life-process [that is, children’s everyday mathematics] for its own most adequate fulfilment” (p. 281). We therefore choose to engage in early mathematics education to help children achieve the fulfilment and enjoyment of their intellectual interests.
In collaboration with my colleagues Carole Greenes and Robert Balfanz, and with the generous support of the National Science Foundation, I have been engaged in the development of a comprehensive mathematics curriculum for little children, Big Math for Little Kids (Ginsburg, Greenes, & Balfanz, 2003). Our goal is to help children to think mathematically and to explore mathematical ideas in depth, over a lengthy period of time and through extended activities. Building on children's everyday mathematics, the curriculum consists of what we think are exciting and enjoyable activities, games, and stories, organised into six major strands, namely number, shape, measurement, patterns and logic, operations, and spatial relations. Our program presents the study of mathematics both as a separate “subject” and as an integrated part of other pre-school activities. Sometimes, the curriculum presents “math activities” like counting or studying shapes. Sometimes, it blends the mathematics into such activities as stories, songs, and block building. The program employs large group activity, small groups, and individual exploration. We believe that young children need to learn how to behave and learn in large groups. But they also profit from the greater degree of teacher attention possible in small groups. And they need time for individual learning and exploration. We characterise the program as offering playful but purposeful learning.

TEACHING COUNTING WITH PERSONALITY AND PIZAZZ

I would like to describe what we learned from one small but I think important part of the program, namely learning the counting words. Our first counting activities were in good measure based on the research already described. We knew that children enjoy counting and like to count to high numbers. We also knew that the first 12 numbers in English are meaningless sounds that need to be memorised, that the numbers from 13 to 19 are “backwards,” and that the numbers thereafter are very regular. In most curricula, 4-year-olds are generally taught to count to about 20, and 5-year-olds to 31 (the highest number of days on the calendar). Just think what this means. We ask young children to learn the harder part of counting before the easier part. They must learn the memorise the first 12 meaningless sounds, then learn the backwards numbers that violate the rules that later become evident, and finally are not allowed to count far enough into the larger numbers so that they could detect the only rational part of the English counting system. It is as if we wanted to make learning to count as hard as possible for young children.

Our solution was to make counting easier by helping young children to count to one hundred rather than 20 or 31. Counting from 21 to 99 makes sense, and then it’s fun to shout “one hundred” at the end. Counting from 1 to 20 does not make sense and is hard to do. So we devised several activities to promote counting. In “Numbers with personality,” children assign each “decade” a distinctive personality. They decide that the numbers from “one” to “nine” will be timid, and say them in a quiet, mousy voice. Later they might describe the twenties as “roaring like a mouse” or the
forties as whining like a baby. We almost always refer to the numbers between “ten” and “nineteen” as the “yucky teens,” because they suffer from ugly design features.

In another variant of this activity, “Counting with Pizzazz,” the children choose different body movements for the decades. They may jump the twenties and hop the thirties. And when they get to the end of a decade, they always say, “cut,” or “think,” to indicate that they have reached the end of a decade and that they must decide what new decade term comes next.

Teachers using our program generally choose to do these activities every day throughout the school year. In New York, our wonderful pre-school teacher, Suzanne Mir, does counting at the beginning of every day during “circle time” (which in her room morphs throughout the year into square, rectangle, and pentagon time). The children enjoy the activities, they seem to be learning some interesting things about counting that I will soon describe, and we all get a good workout.

INTRODUCING NUMERALS

For some time, we taught counting with the activities described above. But then we developed another aspect of the counting curriculum. The story begins with an observation of a 3-year-old’s behaviour. One of our activities is a game in which children step from one written numeral, printed on a large cardboard card, to another. They may start on 1, then have to locate 2, step on it, and then proceed in order to 5 or 10. This obviously helps them recognise the sequence of written numbers. For our present purpose, the game itself is not important. What is interesting is that one day, 3-year-old Arlo went to the place where the numerals were stored, took them out, and during free play tried to arrange them in order. He was successful in arranging the first several numerals, but skipped one of them. He then put a few numerals in the wrong order. After receiving some help from one of the graduate students working on the project, Angelika Yiassemides, he quickly learned to order the numerals to 10. Then he continued, and within a few days, got up to about 30 with few mistakes. He kept asking for more numerals to arrange in order, and we had to keep making them. We eventually made numerals up to 100 and he was well on his way to mastering the entire sequence.

I was surprised at his intense interest in these symbols. But then it occurred to us that use of numerals could aid counting. Numerals after all are perfectly regular with respect to place value and the base ten system and hence may be easier to deal with than English counting. The tens are always on the left and the units on the right. There are no irregularities like “thirteen.” We write “thirteen” as 13, not 31, (which is similar to the way we say it). Of course, knowledge of counting can help children learn to read and give meaning to the numerals. In brief, if children are interested in counting and they are also interested in numerals, then the two activities might
reinforce each other. Further, from the child's point of view, reading numerals is even more "grown-up" than counting them.

So we devised a number chart in which starts with numerals ending in 0 on the left and 9 on the right. We developed activities in which the teacher pointed to the numerals as children counted out loud. "Cut" or "think" was always said when children reached a numeral ending in 9. The new decade could be found by going down a row and to the end at the left. At first the teacher said nothing about the numerals. Gradually she pointed out various features, for example that the 3 in 34 referred to thirty; that 20, 30... are just like 2, 3...; and that as you go straight down a column all numbers end with the same numeral. She sometimes left out a numeral in the chart and asked the children to tell what was missing. In short, we felt that linking written numerals to spoken numbers could make underlying patterns relatively transparent and thereby facilitate their discovery.

One of our reasons for doing this is that our previous research showed that discovering and using patterns is one of children's most frequent everyday activities. Children are pattern detectors—in language, perception, and mathematics. This is not really a constructivist idea; it is a "realist" notion. Patterns exist in the world—sometimes the constructed world of mathematics—and can be detected. The detection may provide the necessary conditions for subsequent construction.

Of course the discovery of mathematical patterns in charts is not new. For example, Trivett (1980) offers a wonderful description of the mathematics that can be discovered in the multiplication table. But what is new, I think, is using this method at the pre-school level to teach counting, and potentially even related notions revolving around place value and the base ten system.

WHAT CAN WE LEARN FROM THE LEARNING OF COUNTING?

These then are some of the ways we teach counting. What can we learn from our experiences? How successful are the activities and what do children learn from them? Although we have not yet done traditional evaluations of Big Math, we have had the opportunity to conduct, over a long period of time, many informal observations of children's learning in our schools in New York, Baltimore and Chelsea, Massachusetts. In my experience, these "anecdotal observations" often point to important phenomena, can provide useful insights, and lead to interesting speculations and topics for further research.

First, almost all children thoroughly enjoy counting activities (and other aspects of mathematics). At the outset, young children seem highly motivated to learn school mathematics—at least in our Big Math curriculum. They are not turned off by early mathematics and do not feel that learning it is an imposition. There is no reason for early childhood educators to fear that little children will find mathematics instruction
to be unpleasant. The issue is rather how and why the initial motivation gets undermined over the course of the first few years in school.

Second, almost all children are proud of their success. Little children see counting prowess as a sign of being a “big kid” and being “smart.” Probably their teachers and their parents share this belief. It is important for little children to achieve big results. Real achievement makes for self-confidence and heightened motivation (Stipek, 1997). It is important to present children with challenging work so that they can master it. We need to allow children to succeed.

Third, it appears that by the end of the year many of the 4-year-olds do indeed succeed. Many can count to at least 100 and can count by tens to 100 as well. (They can also achieve at a high level in many other areas of our curriculum.) Yet I do not want to exaggerate their success. It is clear that not all children succeed at this level. For example, one child I recently observed (after about 7 months of counting activities) claimed that “twenty” comes not only after “nineteen” but also after “thirty-nine” and any other number she was asked about. Clearly, careful evaluations with pre- and post-tests and control groups are necessary to make firm statements about children’s achievement.

Fourth, we have observed that some 3-year-olds in the classroom participate in the counting activities for many months without saying anything, but after a period of time may suddenly start counting to a reasonable level. They seem to be absorbing a great deal without exhibiting their learning in external behaviour. It will be important to investigate the kinds of learning in which 3-year-olds engage during systematic mathematics instruction.

Fifth, we have observed that children’s learning seems to be very inconsistent. Some children seem to “get it” on one day but not another. Others, like the 3-year-olds, seem not to “get it” at all for long periods of time but then seem to catch on very quickly. Most often we assume that that learning is more or less orderly. But writers like Siegler (1996) have pointed to the inconsistencies and general messiness of learning, and researchers like Dowker (1998) have highlighted the important role of individual differences in mathematical abilities. Clearly, greater insight into these matters will help us calibrate instruction to young children’s needs. Our teachers sometimes worry that the children do not seem to be learning immediately. (Some parents are even more worried about this than the teachers.) We have learned to ask teachers (and parents) to be patient and not to worry about whether the children “get it” right away. I think our advice is generally sound; but it would be useful to have a deeper understanding of these issues and some firmer evidence upon which to base the recommendations.

Sixth, what mathematical ideas, if any, do children learn when they are learning to count in the Big Math program? Our observations suggest that they learn not only to
say the counting words, but to discover the rules that underlie counting and to explore patterns that can be discovered in the counting numbers. Even though it is a highly symbolic and abstract activity, learning to count can be an exciting pattern detection and generation activity. Exploring patterns in mathematics need not involve manipulating concrete things. Instead, counting involves the manipulation of words and of ideas about words. The children also seem to learn that counting and numerals are related and have a similar structure, which, of course, involves ideas about place value and the base ten system. At the same time, the children probably do not learn from our counting activities very much about cardinality. But that does not necessarily imply that the children are failing to do interesting mathematical work when they count. Cardinality is not the only important thing there is for young children to learn about mathematics. (Of course, other parts of our program deal directly with cardinality). In brief, even learning a counting language and relating it to abstract written symbolism can present little children with important intellectual challenges and enable them to do some interesting mathematics. There's a conjecture for further research. And of course, studying many other topics at the pre-school level can also lead to genuine mathematical learning.

Seventh, although I have been stressing young children’s competence, it is also clear that there are many things they cannot do and learn. We have not had great success in teaching ordinality, for example, and I can once again confirm that ideas of equivalence are very difficult for young children. Little children cannot learn everything. But the central message is that they can learn a great deal and we don’t yet have a clear idea of the limits on their learning when they are engaged in an exciting curriculum with a good teacher.

Eighth, group instruction appears to be very effective in teaching counting and almost all aspects of our program. Most of our Big Math activities are introduced in the group setting, later extended to small groups, and then to individual work. I was never a believer in group instruction for little children. In fact, I think I have written some nasty things about this practice. Yet I have been surprised at how effective it can be. But I don’t understand how it works and how effective teachers operate. Little is known about group and individual pedagogy in the early childhood setting; learning more about it would no doubt lead to many practical benefits, including effective teacher education.

And finally, our experiences teach us something about the processes of research and curriculum development. We began with some research on young children’s abilities. Drawing upon this research, along with other resources, like our informal experiences with young children, we developed a curriculum. In the process of trying it out, we observed that children were engaged in some surprising learning. Indeed, it is fair to say that the children would not likely have exhibited this learning
and the competencies it implies had we not developed the curriculum. The observation of the new learning then led to the revision of our educational goals and the creation of new curriculum, which in turn led to new and perhaps unexpected behaviour that needs to be studied and explained. So research leads to curriculum and curriculum leads to research. Exciting mathematical environments create new expressions of competence, which is not static. As Vygotsky (1978) maintained, we need to study the “...dynamic mental state, allowing not only for what has been achieved developmentally but also for what is in the course of maturing” with adult assistance (p. 87). Observing children within a challenging curriculum allows us to do this.

CONCLUSIONS

Yes, mathematics is big, but little children are bigger than you might think. Early mathematics education is a great opportunity for children, teachers and researchers alike.

RESEARCHING PRIMARY NUMERACY

Margaret Brown
King's College, University of London

Abstract: I describe a major research programme on primary mathematics in the UK, the Leverhulme Numeracy Research Programme, and give a sample of some of the preliminary results. The Programme combines large-scale longitudinal survey and case studies, quantitative and qualitative data, and observation and intervention studies in order to try to ascertain how and in what way different factors affect pupils’ progress. The case-studies have focused on factors relating to home cultures, pupil behaviours, curriculum and teaching styles, teacher subject knowledge, and school policies/leadership. The results quoted relate to these areas and also to effects of the implementation of a national reform which occurred during the research programme.

BACKGROUND

As in other countries, there has been continual concern over the standards of calculation in primary schools (ages 4-11) in the UK (Brown, 1999). This has become more urgent and more political with the publication of international comparisons first at secondary and more recently at primary level (e.g. Lapointe, Mead & Askew, 1992; Mullis et al., 1997), and the realisation that countries in the developed world will need a highly skilled workforce to maintain their economic competitiveness.

In English-speaking countries this has led to an increasing desire by governments to control primary mathematics. In England this first led from complete freedom for teachers over both curriculum and teaching methods in the 1970s to a legally imposed broadly defined national curriculum in 1989/90 (Johnson & Millett (Eds.) 1996) together with related national tests to be at the end of each stage (2 to 4 years). More recently continuing political concern over standards of basic skills in primary schools led to a National Numeracy Strategy, introduced in 1999/2000, which has incorporated a much tighter prescription of content, teaching sequence and teaching methods.

The key features of this National Strategy are:

- an increased emphasis on number and on calculation, especially mental calculation, including estimation, and selection from a repertoire of strategies;

- a three-part template for daily mathematics lessons, starting with 10-15 minutes of oral/mental arithmetic practice, then direct interactive teaching of whole classes and groups, and finally 10 minutes of plenary review;
• detailed planning using a suggested week-by-week framework of objectives, specified for each year group, which introduces many skills at an earlier stage than previously, and covers areas of mathematics other than number;

• a systematic standardised national training programme, run by consultants locally and by school mathematics co-ordinators in all schools, using videos to demonstrate 'best practice', with in-school support for low-performing schools.

Although not legally imposed, the Numeracy Strategy has been almost universally implemented, and is being extended in a slightly modified form to secondary schools.

The meaning of numeracy reflects the social context of its use (Brown et al., 1998). It was accepted by educational policymakers in the UK that numeracy was to be defined broadly, as in other countries, as the competence and inclination to use number concepts and skills to solve problems in everyday life and employment. Nevertheless it was felt necessary, for political and educational reasons, that the aspects of numeracy to be newly emphasised at primary level should focus on proficiency (DfEE, 1998), regarding numeracy as a culturally neutral and value-free set of autonomous skills, underpinned by visual models (e.g. the number line). In contrast to 1980s developments, there are few references to problem-solving and those which occur are mainly traditional 'word-problems', with artificial contexts. In the remainder of this paper 'numeracy' is to be interpreted in this narrow way, although I would espouse a much broader interpretation relating to social practices (Baker & Street, 1993).

The national concern about numeracy also led the Trustees of the Leverhulme Trust, a charity, to fund a £1 million 5-year study, the Leverhulme Numeracy Research Programme, to run from 1997 to 2002. The aim of this programme is

• to take forward understanding of the nature and causes of low achievement in numeracy and provide insight into effective strategies for remedying the situation.

The design of the research programme is reported in the next section. We wanted to examine the contribution of many different factors to low attainment, in individual children, classes, schools or population groups, by studying, on both a large and small-scale, cases in which these factors varied. Intervention studies were also planned.

When the proposal was written it could not have been anticipated that a new government would quickly implement the National Numeracy Strategy. Clearly this has affected the Leverhulme Programme as the implementation occurred in the middle year (1999/2000) of the 5-year programme. For example it has meant that curriculum objectives, teaching sequence and aspects of teaching methods no longer vary between classes, and thus the effects of differences in these can only be perceived in data from the early years of the project. An intervention project concerning teacher professional
development has also had to be modified to fit with the Strategy training courses. The Leverhulme work addresses fundamental issues in primary numeracy and will not merely act as an evaluation of the implementation of the Numeracy Strategy, which is being done, with the parallel Literacy Strategy, by a Canadian team (Earl et al., 2000, 2001). But inevitably our data can be used to inform some aspects of the evaluation.

RESEARCH DESIGN

The Leverhulme Numeracy Research Programme is a longitudinal study that combines large-scale survey in a ‘core project’ with case-study data in five ‘focus projects’. Two of the focus projects take the form of intervention projects.

**The Core Project: Tracking numeracy** (*Margaret Brown, Mike Askew, Valerie Rhodes, Hazel Denvir, Esther Ranson, Helen Lucey, & Dylan Wiliam; 1997-2002*)

**Aim:** To obtain large-scale longitudinal value-added data on numeracy to:
- inform knowledge about the progression in pupils' learning of numeracy throughout the primary years, and
- to assess relative contributions to gains in numeracy of the different factors to be investigated in the programme.

**Methods:** Data on pupil attainment has been gathered twice a year for 4 years, on two longitudinal cohorts of about 1600 pupils, one moving from Year 1 (age 5/6) to Year 4 (age 8/9) and the other from Year 4 to Year 7. Each cohort includes all children of the appropriate age in 10 primary schools in each of 4 varied local education authorities (about 75 classes). Detailed data is collected on pupils, teachers and schools including lesson observations, teacher interviews and questionnaires. Many instruments are modifications of those designed for our ‘Effective Teachers of Numeracy’ project (Askew et al., 1997). This data forms the basis for both statistical and qualitative analysis to investigate the relative contributions of different factors. (The methodology of the testing in this project is discussed in a paper (Brown et al., 2002) in the PME 26 Research Forum: Measuring Mathematics Learning and Goals for Systemic Reform.)

The core study provides a base for the case-study investigations in the focus projects, and has both generated hypotheses to be explored in the focus projects and allowed hypotheses arising from those to be checked on a larger sample.

**Focus 1) Case-studies of pupil progress** (*Mike Askew, Valerie Rhodes, Hazel Denvir, Margaret Brown & Helen Lucey; 1997-2002*)

**Aim:** To obtain a clear and detailed longitudinal picture of the numeracy development of a range of pupils taught in a varied set of schools and to examine this in the light of their classroom experiences, to ascertain what works, what goes wrong, and why.
Methods: This project is exploring the classroom practice factors influencing pupil attainment, including school, teacher, teaching, curriculum and individual pupil factors. From the longitudinal core sample we selected 5 schools which presented interesting contrasts. In each of these schools we selected children of varied attainment, six from a Reception (age 4/5) and six from a Year 4 class to provide longitudinal case study data, plotting progression in learning over 4 or 5 years. Children are observed and informally interviewed in two blocks of five lessons each year, and their written work collected. Longer interviews concerning perceptions of progress, attitudes and home support, and involving assessment questions, occurred at the end of Years 3 & 6.

Focus 2) Teachers' conceptions and practices and pupils' learning (Mike Askew, Alison Millett & Shirley Simon; 1999-2002)

Aim: To investigate the relationships between teachers' beliefs about, knowledge of and practices in teaching numeracy and whether changes in beliefs, knowledge and/or practices raise standards.

Methods: The project is following twelve teachers before, during and after their experience of a short course of professional development as part of the National Numeracy Strategy. We are adapting the methods of eliciting teachers' subject knowledge and beliefs from our earlier work (Askew et al., 1997) in order to construct teacher profiles. Changes in teachers' practices are monitored using video recording of lessons, and changes in pupils' attainment by using the tests developed for the core project. The teachers' profiles, their classroom practices and their pupils' attainment will be monitored over three years.

Focus 3) Whole school action on numeracy (Alison Millett & David Johnson; 1997-2001)

Aim: To identify whole-school and teacher factors which appear to facilitate or inhibit the development of strategies for raising attainment in numeracy.

Methods: This research focuses on six schools as they each experienced an inspection and then implemented the National Numeracy Strategy. Each school had identified the need for improvements in their teaching of numeracy and we have collected data both on the strategies schools used to develop the teaching of numeracy and the effect of these strategies on pupils' attainment. The research is investigating the complex interplay of school factors (policies, leadership) and teacher factors involved in the implementation of change over four years. The research uses documentary analysis, observation in classrooms and at meetings, and interviews with a range of informants (headteachers, maths co-ordinators, classroom teachers, governors and parents).
Focus 4) School and community numeracies (Brian Street, Alison Tomlin & Dave Baker; 1998 - 2002)

Aim: To refine and establish the meanings and uses of numeracy in home and school contexts; to establish differences between practices in the two environments and to draw inferences for pedagogy.

Methods: This project is investigating the influence of social factors on attainment, in particular differences between numeracy practices, and the linguistic practices associated with them, in the pupils' home and school contexts. Three schools were selected to provide a range of home cultures. Case-study pupils were then chosen from Reception classes (age 4/5) and followed through Year 1 and into Year 2. We have been using ethnographic methods including participant observation of classrooms and of informal situations in and out of school, and interviews with teachers, parents and pupils. The study extends previous work on literacy practices (Street, 1996) into numeracy, but retains a comparative element between the two.

Focus 5) Primary CAME (Cognitive Acceleration in Mathematics Education) (David Johnson, Mundher Adhami, Michael Shayer, Rosemary Hafeez, Sally Dubben, Ann Longfield & Jeremy Hodgen; 1997-2000)

Aim: To investigate the effect on the development of numeracy of managed cognitive challenge/conflict designed to encourage verbal interactions and metacognitive activity in whole-class and various small group arrangements of children in Year 5 and Year 6

Methods: An experimental design is used to investigate whether intervention in classroom practices aimed at promoting intellectual development can be effective. It extends our earlier work on CAME (Cognitive Acceleration in Mathematics Education) in secondary schools (Adhami et al., 1998) which uses Piagetian and Vygotskian paradigms. The research team, including teacher-researchers in each of two laboratory schools, first devised and trialled a sequence of mathematical problem situations designed to challenge children, and promote teacher-child and child-child discussion in cooperative small group work and whole-class discussion. This led to the main fieldwork involving research with teachers in a further 8 schools, with the teacher-researchers as tutors. We have used systematic observation of lessons and professional development sessions, and pre- and post- intervention pupil assessments of cognitive development and mathematical attainment. A linked study is demonstrating how this intervention acts as a basis for teachers' continuous professional development.

Coherence of themes

Although the structure of the Leverhulme Programme has been described as six projects, there has been great added benefit in the projects being part of the larger
programme. The results of the programme will be published under a sequence of four common linked themes, to each of which several projects contribute.

- children’s learning and progression
- home, culture and school
- teachers and teaching
- professional development of teachers.

In the next sections it is not possible to report the complete findings of the programme under each theme, but I will provide some sample results. This not only for lack of space (we are contracted to write a series of four books for Kluwer), but because at the time of writing we have not analysed all the data (we have another six months which will be devoted to data analysis). The results presented here must be regarded as provisional since neither all the data nor all the analysis has been finally checked.

SOME RESULTS: CHILDREN’S LEARNING AND PROGRESSION

1a) Lessons aimed at accelerating the cognitive level of children’s mathematical thinking appear to show some generic results, but the results in terms of national assessment levels are more ambivalent.

The fifth focus project Primary CAME generated a series of ‘Thinking Maths’ lessons which teachers could use occasionally alongside the National Numeracy Strategy. The results in the group of experimental schools showed a significant difference compared with control schools in the rises in children’s generic cognitive level as measured on a well-validated test. There was a problem administering a final mathematical problem-solving test because it was close in time to national tests at the end of primary school, so the raw national test scores were used instead as a post-test. Although there was some indication of a higher performance for experimental schools, there was no significant overall effect because of unexplained unexpectedly high results in the national tests from two control schools. This raises questions about using high stakes test results as a research measure as they may not be sufficiently reliable.

1b) The proportion of pupils who can answer a specific question increases with age approximately following a cumulative normal distribution with variations from this relating to the curriculum and testing regime. Changes in the curriculum as a result of the National Numeracy Strategy have had a significant effect on attainment in some areas.

Where children are exposed at an early stage to a fact, skill or idea the improvement in facility (the proportion of pupils who are successful) follows roughly a cumulative normal curve, as one might expect. The items that occur over several years in our tests which most closely match this model are those relating to multiplication facts shown in Table 1.
Interestingly there is no evidence of significant improvement on multiplication facts between the earlier results for the start of Year 4 in 1997 for the older cohort and the end of Year 3 in 2001 for the younger cohort; yet improvement of knowledge of multiplication facts was what the Education Minister promised the public as the effect of the Numeracy Strategy.

However there is evidence of the effect of the Strategy on other items. (This can be seen also in Table 1 in the other paper on the Programme in the PME26 Proceedings (Brown et al., 2002)). On average, performance at the end of Year 3 is 10% higher than expected for the younger cohort who have experienced the National Numeracy Strategy; this is the equivalent of about 4 months’ learning.

This effect seems to reflect a curriculum which is both more ambitious in that pupils are taught some material earlier than previously, and more focused on mental strategies which are a focus of the tests we use. (This comparison before and after the Numeracy Strategy will become clearer when we have the 2001/2002 results analysed for the younger cohort in Year 4 to compare with the previous cohort 4 years earlier.)

It might be claimed that the improved performance was due to changes in generic pedagogy rather than curriculum content but an examination of differences in performance on individual items shows that this is unlikely.

We found that for six items out of 65, the younger cohort at the end of Year 3 in 2001 had percentage success rate greater than 10% higher than that for the older cohort at the start of Year 4 in 1997 (and for only one item was the facility more than 10% higher at the start of Year 4). In the case of all these items improvements can be explained by references to curriculum change, in particular to increased early emphasis on the number line, inverse operations, and horizontal recording. This seems to provide evidence of effectiveness of curriculum change in enhancing achievement, but early introduction may not necessarily result in long term benefit.

These results depend on data from the large-scale survey, although they can be understood by reference to case-studies. For example it was clear that at the start of the

project in 1997/8 most schools were following broadly similar curricula related to one or more published schemes. However St. Luke's, a case-study school in the second focus project *Case-studies of pupil progress*, was following a significantly more ambitious curriculum than all the others. Most children in the class right from Reception year (age 4-5 years) were using textbooks intended for children one year older. The results from that school in both our tests and the national tests were exceptionally high. (The school had a somewhat above average intake, sufficient to make this policy viable but not to fully account for the results.) By the end of the project the school had purchased a new set of texts which were matched to the National Numeracy Framework, but this time most children were following the books intended for the correct year group, as the school was satisfied that the Numeracy Strategy curriculum was sufficiently ambitious. Correspondingly the results of the school although still above average are now somewhat lower than previously in relation to those of other schools.

Strong curriculum effects have been suggested by international studies at secondary level such as SIMS (the IEA Second International Mathematics Study) (Burstein, 1992). Nevertheless the between-countries, within-topic correlations between coverage and attainment across countries in SIMS were quite low (Robitaille & Garden, 1989). It is also true that when curriculum variation was taken into account in TIMSS - the Third International Mathematics and Science Study, only very small changes in the international rankings resulted at both primary and secondary levels (Mullis *et al.*, 1997, Beaton *et al.*, 1996). Other TIMSS studies suggest more subtle relations between curriculum and attainment (Schmidt *et al.*, 1996; Stigler & Hiebert, 1997).

1c) Over several years most children remain at roughly the same percentile of attainment, although with some oscillation. A few however gradually change their relative positions. The progress of some children appears to be held up because of some fundamental conceptual gaps.

We have been observing classroom behaviour in mathematics lessons of 30 children in each cohort (6 from each of 5 classes in different schools) over 4/5 years, and related these to their test results. For most pupils their percentile in the sample remains roughly constant with minor oscillations; however in some cases there seem to be longer-term trends.

Debbie, in the older cohort at Pinedene school, is a child whose test results oscillate considerably around the median, with no obvious long term trend. She started at about the median in Year 4, moving up to the 65th percentile at the end of the year but her performance dropped gradually through Year 5 to about the 35th percentile at the start of Year 6. By the end of Year 6 and again at the end of Year 7 she was back at about the 60th percentile. When we talked to Debbie she felt that she had learned a lot in Year 4...
but had found the teacher and the work in Year 5 difficult to understand, and had recovered in Year 6 with a more supportive and more relaxed teacher. Her perceptions of the quality of the teaching and of her reaction to it correspond to our classroom observation data. This, and the fact that the changes in her performance are similar to, but more extreme than, the changes in the class performance suggests that in her case the quality of teaching is a key factor and that Debbie was particularly sensitive to it. (Some case-study children in the class did not follow the trend of class performance.) It also seems likely that her parents splitting up in Year 5 might have exacerbated the problems that year.

However it is also instructive to look at Debbie's mathematical profile. Although we saw her working with her friend excitedly learning about equivalent fractions in a pictorial context in Year 4, more abstract fractions, and more especially decimal fractions, remained a problem; in our tests she made no progress in this area between the end of Year 4 and the start of Year 6. Debbie volunteered to us in Year 5 that she did not understand these ideas and always got wrong answers in tests. The teaching we observed in that year was not addressing her problems. However during Year 6 the ideas fell into place and she scored quite well on those items at the end of that year and in Year 7.

Another child whose progress was held up by fundamental conceptual problems was Joseph. Joseph, at St. Luke's School and like Debbie in the older cohort, had a performance which gradually declined from near the 80th percentile at the start of Year 4 to about the 60th at the end of Year 6 and Year 7. Our classroom observation suggests that Joseph tried hard to remember standard algorithms but he often became confused and had a fragile understanding of place value to fall back on (his parents had arranged for a private tutor the previous year but Joseph said he did not find this useful). This apparent gap in understanding led to some continuing quite basic errors in place value, although at the end of Year 6 in some areas like fractions he showed quite sophisticated understanding. After a year in a high set at a prestigious school, Joseph's performance in the test deteriorated, both on fractions and on place value. It is interesting to speculate whether, in contrast to many successful children in his class, Joseph's poor progress was part of the 'collateral damage' of the decision by St. Luke's referred to earlier to accelerate the curriculum by a year.

Thus the progress of individual children shows many variations and appears to depend on many factors, relating to the child's ability, personality and inclinations, the home circumstances, and especially to whether the teaching addresses the mathematical ideas causing problems. For different children the balance of importance of these factors also changes. In spite of general trends, it is impossible to predict the future progress of any specific child from one or two test results.
SOME RESULTS: HOME, CULTURE AND SCHOOL

In this area we probably have as yet fewer conclusions than elsewhere since we are still writing up case studies and are awaiting the full data set on the tests before doing the analysis for gender, ethnicity, postcode, parental pattern, etc.. However we still have a few results, both on a micro and a micro-level, which suggest the likely final pattern.

2a) While the numeracy attainment of a school is quite closely related to a 'poverty indicator' of its intake, the gains made in numeracy are independent of this indicator.

In the UK as in some other countries the only readily available indicator of the background of the children in a school is the proportion of children claiming an entitlement to free school meals. As is generally the case with educational data (Levin, 1999) we found a negative correlation between this and average attainment for the school. For example in Year 5 the correlation was -0.63.

However when we looked at the relation between the gains children made over a year and the proportion of children claiming free school meals this correlation was reduced to almost zero (-0.06 for Year 5). This suggests that it is the fact that children from less advantaged homes start behind others which causes continued weak performance; there is no evidence that they make slower progress (see also Burstein, 1992). This is however an average result and the case studies point to many individual variations.

2b) The relationship between numeracy attainment and home circumstances for any individual child is very complex.

In the fourth focus project School and community numeracies, we have been studying social factors which may affect children’s progress, with case study children moving from Reception to Year 2 in three schools, one an inner city multi-racial school, one a school in a prosperous suburb, and one on a long-established social housing estate with many social problems but with mainly white pupils.

This has thrown up some counter-examples to the general relationships referred to above. For example one of the most materially deprived families is that of Aaysha, whose parents are recent immigrants from Pakistan, as yet unemployed, speak little English (although her father attends classes) and live in temporary accommodation where facilities are basic and shared with many other families. Some of their home numeracy practices (e.g. methods of finger counting) differ from those taught at school. Nevertheless Aaysha is doing very well at school, becoming fluent in English and good at mathematics. An explanation for this is that both parents are well-educated and numerate, and worked in the insurance business in Pakistan; indeed her father has an
MA in statistics. Thus they have intellectual and educational, if not economic, capital, and a determination to succeed which is associated with recent immigrants.

On the other hand some second generation immigrants are less well placed. For example Kim lives with his mother and grandmother. His mother works long hours in a reasonably well-paid full-time administrative job which involves some numeracy, and he spends a lot of time with his grandmother, a nurse working shifts who many years previously had run a small ‘home school’ in Jamaica. Like many other children, Kim is expected to practise his numeracy skills at home. The problem in the Reception class (age 4/5) was that the pedagogy and underlying epistemology used by Kim’s grandmother seemed to be out of line with those of the school. She expected Kim to be able to recall quite sophisticated number facts which he could not do, while asserting that the homework set by the school was too difficult. Kim therefore refused to engage with much of the numeracy work either at home or at school, and his frequent condoned absences led the school to believe that he was overindulged. There was improvement in home-school understanding and in Kim’s attainment in Year 1 when his mother arranged for a discussion with his male teacher, also of Jamaican origin.

The experiences of Kim illustrate a general point that many families of our case-study children expect children to regularly do school mathematics at home, in addition to the homework set (normally an hour per week). Thus the predominant numeracy practices at home may not be domestic but those the parents perceive as ‘school practices’. Some parents say they do this to support the work at school; for others it is to compensate for what they see as a lack of challenging numeracy teaching in the school. These practices occur across all social groups.

Yet in some cases, like Aaysha, this additional home support seems to be informal, sensitive and successful and in other cases, like Kim, to be limited to recall of facts with an unproductive outcome that adds to the child’s sense of failure and discourages them from engaging further. It may be that families with greater intellectual and social capital can be more supportive as they are more sensitive both to the child’s needs and to the nature of school numeracy practices (Galbraith & Chant, 1990).

SOME RESULTS: TEACHERS AND TEACHING

3a) It is difficult when comparing across many classes of the same age to find a clear relationship between factors relating to teachers or teaching and the learning which occurs.

We looked in two different ways for relationships between different factors and the average gains for each class in a particular year group between October and June. First we correlated against the gains in attainment for Years 4 and 5 all our data from teacher
questionnaires (at least 60 were returned from the 75 classes in each year group; many of the omissions were due to changes of teachers) which related to personal qualifications and experience and also to self-reported practices and beliefs. Several items were, with permission, taken from TIMSS (Mullis et al., 1997).

There were no factors which had significant effect sizes for both year groups, and only a very small number which were significant even for one year group. The factors included the age, length of teaching experience, training and qualifications of teachers, as well as frequency of whole class teaching, type and frequency of homework, and use of calculators and computers. These results are consistent with those for TIMSS both internationally (Beaton et al., 1996; Mullis et al., 1997) and when the English results were analysed independently for the Numeracy Strategy Task group.

In a previous study (Askew et al., 1997) we found that teachers who were effective in teaching numeracy, defining effectiveness in terms of gains achieved by their classes over the year, tended to have a particular orientation to the teaching of numeracy which we characterised as ‘connectionist’. In the Leverhulme study we wondered whether in the same way we could characterise ‘teaching’ as more or less effective. There have recently been several ‘evidence-based’ claims in the UK for effective styles of teaching (e.g. DfEE, 1998; Hay McBer, 2000; Muijs & Reynolds, 2001) and it seemed useful to see whether we arrived at similar results.

Having analysed what seemed to differentiate the lessons observed of Year 4 teachers whose classes made high and low average gains in 1997/8, we compiled a list of characteristics which were organised using an adapted version of a framework from Saxe (1991). We used this to devise a scale and rated the lessons of teachers in Years 1 and 5 the following year and Years 2 and 6 in 1999/2000. However the correlations with average gains were very low (\(r<0.2\), except in Year 6, where \(r= 0.39\)). (It is not clear why the correlation was higher in Year 6 but it might be that the curriculum variation is reduced that year because of the high-stakes national tests). We tried another way of rating the lessons in terms of the connections between the mathematics, the teacher and the children. However again the correlations were low (\(r<0.2\)).

This suggests either that our observations, our ranking systems or our tests are unreliable, or that compared with pupil factors, teaching and teachers have a rather small effect on pupils’ gains. Again this would not be out of line with other findings (e.g. Mortimore et al., 1988; Creemers, 1997; Burstein, 1992), which suggest that even after the effect of the pupil variables have been removed the teaching accounts for at most 10% of the variance in attainment.

3b) For a particular class across different years, the relationship between teaching and learning seems clearer than across different classes.
We have not yet analysed the data from the full sample in terms of progress made in different years by the same class, but examination of case study data suggest that controlling the pupil factors more closely in this way means that the factors relating to teaching become more salient. Classes appear to make slower progress in years where the teaching ranking is low on our adapted Saxe scale. Those case study children who can review their progress over different years are generally able to identify accurately the years when least and most progress was made, and attribute this to the teaching.

SOME RESULTS: PROFESSIONAL DEVELOPMENT OF TEACHERS

4a) A short programme of professional development supported by in-school action can be almost universally effective in implementing change in curriculum and in aspects of teaching.

Teachers and headteachers in our sample have universally welcomed the National Numeracy Strategy and the support it has given them. They report improved grasp of the priorities for teaching and have changed their methods and curriculum to meet these (see also Earl et al., 2001, 2002). They have praise for the training delivered in local centres, and in schools by the mathematics co-ordinators who are fellow-teachers. It is clear from our interviews and observations that all teachers have changed their practices and their curriculum. In some cases we have observed the same teacher with a Year 4 class in 1997/8 and 2001/2, and found a noticeable change in confidence.

Data from the six case study schools in the third focus project, Whole school action on numeracy, suggested that there were six factors relating to the effectiveness of the co-ordinator in improving the standards in the school:

- clarity of vision about priorities of action and ways of working;
- enthusiasm about the role;
- balance between headteacher and co-ordinator, each valuing each others' role;
- high priority to resourcing the co-ordination role, for example to enable co-ordinators to work with other teachers in their classrooms;
- coherence and consistency within the school community;
- regular external support available and used.

In the three schools where most of these factors were not present, a change of co-ordinator occurred during the implementation of the Numeracy Strategy. By the end of that year all three schools had improved their position with respect to these factors and the results in national tests correspondingly improved (Millett & Johnson, 2000).
4b) Professional development which changes and links together teachers' subject knowledge, beliefs, and practice is a much longer term and more difficult enterprise.

In the second focus project *Teachers' conceptions and practices and pupils' learning* we have been examining the changes taking place in relation to a 5-day Numeracy Strategy training course focusing on teacher subject knowledge. Although some of the teachers reported that it had increased their confidence, and some superficial changes in practice and curriculum occurred due to new aspects of pedagogical subject knowledge (e.g. the teaching of different methods of calculation), the course did not appear to have been sufficiently sustained or to have involved enough informed collaborative reflection (Cobb *et al.*, 1997) to have had a strong effect in terms of subject knowledge, beliefs or practices.

In contrast the professional development practices developed in the fifth focus project *Primary CAME* involved teacher researchers modelling lessons in which teachers acted as pupils, then teachers trying lessons out in their own schools and finally meeting to discuss the outcomes. The cycle has similarities to the Japanese model (Stigler & Stevenson, 1991). These meetings continued over two years which was judged to be generally necessary for teachers to develop their beliefs, teaching practices and subject knowledge. The essential ingredients were *cycles of practice and (collective) reflection*, informed by *clear theoretical perspectives*.

**CONCLUSION**

The opportunity to view primary numeracy from many different perspectives, using different research methods, has allowed a holistic view of teaching and learning and avoided simplistic conclusions. Factors relating to individual pupils have strong effects. Curriculum seems a more salient factor than generic pedagogy. Both these can be changed quite rapidly at a systemic level, but development in teachers' deeper understanding is a long term process.

HOW STUDENTS STRUCTURE THEIR OWN INVESTIGATIONS AND EDUCATE US: WHAT WE'VE LEARNED FROM A FOURTEEN YEAR STUDY

Carolyn A. Maher
Rutgers University, New Jersey

This talk reports on a portion of a fourteen-year study of the mathematical thinking of a cohort group of students that is based on an identifiable perspective on how mathematical ideas are built. Three videotape episodes are presented so that we can view together groups of students working together at three points in time: as fourth graders (ages 9-10), and in grades 10 and 11 (ages 15-16). Excerpts from interviews are offered to provide student perspectives on their own learning over the years.

INTRODUCTION

Choosing a theme for this paper has been difficult; fourteen years of research have provided many possibilities. After much deliberation, I decided to focus on how students, working in small groups, structure their investigations and what we have learned so far by studying how their ideas develop. This talk will introduce some of the students who participated in elementary and secondary school, and later as college students. During the last few months, several of these students have talked with us about their participation in the long-term study. These data along with interview data from their upper-high school years are included here.

Videotape and written data come from students’ early investigations of counting problems in elementary school, through their investigations of combinatorics and probability in middle and high school, and their investigations of ideas related to calculus in high school time (Kiczek, 2000; Kiczek, Maher & Speiser, 2001; Maher & Martino, 1996a, 1996b, 2001; Maher & Kiczek, 2000; Maher & Speiser, 1997; Martino, 1992; Muter, 1999; Speiser, 1997; Speiser, Walter, Maher, 2001). Observations and analyses of the students’ early explorations provide foundations for later thinking about particular ideas in mathematics. Videotape data make it possible

---

1 We would like to thank the Kenilworth students for their continued, invaluable contributions to our work. Thanks, also, to the research team for their dedicated work on the project.
2 Jeff, Romina, Michael and Brian, now second year college students, joined graduate seminars in which video segments of problem solving were viewed together. The seminar sessions were audio or videotaped. In these sessions, the students talked about how they learned by working together.
3 Fred Rica, Principal of the Harding Elementary School, Kenilworth invited me, in 1984, to visit his school and to observe mathematics lessons. These earlier classes, for the most part, emphasized drill and memorization. Inspired by the belief that the children’s mathematics learning could be significantly improved, a three-year teacher development project was launched in 1984 between the Kenilworth Public Schools and our group at Rutgers (See O’Brien (1995) for a ten-year analysis of the teacher-development project). The longitudinal study was an outgrowth of the partnership.
to view these sessions together. The three episodes -The Gang of 4 (ages 9-10); Romina’s Proof (ages 16-17), and the Night Session (ages 17-18) - taken together, provide illustrations over time of how the students worked together in small groups, and of how the teacher(s)/researcher(s) interacted with them. Finally, video clips of student interviews (ages 17, 18, and 19) provide further commentary by participants about their own learning. Jeff (March 2002), reflecting on his participation in the research since grade one, focuses on the depth of their investigations and the impression this left on him.

You didn’t come in and say, “this is what we were learning today and this is how you’re going to figure out the problem.” We were figuring out how we were going to figure out the problem. We weren’t attaching names to that but we could see the commonness between what we were working on there and maybe what we had done in school at some point in time and been able to put those things together and come up with stuff and to do these problems to come up with, what would be our own formulas because we didn’t know that other people had done them before. We were just kind of doing our own thing trying to come up with an answer that was legitimate and that no matter how you tried to attack it, we could still answer it. It was a solid formula that works no matter how you tried to do it.

BACKGROUND, PURPOSES, RATIONALE

The study was initiated in 1989 with a class of 18 first-grade children at a public school in a working-class community (Martino, 1992; Maher and Martino, 1996b). The work reported here is a component of the longitudinal study of the development of students’ mathematical ideas. Attention has been given to studying how learners build mathematical ideas, create models, invent notation, and justify, reorganize, extend, and generalize their ideas. Data come from a cohort group of students whose mathematical activity has been followed by the research team for over 14 years.

The main objective of our research has been to gain a deeper understanding of mathematical learning when particular conditions are in place. We have been interested in creating conditions whereby we can give children an opportunity to show us how they think about mathematics. These conditions are essential to the context of the study and may be helpful in understanding issues of commitment, motivation, and value to participating students. In the early years of the project,

4 The class was one of three first grades in the elementary school. The students in each class remained together for their first three years of elementary school. In grade four, new classes were formed. The study continued with a smaller subset of the original class and several other students who joined. The group that was followed for fourteen years consists of seven students; others (seven) participated for approximately eight years.

5 Earlier work for this study was supported, in part, by National Science Foundation grants MDR9053597 (directed by R.B.Davis and C.A.Maher) and REC-9814846 (directed by C.A. Maher) The opinions expressed are not necessarily of the sponsoring agency and no endorsement should be inferred.
when the research was conducted in classrooms, these conditions, negotiated with the participating school district administrators and classroom teachers, guided the establishment of the context for our research. What came to be called “Rutgers mathematics” occurred in the early elementary years four to six times a year, for three days duration. For two of the days, their math period was extended approximately an hour to an hour and a half. The third day was the regularly scheduled math time of about 45 minutes. Students continued conversations through follow-up individual or small group interviews the same or the following week. When feasible, the classroom teacher observed the interview.

Interview design was motivated by our observations of the children doing mathematics in the classroom and of our study of videotapes and researcher notes. For example, we might notice that there would be an interesting idea that was being pursued by a child or a group, and we would ask the children to tell us about what they were doing. In the interview setting, we invited the reconstruction and extension of ideas put forward. To a large extent, the direction we took in the presentation of investigations was inspired by what the children showed us in their talking, drawings inscriptions, and building of physical models.

Students were invited to think about mathematical situations, often over long periods of time. They were asked to present their ideas with suitable justifications that were convincing to them (and to us) and to consider generalizations and extensions. They were not graded for their work; they revisited problems over months and years; they offered arguments for the validity of their solutions. Ideas were listened to and treated with respect by the teacher/researcher(s). In the early years, we called the students’ attention to the variety of ways they represented their ideas, with the intent of making public both similarities and differences in their thinking (Maher, 1998a). We invited reflection and discussion among students about such differences (Maher, 1998b; Maher, Martino & Pantozzi, 1995; Maher, Davis & Alston, 1992). The children, in justifying their ideas, provided arguments that exemplified several important types of mathematical proof, for example, proof by contradiction, proof by cases, and reasoning by induction. In the later years, we observe students using all these forms of reasoning as natural parts of their discourse.

During the first eight years, the study was classroom based. Since high school, cohorts of students participated in small group after school sessions. This came about, at least in part, because the county school district formed a regionalization of the high schools. This resulted in the closing of the Kenilworth high school for several years. Most of the children, upon completing 8 years of elementary school, continued to a regional high school in another town. Others attended parochial schools in the area. Public pressure from Kenilworth citizens (and from some neighboring communities) to regain their local high school led to a public referendum that resulted in a vote to de-regionalize the schools, an historical event for the state. Some local high schools,
including Kenilworth, re-opened in 1997 and most of the original students in the study were reunited. In that interim year, we continued our research with several students after school hours in private homes. The interest of students to continue once their high school was re-opened sparked the continuation of what we refer to as "after-school" mathematics. In 1996, classroom research was replaced largely by small group research.

THEORETICAL PERSPECTIVE ON LEARNING

We investigate the development of mathematical ideas by examining, from moment to moment, the development of students' thinking as it is indicated by their conversation and their inscriptions as they work on well-designed investigations. The guiding framework for this level of analysis comes from research on representations (Davis, 1984; Davis & Maher, 1990; Davis & Maher, 1997; Goldin 2002, 2000; Kiczek & Maher, 1998; Kiczek, Maher & Speiser, 2001; Maher & Martino, 1997; Maher & Davis, 1995). In doing mathematics, mental images can be formed by individuals, to be used in building representations of mathematical ideas. These representations can be carried forth and used, and revisited and modified, in the light of new experiences. Although the internal, cognitive representations are not available to us and perhaps the individual, certain features of them can be made public and open to discussion. This can occur as ideas are explained, justified and shared with others. To represent an idea, an individual may create a structure or present a notation. In this way, the ideas are made public in their discourse in the form of explanations, actions, writings, and notations. Records make possible later re-examination of the relationships between ideas. In this way, the ideas can be discussed and reflected upon (Dörfler, 2000).

RESEARCH METHODS

We regard events as connected sequences of utterances and actions by the learners. An event is called "critical" when it demonstrates a significant advance from previous understanding, or a conceptual leap in earlier understanding, or the identification of a cognitive obstacle (Maher & Martino, 1996a; Kiczek, 2000; Steencken, 2001). These episodes are obvious and striking in that they can be connected to prior events. Identification of critical events makes it possible to examine their influence on later understanding and to trace the development of ideas.

Data Source. Our main sources of data are: (1) behavior of students as they work on mathematical investigations recorded on videotape; (2) written work of students; (3) follow-up interviews of individual or small groups of students, often taking the form 6

---

6 The mathematical investigations posed are central to the research. To view the tasks, visit the Robert B. Davis Institute for Learning website, http://www.rbdil.gse.rutgers.edu
7 Willi Dörfler (2000) makes an important distinction between the visible representations and the internal, cognitive (re)presentations that are not visible to us.
of teaching experiments; (4) individual student interviews; and (5) researcher notes. Groups of us observed the children, took notes, noticed behaviors, and developed interests in what they produced individually, together, and through sharing with others. At various times, students revisited tasks and talked about their ideas. It was not uncommon for ideas to re-emerge for discussion over long periods.

**Videotaping.** Videotapes are made of nearly all sessions or task-based interviews. These have three main forms: (1) videotapes of task-based (or “clinical”) interviews, where there would usually be one interviewer, one student, and two camera operators (one to record work; the other to record the conversation.) Also, two or more observers take notes, but not in view of the student; (2) videotapes (made outside the classroom in an office or quiet setting) similar to those just described, with 2-5 students working together on a task. During student investigations, there is usually no interviewer present. There are two cameras and a sound technician; (3) videotapes made in actual classroom settings, but otherwise similar to the second category with small groups of students working together. There are three cameras and two sound technicians. Our research results emerge through systematic study of extensive, archived videotape data, often from tape segments, which now, because of recent data, have been re-analysed from new directions, with newly developed tools and a more detailed framework.8

**FRAMEWORK FOR ANALYSIS**

A framework is offered that takes into account how ideas develop and travel within the group and how the teacher/researcher interacts in the process. The analysis begins with the identification of critical events. The mathematical content of each critical event is identified and described, taking into account the context in which the event appears, the identifiable student strategies and/or heuristics employed, earlier evidence for the origin of the idea, and subsequent mathematical developments that follow its emergence. Together, these components provide a “trace”, the data tracking the development of the idea(s) (Maher & Martino, 1996a; Maher, Pantozzi, Martino, Steencken & Deming, 1996; Kiczek, 2000; Steencken, 2001).9 We identify and code their traces in the form of diagrams. Concurrently, transcripts are verified, and explicitly co-ordinated to diagrammed events. Our interpretations evolve from all of these.

**Event diagrams and codes.**10 Each critical event defines a timeline, consisting of a past, a present and a future.

---

8 See Davis, Maher & Martino (1992) for a discussion of using videotapes to study the construction of knowledge.

9 The set of connected critical events with past, present and future defines a “pivotal strand”. See Kiczek (2000) and Steencken (2001) for a discussion of pivotal strand.

10 The framework was developed for the National Science Foundation grant MDR9053597 and further elaborated and extended in the project work. See Speiser (1998) for a prototype-coding...
The critical event itself defines the present. Prior images to which the critical event folds back define the past (both recent and more distant), while later events which help us understand (or fold back to) the present critical event define its future. The timeline is followed in strands of analysis, all of which are coded.

**Constructing a storyline.** Coded nodes denote events along the timeline, and descriptive codes are used to mark strands of events which we call the "flow of ideas". The construction of a storyline begins with the flow of ideas. We examine and identify codes and their respective critical events in an attempt to trace an emerging and evolving story about the data. A storyline is constructed from a coherent organization of the critical events, and often involves complex flowcharting. Hence, the process of producing a trace involves identifying a collection of events, coding those events, and then interpreting them, to provide insight into a student's cognitive development. The trace contributes to the narrative of a student's personal intellectual history as well as to the collective history of a group of students who collaborate.

**Constructing narrative.** In our model, a narrative phase enables researchers to view the recorded material from the data set holistically. Although they appear last, interpretative actions actually begin from the inception of research; they are originally formulated through theoretical perspectives and research questions of interest (Powell, Francisco & Maher, 2001).

**TASKS AND VIDEO SEGMENTS**

Three tasks and video episodes are considered here. The tasks are selected from the counting/combinatorics strand and the episodes span an eight year period.

**Grade 4 Task: Building Towers.** Convince each other and the researchers that you found the number of towers that could be made 3-cubes tall, selecting from two colors.

---

scheme for critical events and Powell, Francisco & Maher (2001) for further discussion of the framework and methodology.

Grade 10 Task: Ankur’s Challenge. Find as many towers as possible that are 4-cubes tall if you can select from three colors and there must be at least one of each color in each tower. Show that you have found all the possibilities.

Grade 11 Task: Pascal’s Triangle. For Pascal’s triangle, how does the addition rule work?

In a May 1999 interview, seventeen-year-old Jeff describes the way the students work. He reports that members of the group would put forth their ideas, review them, and select the most salient. He points out that the ideas of others are to be valued.

*Well, we break up into groups...like five groups of three, say, and everyone in their own groups would have their own ideas, and you’d argue within your own group, about what you knew, what I thought the answer was, what you thought the answer was and then from there, we’d all get together and present our ideas, and then this group would argue with this group about who was right with this...*

Grade 4 Task: Building Towers. In grade 3, the students worked on building towers, 4-tall and 5-tall, selecting from two colors. Sixteen months later, in the fourth grade, they investigated towers 5-tall. About one month later, a group interview with fourth graders: Jeff, Michelle, Milin, and Stephanie was conducted. In this session, we were especially interested in what made the students’ reasoning convincing. For about half an hour, the students shared their different approaches.

Grade 4 Video Episode: Gang of Four. In grade four, Jeff, Michelle, Milin and Stephanie discovered the idea of mathematical proof. For at least a year before this, the children had been building arguments in their block tower investigations in which they controlled for variables, argued by cases, and used inductive reasoning and argument by contradiction. For example, in the case of towers, students noticed that, as they built from towers of height $n$ to height $n+1$, they could choose one of two colors, thereby doubling the number of towers. So they investigated a doubling idea and come up with a doubling rule and posited this as a generalization. Other students, in looking for patterns, recognized certain organizations that accounted for all possibilities of a given height, and suggested an argument by “cases”.

In an interview, Mike (May 1999) talks about exploring and gaining understanding:

*In our class, all we did was just explore. We took days at a time, and I have a good understanding of it...like, if you were going to, I guess, a normal class, you’d have to be, like, only selected kids might understand it. But in a class where everybody’s working*

---

13 For a full discussion, see Muter (1999).
14 See Maher & Martino (1996a, b) for a transcript of the videotape session and an analysis of the data.
together, everybody's a part of the teaching, and everybody, or at least the majority of kids will understand it.

**Grade 10 Task: Ankur's Challenge.** In the 10th grade, five students (Ankur, Brian, Jeff, Romina, and Michael) met again and considered variations of the tower problems. First, they were asked to find all 5-tall towers, choosing from colors, red and yellow, such that each tower contains 2 red cubes, and to justify their solution. Mike and Ankur quickly solved the problem. While they were waiting for the rest of the group, Ankur poses another problem:

*How many combinations can you make with towers four tall, selecting from a choice of 3 colors, and using at least one of each color in every tower?*

They worked on Ankur's new problem for approximately 15 minutes. Mike and Ankur, after calculating that there were 81 total towers when selecting from 3 colors, returned to the conditions of the problem and, by subtraction, came up with 39 towers. Romina, working with Jeff and Brian, said that there were 36 towers. Michael continued to work on the problem by himself. Unaware of the work of Romina and her group, he asked to hear their solution. Romina went to the chalkboard and presented her justification.\(^{15}\) She indicated that the set of all possible towers could be partitioned into six groups. Since every tower would have two of one color, Romina focused on the placement of the duplicate color, using x and o. She indicated that for each placement of the first or duplicate color, there would be two possible combinations for the second and third colors. She also indicated that these combinations would have two opposite arrangements for the second and third colors. She then tripled the 12 possibilities to represent every color, concluding that there should be a total of 36. Romina was asked to write her solutions. Figure 1 shows the refinements in her written work presented at the next after-school session.

**Grade 10 Video Episode: Romina’s Proof.** In an earlier session, Michael introduced the idea of using binary notation to count towers. Other students soon integrated binary numbers in their coding. When Michael indicated that he was “ready to listen”, Romina shared her solution with the group.

Romina (March 2002) comments on the way they worked:

*If I didn’t understand the problem, or if I didn’t work enough to it, by myself to understand, and I guess if Michael didn’t know where I was heading with what I was doing, and if I didn’t understand where the other person was heading I would like to work on it before I came up with a couple of options myself to see which one we take.*

\(^{15}\)See Muter (1999) and Muter & Maher (1998) for a more complete discussion.
TOWER PROBLEM

How many towers can you build four high with the choice of three colors and having all three colors in each tower?

I first approached the problem realizing that if there are three different colors and four different ways where they can be put, then there will be a total of six colors, and two distinct cases, in each tower. I then tried the problem with the colors yellow (Y), blue (B) and red (R) with red being the duplicated color:

[Table showing combinations]

I placed the two reds in every possible way they could be, which left me with 6 possibilities. In the remaining blocks there can only be a combination of the possibilities: yellow and blue OR blue and yellow. Since there are only two remaining possibilities of combination the total must multiply 6 by 2 leading to 12, which represents the number of possibilities of towers being built with the duplicated color, since there are 3 cases, and each can at the duplicated color, one must multiply 12 by 3, indicating the way yellow and blue have been the duplicated combination each leaving one with the amount of 36 for the number of all possible combinations.

Figure 1. Romina's written work of her solution to Ankur's Challenge.
Grade 11 Task: Pascal's Triangle. In May of their junior year, the high school students returned to school one evening around 7:30 pm for a research session. The researcher began by asking the students to review what they had discussed in their pre-calculus class earlier that day. They reported that the class had learned to use a calculator to find the coefficient of any term in the binomial expansion without having to write out rows in Pascal's Triangle. The students were also asked why the addition rule for Pascal's Triangle worked. In response, they showed a 1-1 correspondence between terms in Pascal’s Triangle and choices in particular pizza and tower problems. During their discussion of these problems, they gave meaning to the addition rule.\(^{16}\)

Video Episode: The Night Session. The students were asked to write the general \(n^{th}\) row in Pascal’s triangle, using the bracket notation for \(nCx\). They responded to the researcher’s request to formulate the addition rule with this notation. They explained the correctness of the notation by referring first to particular cases of the pizza problem,\(^{17}\) and then to the meaning and structure of the addition rule as additional toppings are added.\(^{18}\) Jeff, assisted by Michael, wrote the following equation on the chalkboard:

\[
\binom{N}{X} + \binom{N}{X+1} = \binom{N+1}{X+1}
\]

Challenged by the researcher to express their result in factorial notation, the students worked together to produce the following equation:

\[
\frac{n!}{(n-x)!x!} + \frac{n!}{(n-x+1)!(x+1)!} = \frac{(n+1)!}{(n-x)!(x+1)!}
\]

After succeeding to write the addition rule for \(nCx\), Jeff remarks:

Do you know, like, how intimidating this equation must be like if you just picked up a book and looked at that.

\(^{16}\) For a full discussion, see Kiczek (2000); Kiczek & Maher (1998); Kiczek, Maher, & Speiser (2001).

\(^{17}\) The metaphoric reference is to the general Pizza Problem. Since grade 5, the students worked on variations of Pizza investigations. The reference here is to a general problem of finding how many different pizzas that could be made using any number out of, say \(n\), different topping choices and of considering how they could account for organizations of pizzas as additional toppings are made available.

\(^{18}\) A detailed analysis of the session is described in Dörfler & Maher (in progress).
Mike (April 2002), in an interview 3 years later, was again asked how he might explain the addition rule. Mike recalled that the group had given a general rule in the 1999 after-school session; he immediately began to reconstruct it. This time, Mike called a row, \( r \) [to denote the number of toppings], and a “spot” in the row, \( n \). He used the notation to show that “\( r \) choose \( n \)” plus “\( r \) choose \( n+1 \)” equals “\( r+1 \) choose \( n+1 \)”, referring again to adding pizza toppings to explain the rule.

In the same interview, Mike talked about how he looks for relationships while he works on problems:

The process while I am doing the problem...I just start understanding more that this is related to that...how this is related to just a triangle that’s made up of numbers. At first when they showed us a triangle, we didn’t know that has anything to do with...once you start understanding things have a relation to each other you just start convincing yourself...and then you come to a point where you know it’s right, or you think it’s right.

**STUDENTS REFLECT ON THEIR LEARNING**

Through a series of individual and small group interviews, we present student views on how they structured their learning, thereby gaining insight into their views of the process.

**Just giving the answer was never enough.** Jeff (May 1999) indicates that the students themselves took on the expectation for presenting a careful argument. Consequently, they reviewed their own argument, focused on meaning, and anticipated questions and “holes”. They questioned each other and put ideas together before offering their solution to the researchers. Listening to and asking questions of each other were essential components of the process of working together.

**Just giving the answer was never enough, in order to do it.** You’d have to have a good, like, structural record. It’s almost like doing, like a proof...like you need to show every step from point A to point B...you couldn’t just, like, skip some things and jump around. You had to go straight, and everything had to be written out and good, and ... understanding, and if you had a problem with somebody, to ask another question about it, so you ended up doing whole types of things, just to get from the beginning to the end, and through it, that’s how you really understand what you were doing, that’s why we’d learn, like what we were doing without actually calling anything a certain thing...

**We would come to it ourselves.** Jeff (May 1999) talks about not being told how to do things.
And then, like, later now, we would be doing things, like, "Oh, that's what we were learning." because Rutgers never really told us what the answers were, or what we were actually doing...like, 'This is what we're going to do today; it's called the... theorem,' or anything like that. We would come to it ourselves, and then later, we would realize that that's what we were doing this whole time.

Jeff (March 2002) indicates a building process.

If we tried to just present a final thing and really didn't know it from the beginning we couldn't explain it in a way that that you would accept from us. So in order to explain it in a way that you would accept we'd really have to start from bare bones, from the beginning.... We didn't start talking about what we were doing with you until very late in what we were doing. There was not a lot of communication back from them to us about the work we were doing.

We got so in-depth. Jeff (May 1999) reviews what they accomplished.

Well, even though we didn't spend much time together, and they [researchers] only came a few times a year, we did so much, we covered so much, we got so in-depth on topics, that it leaves an impression. I mean, we could talk about doing the blocks in first grade, and we can almost go through problems: We did shirts and pants in second grade. I mean, how many other people can tell you the math that they were doing in second grade...like a word problem, you know? Because you go in deep, you work on it so much, and you go so far into it, that it just sticks with you...That's why it leaves such an impression, because of the depth you get into it...

We just sat and thought for hours a day. Romina (July 1999) talks about the confidence she gained. She indicates that they spent days thinking about problems and that presenting them to others was a valuable undertaking.

We did a lot of problem solving. We did a lot of thinking. We just sat and thought for hours a day, and we came up with a lot of interesting things. We were able to go in front of a large audience and talk about our ideas and argue our points, and prove our points. I think it was a very good experience.

I think a lot of what we were doing was working together. Jeff (February and March 2002, respectively) talks about the benefits of collaboration and the frustration of working alone.

Well that's...how we got to wherever we were going...we were like four different people with four different ideas and we all thought we knew something on how to do a problem but...you
just cover so much more when everyone is discussing what you’re doing, I mean that’s what it was really all about...that’s really how we got anywhere was kinda work, doing our thing together, you know, and using what we each knew, to work something out.

I think it would have been very different if it was all of us producing our own solutions....I think a lot of what we were doing was working together. I think when you are working alone, when you reach a part where you don’t know anymore it is very easy to just be frustrated and say I don’t know anymore. I’m not going to do this. I can’t think about this. Like forget it. I think that by working with everybody when you got to that point, you can kind of peak over a little bit and it was all right...it was encouraged. That allowed everybody to really we could all move forward.

Everything has to make sense. Romina (March 2002) talks about understanding.

Everything has to make sense in my terms. Someone else may have done it already in a book, but I just don’t understand it unless I try it myself and put it in my own term.

CONCLUSIONS AND IMPLICATIONS

We have engaged in a research program, extended over 14 years, within which sense making has become a cultural necessity. An aspect of this culture has been the emergence, beginning in the elementary grades, of argumentation, justification, proof making, and generalization. Such processes have developed in the context of coherent strands of mathematics. The reflections by students about their learning over the project years gives further insight into the process of how they worked together and structured their learning. They reported that giving the answer was never enough. They understood that they would be expected to provide a written account to support their reasoning and that details in arguments were important. They accepted that they were not to be told the answers or how to solve a problem and took on early the expectation that they would produce the result and offer appropriate support for it. The support came from convincing first themselves and then each other. Student expectations guided how far they were willing to go in solving problems. These expectations came from interactions with researchers, who challenged them to be attentive to details, provide evidence for their results, and consider extensions and generalizations to investigations posed. The students reported that they were aware of what would be asked of them and took upon themselves on the responsibility of developing satisfactory solutions beforehand. Their work and conversation, backed by extensive interviews, indicate that they maintained high expectations for themselves and for each other, and these expectations help explain the way they worked together, over months and years. As evidenced by their comments, they took on, progressively, responsibility for their own learning and for the maintenance of communication and collaboration in their working groups. They reported increased
confidence over the long run, which may explain, at least in part, their evident commitment and responsibility for helping the project to continue and evolve through time.

MATHEMATICAL EPISTEMOLOGIES AT WORK

Richard Noss
School of Mathematics, Science and Technology
Institute of Education, University of London

In this paper, I draw together a corpus of findings derived from two sources: studies of students using computers to learn mathematics, and research into the use of mathematics in professional practice. Using this as a basis, I map some elements of a theoretical framework for understanding the nature of mathematical knowledge in use, and how it is conceptualised by practitioners. I then draw some provisional implications for a set of design principles for activity systems aimed at fostering mathematical learning. I propose a central role for digital technologies, both in assisting understanding of the genetic construction of knowledge, and in developing learning environments that instantiate the design principles.

In mathematical terms, there is a celebrated tension between forms of discourse and cognition that are delicately tuned to cultural practices, and those that are focused explicitly on mathematics per se, recognisable by its symbolic forms and epistemological structures. This tension parallels (and is perhaps derived from) the epistemological duality of mathematical thought as both tool and object, simultaneously as a component of pragmatic activity and theoretical endeavour.

The preparation of this paper has afforded an opportunity to reflect retrospectively on this duality, and on a corpus of research in which I and my colleagues have been involved, spanning a variety of sub-fields and a couple of decades. I hope it is not too fanciful to impose upon this work a narrative that was not necessarily evident to any of us while we were engaged upon it. Here is a first outline of that narrative.

I will begin with a pervasive finding that arises from investigations with (mainly young) people expressing mathematical ideas with computers. These studies led to a series of thoughts concerning the generation of mathematical meanings that nagged away until the early nineteen nineties, when Celia Hoyles and myself began to formulate a theoretical framework for describing the phenomena we encountered. Shortly after this, we had the opportunity to work in a variety of settings with the broad common aim of elaborating the mathematics used in working practices. I will illustrate how these studies began to throw light on some fundamental questions, particularly concerning the nature of mathematical practices, and encouraged us to investigate further the problem of mathematical meaning from both cognitive and sociocultural perspectives. This effort has led to some general principles about the design of mathematical activity systems for learning, and in particular, the rather special role that digital technologies may play within them. Thus, perhaps fittingly
but probably over-ambitiously, I will conclude where I began, with the assertion that
digital technologies can play an unusually powerful role in helping us to understand
and reshape the nature of mathematical sense-making.

Before I start, I would like to make two general observations. The first concerns my
wish to consider both cognitive and social dimensions. To steer a course between
these two approaches is not easy, not least because proponents of each often ignore
the work of the other, or denounce as mere eclecticism any attempt at synthesis
(there are important exceptions to this: see for example, Cobb and Bowers 1999;
Kieran, Foreman & Sfard, 2002). One organising idea for thinking about this
apparent dichotomy has been suggested by Andy diSessa (personal communication)
who distinguishes between phenomena that are distally and proximally social. Much
of what I have to say comes from a recognition that many phenomena concerned
with mathematical meaning are proximally social, in that they manifestly involve
social and cultural relations between people and within communities. But I also
recognise that many facets of human thought are only distally social; while it is true
that what I think, and the techniques I use for thinking and communicating are
shaped both socially and culturally, I think in ways that are structured by my
personal cognitive history at least as strongly as by the socio-cultural relationships in
which I find myself embedded. No attempt to understand how mathematics is learned
by human beings can afford to ignore this, essentially cognitive element, any more
than it can afford to ignore the social and cultural relations in which cognitive
activity is embedded. Thus, in what follows I hope to illustrate, not only that such a
perspective need not necessarily lapse into eclecticism, but rather that the
coordination of the two approaches provides a possible and even necessary
methodological stance.

The second observation concerns the title of this paper. I recognise that it is bad form
to tell a joke and then explain it. Forgive me then, if I explain the double entendre in
the title. I want to talk about mathematical epistemology as it is found in work, to
understand how mathematics is used, and how it is conceived by participants in their
cultural practices. But I also want to talk about mathematical epistemology as a
crucial element at work in learning situations; how we, as mathematics education
researchers can develop, not just new approaches to teaching, but new mathematical
epistemologies, that is more learnable and, at least for all but the few, more
expressive.

INSIGHTS FROM OBSERVATIONS OF ACTIVITIES WITH COMPUTERS

Over some two decades, Celia Hoyles and I have engaged in studies of children and
adults interacting with computational systems designed to afford mathematical
expression. Throughout this time, we have noticed an interesting phenomenon,
which we can simplistically characterise as follows: learners are often able to express
themselves in terms that might be considered abstract, yet which seem to be bound
tightly into the tools and symbols of the computational world. Learners can, in other words, say and do things with suitably-designed systems that they may be unable to say or do without them, and they can often do so in ways that are interestingly different from conventional means.

I would like to elaborate two points. The first centres on the ways that learners use technology to shape their mathematical expression, how some elements of the invariant relationships between the given objects are identified and related within the symbolic discourse of the environment. In the sense that these invariant relationships remain articulated only within activity and interaction using the notational system of the virtual world, they might not be said to constitute a formal abstraction. But to the extent that they become transformed into something coherent, reusable and general, it does make sense to consider such activity as involving an abstraction of some kind. For further elaboration of this argument, in the context of stochastic thinking, see Pratt, 1998; Pratt & Noss, in press: for a study in relation to students' conceptualisations of non-euclidean geometry from a similar perspective, see Stevenson, 1996; Stevenson & Noss, 1999: and for a recent study on 12 year-olds' understandings of symmetry and reflection, see Healy, 2002.

The second aspect is related to the first, and concerns differential performance. Put bluntly, children who may be apparently unable to express any relationships about their figures with pencil and paper, are able to express them quite adequately (and sometimes quite elegantly) with the computer.

Reports of differential performance depending on context are commonplace. There are consistent and widely-reported findings concerning the differential performance between adults carrying out tasks in everyday settings, and when given written assessments. For example Scribner's (1985) study of the dairy industry, Lave, Murtaugh and de la Rocha's (1988) investigation of weight-watchers, and the seminal work of Saxe (1991), and Nunes, Schlimann and Carraher (1993) on street vendors, have all shown convincingly that people who are error-prone in tests are mostly error-free in familiar practical contexts, and that there is a major disjuncture between the strategies used in the two settings. More generally, and especially since the work of Jean Lave and Etienne Wenger (1991) and others in broader anthropological contexts, we may more or less take for granted the situated view of knowledge genesis. A key insight is that people construct solutions in the course of action, and that these solutions are structured by activity. In the supermarket, for example, Lave illustrates how people avoid doing what might be classified as school mathematics not because it is too hard, but because the practice of supermarket shopping carries with it its own discourse, and its own mechanisms for meaning-making. One point that is often missed, however, is that we cannot conclude that there is nothing that passes for mathematical in shoppers' activities. The point is that when shoppers do use mathematics, it is supermarket mathematics, a mathematics made possible through the resources of the setting.
Since these studies, the situated cognition perspective has become ubiquitous. In its extreme version, it states that 'every cognitive act must be viewed as a specific response to a specific set of circumstances' (Resnick, 1991, p. 2). However, such arguments – compelling as they are – face researchers of mathematical learning with a number of seemingly intractable difficulties. If mathematics cannot be regarded as a decontextualised resource to be learned and then mapped onto settings, if it can only be defined in relation to specific situations, then we seem to have come close to distilling the mathematical essence out of mathematical thought.

As a way out of this cul-de-sac, Hoyles and myself proposed, some ten or so years ago, the idea of situated abstraction (a first attempt is in Hoyles & Noss, 1992) as a tool to aid in understanding how learners construct mathematical ideas by drawing on the material and discursive components of a particular setting (other attempts have been made by Cheng and Holyoak, 1985; Cheng, Holyoak, Nesbitt and Oliver, 1986; Nunes et al., 1993). Situated abstraction seeks to describe metaphorically how a conceptualisation of mathematical knowledge can be both situated and abstract. It may be finely tuned to its constructive genesis – how it is learned, how it is discussed and communicated – and to its use in a cultural practice, yet can simultaneously retain mathematical invariants abstracted within that community of practice.

The idea of abstraction as a conceptualisation or a piece of knowledge lying in a separate realm from action, tools, language or indeed from any external referential sign system, is important from a perspective of mathematical discourse, since mathematical discourse is normally conceived as self-contained: it forms part of a system that has its own objects and its own rules for transforming them (see Piaget, 2000). This characteristic of formal mathematical abstraction is central to its utility: situated abstraction does not seek to challenge that utility, but questions whether mathematical abstractions can ever be fully separated from the context of their construction or application (see also Wilensky, 1991). Our broader hope is that the idea of situated abstraction will contribute to a theory of how mathematical knowledge is used or ‘transferred’ across settings (for other contributions to this emerging theory, see for example, Carraher & Schliemann, 2002; Sfard, 2002; Nemirovsky, in press; Hershkowitz, Schwarz and Dreyfus, 2001).

At the point in which Hoyles and myself began to formulate these ideas, they were essentially hypotheses, based only on data derived from children and adults, engaged in computationally expressive media. Fortunately, we were subsequently able to test these ideas in studies of mathematics in work, affording the opportunity to focus on the situativity of mathematical meanings by investigating their use rather than their genesis.

INTO THE WORKPLACE

While it is clear that persons studied in their communities yield rich and useful data which describes what they do, it remains desirable to locate and elucidate the
mathematical knowledge that they know. To achieve this aim, our group in London has employed ethnographic and interview data to capture meanings created in situ and the dialectical relationship of these meanings with mathematical expression on the one hand and professional expertise on the other. This has involved Celia Hoyles, Stefano Pozzi and myself in a series of studies with investment bank employees, paediatric nurses and commercial pilots; more recently, Phillip Kent and myself have been working with a group of structural engineers. The professional groups differ in substantial ways, but there are similarities: in the explicitness of their mathematical training, and in their intolerance – to a greater or lesser extent – of errors. We have developed a map of mathematical workplace activities comprised of documentary analysis, interviews with senior staff in each profession, general and task-based interviews with practitioner volunteers, and ethnographic observation of these subjects in the workplace.

I will now try to summarise some of the outcomes of this research. I will do so by sketching five vignettes, chosen to illustrate the outline of the theoretical position I wish to advance in the form of a set of provisional 'results'. The text of each vignette is based on the relevant co-authored papers that are referenced within it.

Vignette 1: The epistemological fragmentation of the workplace. The first vignette is drawn from a study conducted with a group of bank employees, part of which attempted better to understand the bankers' ways of thinking about quantitative data (see Noss and Hoyles, 1996a).

In responding to tasks involving the interpretation of functional relationships represented as graphs, the responses of the bank employees were surprisingly uniform. Most identified graphs as a visual display of numbers, as a pictorial representation of underlying data rather than as a functional relationship, and as an indication of a trend in data that allowed prediction. Where we saw graphs as a medium for expressing relationships (e.g. between quantity and time) bankers saw a display of data.

The origins of this epistemological diversity are almost certainly to be found in the tools of the system in which the bankers operate. On each employee’s desk were several computers. Some, the traders and the operations staff, had three or four. On all but a very few screens, there were columns of data, graphs, and more columns of data: in every sense, graphs were pictures of numbers, rather than graphical representations of a functional relationship.

This epistemological standpoint with respect to graphical representations can, it seems, be thought of as the graphical face of a fragmented knowledge structure that characterises the practice of investment banking. We encountered departments specialising in the finest detail on one financial instrument, sharing a common wall but no common language with another – essentially similar – department. Of course, similarity is in the eyes of the beholder: while we might view, say, Nominal
Certificates of Deposit and Treasury Bills as flavours of similar financial instruments sharing the same (or nearly the same) mathematical structure, the bankers saw finely-tuned pragmatic knowledge and strategies, and a discourse that served to reinforce the differences between them.

**Result 1:** There is an epistemological fragmentation of the knowledge structure of the workplace that shapes, and is shaped by, the discourse of the working practice. Strategies are finely tuned to the pragmatic demands of work activities, with little tendency to strive for a theoretical orientation involving generality or appreciation of unifying models.

**Vignette 2: The role of artefacts and tools.** The idea that people think and act within sociocultural contexts which are mediated by cultural tools is now commonplace. The work of Vygotsky, Luria and Leont’ev, indeed the entire corpus of work on activity theory, offers compelling evidence that individual and social acts of problem solving are contingent upon structuring resources, involving a range of artefacts such as notational systems, physical and computational tools, and work protocols (Gagliardi 1990).

Workplace settings are, naturally enough, littered with artefacts. These artefacts are, for the most part, a simple expression of work protocols, so that in routine use – and the overwhelming majority of time in working practices is spent on routine – the structure of the artefact is hidden from view. For example, in one study on a hospital ward (Pozzi, Noss & Hoyles, 1998), we found that a seemingly straightforward artefact like a fluid balance chart, contained within it the crystallised activity (Leont’ev, 1978; see also, Wertsch 1985) of the hospital community, shaping in complex – but unnoticed – ways the actions and discourse of those using it. A central part of this crystallised activity was a mathematical model of essential variables and relationships embedded in the activity: evidence for both the complexity and the invisibility of this mathematical model was gained by observing the ambiguity and uncertainty felt by a newcomer to the paediatric ward, as well as the extreme difficulty faced by the old-timers in communicating to her the structure that they had come to take for granted.

The arrival of the newcomer on the ward served to trigger a 'breakdown' or decision point within routine practice, a situation in which the models underpinning artefacts and the representational infrastructures on which their use depends, rise to the surface, and become open for inspection and negotiation by participants (and observation by researchers). That this model is normally hidden should cause no surprise: we have already noted that the purpose of an artefact is to facilitate the pragmatic activities of the workplace, not to learn mathematics or to gain insight into underlying models. Nevertheless, when breakdowns do occur, invisible relationships buried in artefacts do not suffice and there is a need for the community to understand at least some of the workings of the models, to examine their strengths and limitations, and to scrutinise the results of the mathematical labour congealed within
them (see Hall, 1998, for a similar finding). At least in breakdown situations, we are
abruptly made aware of circumstances that require more than mere procedural
routine and the learning of work protocols, but systemic interpretation – the
individual is required to make sense of what she does within the broader socio-
technical system.

Result 2: Tools and artefacts shape activities and thought in ways that only
become visible at times of breakdowns to routine. In disruptions to routine,
individuals need to develop a broader interpretative view of the model that
underpins their routine practice.

Vignette 3: The anchoring of mathematical meanings in practice. It will help to
focus on a specific knowledge domain: I will turn to one of the most widely-
researched topics in the field, ratio and proportion. Researchers on proportional
reasoning in school and the workplace have distinguished two ubiquitous classes of
strategies for making proportional calculations, functional (across measure) and
scalar (within measure): see Vergnaud (1983) for a thorough analysis. Nunes,
Schliemann and Carraher (1993), have suggested that scalar strategies offer a
mechanism for holding on to situational meaning by keeping only one measure in
view. By way of contrast, functional strategies tend to be seen as semantically sparse
manipulations of numerical quantities per se. It appears that this difference is the
reason why people tend to prefer scalar strategies, even when it results in a more
computationally awkward calculation, and is the crux of the counterposition in the
literature of scalar and functional approaches, in that the privileging of the former
has arisen from the apparent necessity in the latter to relinquish meaning in the form
of a situational referent. Nunes, Schleimman and Carraher concluded that scalar
approaches are drawn from experiences in everyday situations, are more flexible and
generalisable than easily forgotten algorithmic approaches, and, most relevant here,
allow people to preserve the meaning of the situation by keeping variables separate
and not calculating across measures.

Let us see how robust this finding is in the case of a group of paediatric nurses who
are similarly expert in their field, but who have had years of school mathematical
education as well as professional training. During ethnographic observations and
interviews, we noticed that while all the nurses' drug calculations were carried out
correctly (unsurprisingly, in written tests, nurses' responses were highly error-prone),
the strategies adopted were varied and exhibited a far richer complexity than would
be suggested either from our interviews or from the existing nursing literature. Of 30
episodes related to drug administration (out of a total of 250) we collected during 80
hours of observation, 26 combinations of ratios were observed with a variety of
drugs, packaging and prescriptions. Of these, only four involved the nursing rule (in
which all were endlessly drilled during training), while equal numbers chose scalar
and functional strategies. Moreover, the nurses often opted for strategies that would,
in the literature, be described as lacking in meaning.
Our interpretation of these findings is that the nurses' knowledge of concentration, that is their appreciation of the invariance of the relationship between mass and volume as evidenced in their drug calculations, was anchored in an intimate knowledge of the drug itself, as well as in the properties of familiar packaging constraints of prescribed doses. The knowledge was mutually constituted and expressed as both mathematical relation and culturally-shared situational noise – the same kind of knowledge that we encountered earlier, in the context of computer worlds and which we called situated abstraction.

**Result 3:** Knowledge is mutually constituted by a coordination produced in activity of mathematical knowledge and situational noise to form situated abstractions.

**Vignette 4:** The qualitative restructuring of mathematical knowledge in activity.

In a recent study, Phillip Kent and myself have been investigating the ways in which mathematical knowledge is conceived and deployed with employees of a large London-based engineering firm (see Kent & Noss, 2001; Kent & Noss, 2002). We have encountered, even with this mathematically educated group, a ubiquitous view that the majority of structural engineers do not "use mathematics" of any sophistication in their professional careers. So, while all believed that it was important for graduate engineers to have an appreciation for advanced mathematics, it is something they would rarely be expected to use:

> Once you've left university you don't use the maths you learnt there, 'squared' or 'cubed' is the most complex thing you do. For the vast majority of the engineers in this firm, an awful lot of the mathematics they were taught, I won't say learnt, doesn't surface again.

I think that this particular engineer's description of mathematics as not "surfacing" is a fortuitous one. We have seen in the case of the nurses, that mathematical knowledge becomes fused with professional knowledge, as situated abstraction, not as abstraction in its pure form. But it is, particularly for mathematically sophisticated groups such as engineers, this pure form that is readily recognisable as mathematics. Our engineer is right that mathematics does not surface; or rather, that it seldom surfaces in the form it was learned and taught. It has been transformed into something else, something at once more usable, more embedded, more noisy. Only the vestigial traces of the college mathematics taught to engineers remains in the mathematics that they actually use in activity.

The transformation in the character of mathematics appears to be not simply a quantitative one, nor merely a replacement of mathematical activity by professional expertise and experience. It represents a qualitative, epistemological and cognitive restructuring of the mathematics as it becomes 'embedded' in engineering expertise. I claim that engineers' conceptualisations of this restructured mathematical knowledge are legitimately considered as situated abstractions.
I will illustrate with an example. The type of qualitative thinking that characterises the use of 'feel' in the engineering design process is exemplified by the concept of load path, the notion that the loads acting on a structure have to "flow down into the ground" like a kind of fluid. It is a powerful, very physical concept, and extremely useful because it provides a way of thinking about a structure before any analysis is done, allowing judgements to be made about the validity of quantitative analysis of the structure.

Formal mathematical analysis, on the other hand, is based on the assumption of static equilibrium, which assumes that nothing is moving in a stable structure, an assumption that appears to conflict with the load path concept. Nevertheless, load path has become a situated abstraction of stability criteria: it allows predictions of behaviour that emerge from fusing together the actual properties of the material (e.g. steel beams) with the associated (mathematically-abstracted) forces.

The relevant point is this: engineering discourse employs, in at least one important way, a kind of knowledge which is at once about mathematical relations and about substance. The idea of flow makes no sense without something to flow through – the beams and struts of everyday engineering practice. Mathematical knowledge has been transformed to the extent that even those engaged in it do not necessarily recognise its existence. This poses sharply two questions: how does the formally-learned knowledge (e.g. the engineers' knowledge of Newton's laws, or the nurses' knowledge of the nurses' rule) become transformed both cognitively and culturally, into something new and more functional within professional practice and what connection, if any, is maintained between them?

I have no data on these questions. For the moment, the key issue concerns the transformation of knowledge, the creation of new epistemologies as a characteristic part of professional expertise. Here, at least, is the explanation of the apparent invisibility of mathematical activity. Here too is a broader, more culturally oriented perspective on the hitherto individualistic notion of situated abstraction that recognises the individual's embedding in an ambient social and cultural space.

Result 4: As mathematical knowledge is embedded in new settings and activities, it undergoes an epistemological and cognitive transformation. What is consciously thought of as mathematics by practitioners appears to be only the visible component of a larger, transformed body of mathematics in use that takes the form of situated abstractions.

Vignette 5: The situativity of abstraction. The final vignette will deal with the most problematic (and so far, under-researched) issue. The challenge is to test the situativity of knowledge, to assess the extent to which knowledge in the form of situated abstraction 'transfers' to new situations (or better still, to find a convincing alternative metaphor for the notion of transfer itself).
In the study of nurses, we undertook a series of task-based interviews, in which the nurses whom we had followed on the ward were faced with situations that were progressively removed from the practices we had observed, yet which retained elements of familiar situations for them (see Noss, Hoyles & Pozzi, in press). We found that when the nurses were faced by a close simulation of their practice, they displayed similar strategies to those identified in the ethnographic studies, together with a strong sense of the invariant relationship of mass and volume – an abstraction. In these cases, the nurses’ reasoning was supported by a synergy of their existing (school) mathematical knowledge and their practical experience. By contrast, an analysis of the nurses' responses to a less familiar scenario, derived from a breakdown observed on the ward, showed that when the texture of nursing practice became unavailable for any reason, the mutually constitutive elements of professional and mathematical knowledge became disconnected and the situatedness of their conceptualisation was apparent.

Result 5 (conjecture): The noise of a situation forms a core part of a situated abstraction. When it can be called upon in a new situation (and only then?) the mathematical knowledge can be 'transferred'.

DESIGNING FOR CHANGE

I promised at the outset to draw the implications of the work studies, and to draw some general principles about the design of mathematical practices for learning. The hypothesis is that the ways in which people reconstruct knowledge for use in work is spontaneous, in the sense of deriving from participation in the practices of the community, and, for the most part, not formally taught within the practice. That being so, we might further hypothesise that – given the effectiveness of this kind of knowledge – we might attempt to design and construct activity systems for learning that harness the features of the workplace, at least those that we perceive as constitutive of learning. For reasons of space, I can only schematically summarise the findings and outline some challenges for the design of learning (and learnable) environments that flow from them: see Table 1.
If... | we should design to...
---|---
1 | knowledge is fragmented and strategies pragmatic | demonstrate the power of invariants
2a | knowledge is pervasively structured by artefacts and their underlying models people need to understand the models | supply lots of Really Useful Things make things that people can see inside
3 | situated abstractions are mutually constituted by mathematical knowledge & situational noise | maximise situational noise in culturally-relevant ways
4 | mathematical knowledge is transformed when it structures new activities | respect the mathematical epistemologies of new representational forms
5 | situated abstractions depend on noise for ‘transfer’ | afford construction of new situations from old ones

Table 1: some schematic challenges of the mathematics in work findings for the design of learnable environments

In our book *Windows on Mathematical Meanings: Learning, Cultures and Computers* (Noss & Hoyles, 1996b), Celia Hoyles and myself argue generally that constructing runnable models in the form of computer programs, affords a compelling example of a learnable mathematics, opening unique opportunities for students to interact with a formal system. In modifying or constructing a model of a system, a student must articulate rigorously its salient relationships, describing mathematical structures in a language that can be communicated, extended, and become the subject of reflection.

There are many advocates of a similar perspective (see Hoyles & Noss, in press, for a review). In a recent study, for example, Sherin (2001) proposes that programming-based representations might be easier for students to understand physics than equation-based representations, and that programming-based representations might privilege a somewhat different “intuitive vocabulary”, i.e. might tap into different things that people 'just know'. I would add a third point: that programming affords a rich set of situated abstractions of physical relationships that I think correspond to what he calls a *physics of processes and causation* (as opposed to algebra-physics which he characterises as a *physics of balance and equilibrium*).

It is not important whether we accept Sherin’s conjecture or not: in *Windows* we refer to LogoMathematics or Programming Mathematics to emphasise that it is a different kind of mathematics that is at issue (this is an instance of the fifth design challenge). What is important is that we recognise that the switch from one representational form to another, carries with it the possibility of a switch simultaneously in epistemology and learnability.
I would like to add one more crucial element to the consideration of design principles for learning environments: the importance of mathematical models, a proximally social issue that I briefly touched on in Vignette 2. I believe the knowledge economy has massively broadened the number of people who need to understand the system they are using: elsewhere (Noss, 1998; 2002) I elaborate a case that competence in constructing, interpreting and critiquing models has become a core part of social and professional life in the twenty-first century. Sharing, critiquing and representing models is massively under-represented in mathematics curricula, still wedded to the epistemological and pedagogical requisites of the nineteenth century rather than transforming both in the face of the demands, and computational possibilities, of the twenty-first (see Kaput, Hoyles & Noss, 2002).

I contend that manipulating, modifying, constructing and sharing computationally instantiated models of mathematical systems affords the best chance we have for designing a more learnable mathematics, and of realising the five challenges outlined in the previous section. We have recently completed a study aimed at instantiating this approach in the Playground Project\textsuperscript{4}, which has involved a group of researchers based in four European countries who have developed a system with which young children, aged less than 8 years old, can play, share, construct and rebuild computer games. Our goal has been to put children in the role of game designers and game programmers, rather than merely consumers of games programmed by adults.

I can, for limitations of space, only sketch an example (see Noss, 2002 for a full description). Mitchell is an eight year-old boy in an inner-city school who has been helping to design and debug the Playground system for about a year. He is playing a game where he controls a character called ‘dusty’, who shoots out flowers every time the force joystick trigger is pressed. Mitchell collects points by hitting an animated target moving vertically up the left-hand edge of the screen. He finds it very easy to play and achieve high scores since he can move his character as close to the target as he pleases.

Mitchell decides that the game would be more fun if it was competitive, so at his request, Miki, the researcher, adds another player character, this one controlled by the mouse. It is at this point that Mitchell plays a trick: demanding that she avert her eyes, he removes a piece of Miki’s program, effectively disabling her mouse by restricting it only to vertical movements, while he has two-dimensional control and can get as close as he likes to the target! Mitchell made use of a surprising and difficult fact: that two-dimensional motion can be instantiated as the vector sum of horizontal and vertical components.

Think for a moment of the knowledge congealed in the innocent phrase "vector sum". Concealed in this phrase, is a taken-for-granted representational infrastructure that includes the definition of a vector, the algebraic system for combining two or more vectors, and a range of properties (e.g. scalar and vector product) that give meaning to the very idea of what a vector is and why it is a conceptually powerful
generalisation of a real number. This structure is relatively complex, and is postponed with good reason until the latter stages of compulsory education, if it is taught at all. Yet the complexity is in the infrastructure, not the idea: the latter is, as Mitchell showed, rather intuitive. The point is that what is intuitive is hugely contingent on the representational infrastructure with which the intuition is expressed. In Mitchell's world, the addition of vectors is instantiated not as an algebraic relation but as a natural property of the representational system. The (object-oriented) structures of the system translated, more or less directly, into what kinds of things Mitchell could take for granted as "just so", what meanings he could derive from them, and most importantly, the ways in which he could make the ideas work for him in achieving his goal. In short, the change in representational infrastructure transformed not only the learnability of the mathematical knowledge, but the mathematical epistemology at work in the activity system.

CONCLUDING REMARKS

This last point brings me to the intention I flagged at the outset, to conclude with the notion of epistemology at rather than in work. What is the connection between the two? A key link is that the analysis of mathematics in work concerns the transformation of knowledge as it is recontextualized across settings. We have seen how a person's mathematical knowledge is not invariant across time and space; it is transformed into different guises, different epistemologies, more or less visible as mathematics. This transformation seems much more powerful than the traditional notion of "application" or "use" that is often employed as a metaphor to describe this process. If formally-taught mathematical knowledge is transformed in this way, it is at least possible that reciprocal transformations may, in the future, take place for Mitchell, and that he may come to recontextualise his piece of knowledge about vector addition in (for him) novel ways.

More generally, the sketch I have provided offers a further point of connection between cognitive and cultural perspectives. In imagining how mathematical structures can be externalised and manipulated within an appropriate symbolic or linguistic framework, it suggests how abstractions constructed within concrete situations may compensate for their lack of universality by their gain in expressiveness. When general relationships can be expressed, they can be explored and become familiar. In the process, the links with knowledge of lived-in-cultures can be maintained, rather than severed in the quest for ultimate pinnacles of abstraction.

Mitchell was immersed in a world that was, I think, every bit as concrete and real to him as the load path on the components of a bridge are to an engineer. And, like his professional counterparts, Mitchell was engaged in an activity that researchers in the field of mathematical learning may recognise as having a mathematical component, but which were to him part of the ecological system – the totality of relationships.
between himself and the environment, and the ways in which these were expressed
and communicated.

That the Playground and mathematical epistemologies run side-by-side should not be
a matter of surprise: there is, after all, no single way in which humans can
conceptualise (mathematically or otherwise) their environment, even though some
are socially and historically privileged within a given culture. Official, symbolic
mathematics is privileged in just this way; and there are good reasons for this. But
the compactness and elegance of mathematical expression does not necessarily make
it equally functional for learning, and if learning is our prior goal, we would do well
to think about new epistemological frameworks in which to embed the mathematics
we wish our students to understand. New epistemologies mean new intuitions, new
things to be built with them, and new means for combining and reconstructing them.
They involve new sets of situated abstractions that are both functional and powerful.
I think this is the major challenge for the design of didactical environments, to create
new systems which might, I think, be justifiably described as new mathematical
epistemologies at work.

ACKNOWLEDGEMENTS

The corpus of data on which this paper is built was the result of several research
projects, and some ten or more years of collaboration with colleagues. I acknowledge
the support of the Economic and Social Research Council UK (grants R 0222 50004
& R 0002 23420) and the EU (grant 29329). Almost all of the data presented here
has been published in collaboratively-written articles, which are appropriately
referenced. My thanks to Ross Adamson, Miki Grahame, Lulu Healy, Celia Hoyles,
Phillip Kent, Dave Pratt and Stefano Pozzi for their collaboration in the various
projects. Lulu offered helpful comments on an earlier draft; Celia helped me redraft
(and stay sane) when Version 1 exceeded the page constraints by a factor of 2.
Windows on Mathematical Meanings has provided a source for the main theoretical
ideas, and in this respect – as in so many others – I would like to acknowledge the
profound help and support of my co-author and collaborator, Celia Hoyles.

NOTES

1 Michele Artigue (in press) has made a related point deriving from the work of Yves Chevallard.

2 diSessa (1980) makes a compelling case that a view of force as momentum flow may more easily engage and refine (rather than deny) students' existing intuitions, and therefore present a more learnable physics than that represented by the familiar $F = ma$.

3 Constructing a computer program no longer necessarily involves writing lines of text.

4 The Playground project was a consortium across four countries, directed by myself and Celia Hoyles. The London team also comprised (at various times) Ross Adamson, Miki Grahame, Sarah Lowe and Dave Pratt. Ken Kahn, the author of *ToonTalk*, was a consultant to the project.
WORD PROBLEMS AS MODELING EXERCISES IN HISTORY AND TODAY

Mathematics provides a set of tools for describing, analyzing and predicting the behaviour of systems in different domains of the real world (Burkhardt, 1994). This practical usefulness of mathematics for understanding the world around us, for coping with everyday problems, and for future professions, has always provided, and still provides, a major justification for the important role of mathematics in the (elementary) school curriculum (Blum & Niss, 1991). In particular, the inclusion of application and modeling problems was mainly intended to develop in students the skills of knowing when and how to apply their mathematics effectively in various kinds of problem situations encountered in everyday life and at work.

The application of mathematics to solve problem situations in the real world, otherwise termed mathematical modeling, can be usefully thought of as a complex process involving a number of phases. There are many different descriptions of this model (e.g., Burkhardt, 1994; Mason, 2001; Blum & Niss, 1991; Verschaffel, Greer & De Corte, 2000), but, in essence, they all involve basically the following components: understanding and defining the problem situation leading to a situational model; constructing a mathematical model of (or: mathematizing) the relevant elements, relations and conditions embedded in the situation; working through the mathematical model using disciplinary methods to derive some mathematical results(s); interpreting the outcome of the computational work in relation to the original problem situation; validating or evaluating the model(ing process) by checking if the interpreted mathematical outcome is appropriate and reasonable for his or her purpose; and, stating and communicating the obtained solution of the original real-world problem.

Evidently, this modeling process can not be described as a linear activity; it has to be considered cyclic (Blum & Niss, 1991; Burkhardt, 1994; Mason, 1997). Moreover, modeling is not a straightforward activity. In modeling, not all aspects of the reality can, nor should, be modeled. The modeler tries to capture the essentials of the situation in the model, but what is considered as essential, and, thus, taken into account in the mathematical model, is not fixed, but relative to the modeler and to the context wherein (s)he is confronted with the modeling task at hand. Ikeda and
Stephens (2001) point to the pivotal task for the modeler of seeking a proper balance between over-complexity and over-simplification, taking into account the goals of the modeling task, certain personal and contextual constraints, etc. Finally, while modeling is often performed in order to answer one or more well-defined questions, this is not necessarily always the case. Modeling also occurs in situations where no well-defined question(s) has been, or will be, posed, but where the goal is to grasp, understand, make sense of, represent, explain, predict, and so forth, a situation or a phenomenon (Niss, personal communication).

Historically, one major way of teaching modeling process is through word problems, i.e. verbal descriptions of problem situations, typically presented in a school context, wherein a question is raised the answer to which can be found by performing (a) mathematical operation(s) on the numbers in the problem (Verschaffel et al., 2000).

An analysis of the very long and worldwide history of word problems reveals that word problems have been included, and are still being used, with the ostensible aim of accomplishing several goals (Kilpatrick, 1985; Niss & Blum, 1991; Verschaffel et al., 2000). I will focus on their oldest, and probably most important goal, namely to offer practice for the situations of everyday life in which mathematics learners will need what they have learned in school. The (implicit) idea behind this goal is to bring reality into the mathematics classroom, to create occasions for learning and practicing the different aspects of applied problem solving, without the practical (organisational, financial...) inconveniencies of direct contact with the real-world situation evoked by the problem statement. By means of such “best alternatives” for the real-world situations outside the classroom, students become prepared for the mathematical requirements they would face in their (future) everyday lives.

For a very long time, word problems have played this application function without much reflection and critical concern. Of course, there have always been individuals showing (some) awareness of the bridging problem between reality and mathematics, and the risks involved (Lewis Carroll is a marvelous example), but many teachers, textbook writers and researchers, have been using, and still use nowadays, word problems as if there was no bridging problem at all.

During the last 10-15 years, it has been argued by many scholars from different disciplines, such as mathematics education, psychology, linguistics, and anthropology, that the current practice of word problems in school mathematics does not at all foster in students a genuine disposition towards mathematical modeling. First, in-depth linguistic analyses of word problems as a text genre have led to serious questioning of the “unproblematic acceptance of concepts of separable mathematical and real worlds and of word problems as a transparent bridge between the two” (Gerovsky, 1997, p. 22). A second relevant line of research comprises studies on “everyday cognition” revealing remarkable discrepancies and difficulties of transfer between applied mathematics in contexts in and out of school (Carraher, Carraher & Schliemann, 1985). Third, empirical studies, mostly grounded in socio-
cultural and socio-constructivist theories, have shown that after several years of schooling many students have constructed an approach to mathematical application problems whereby this activity is reduced to the execution of one or more arithmetic operations with the numbers in the problem, without any serious consideration of possible constraints of the realities of the problem context that may jeopardize the appropriateness of their standard models and solutions (Boaler, 1994; Lave, 1992; Nesher, 1980; Reusser & Stebler, 1997; Schoenfeld, 1991; Verschaffel et al., 2000). Altogether, these three related lines of research have led to a scepticism about word problems as a vehicle for promoting the development of students’ disposition towards authentic mathematical modeling.

I will continue with a brief review and discussion of this third line of research carried out to investigate this phenomenon of “suspension of sense-making” (Schoenfeld, 1991) when doing school arithmetic word problems, beginning with ascertaining studies documenting and marking out the phenomenon, and then wending my way to an explanation of the observed effects, which will be found in the culture of the mathematics classroom. This explanation will be followed by a sketchy review of some design experiments wherein researchers have tried to develop a new instructional approach aimed at the development in pupils of more appropriate conceptions about, and strategies for, doing word problems, based on the modeling perspective. Finally, I will discuss a number of educational implications of the research done so far as well as some challenges for the future of teaching mathematical applications and modeling.

EVIDENCE OF LACK OF SENSE-MAKING AMONG STUDENTS

The most spectacular, and probably also the most quoted, case of “suspension of sense-making” is that of the French and German researchers (Institut de Recherche sur l'Enseignement des Mathématiques de Grenoble, 1980; Radatz, 1983) who posed non-sensical problems such as “There are 26 sheep and 10 goats on a ship. How old is the captain?” and found that many elementary school children supplied answers produced by arithmetical operations on the numbers in the text without expressing any concern about the appropriateness or meaningfulness of their computation-based answers on these absurd problems.

Another famous example is the buses item “An army bus holds 36 soldiers. If 1128 soldiers are being bussed to their training site, how many buses are needed?”, that was used for the first time in the Third National Assessment of Educational Progress in the US (Carpenter, Lindquist, Matthews, & Silver, 1983) with 13-years-old students, and that elicited a remarkably large number of non-whole number answers (“31.3 buses”) and answers wherein the outcome of the division was rounded to its nearest whole-number predecessor (rather than its contextually much more appropriate successor).
Inspired by these striking examples of suspension of sense-making in school mathematics (as well as some other examples), Greer (1993) and Verschaffel, De Corte and Lasure (1994) carried out pencil-and-paper studies with upper primary and lower secondary school students, using a set of problems including those listed below:

- Steve has bought 4 planks each 2.5 meters long. How many planks 1 meter long can he saw from these planks?

- A man wants to have a rope long enough to stretch between two poles 12 meters apart, but he only has pieces of rope 1.5 meters long. How many of these would he need to tie together to stretch between the poles?

- John’s best time to run 100 meters is 17 seconds. How long will it take him to run 1 kilometer?

They termed each of these items “problematic” (P) in the sense that they require (from our point of view) the application of judgment based on real-world knowledge and assumptions rather than the routine application of one or more simple arithmetical operations. Each such P-item was paired with an S-item (for “standard”) in which the “obvious” calculation is (we would argue) appropriate. For each item, the students, as well as recording an answer, were invited to comment on the problem and their response. A response to a P-item was classified as a “realistic reaction” if either the answer given indicated that realistic considerations had been taken into account or if a comment indicated that the student was aware that the problem was not straightforward. For example, a classification “realistic reaction” for the planks P-item would be given to a student who gave the answer “8” or who made a comment such as “Steve would have a hard time putting together the remaining pieces of 0.5 meters”. In both studies, students demonstrated a very strong overall tendency to exclude real-world knowledge and realistic considerations when confronted with the problematic versions of the problem pairs. For instance, in Verschaffel et al.’s (1994) study, only 17% of all reactions to the P-items could be considered as realistic.

These initial studies were replicated in several other countries (e.g., Chili, China, Germany, Japan, Switzerland, The Netherlands, Venezuela), using similar methodologies and, to a considerable extent, the same items. The findings were strikingly consistent across many countries (see Verschaffel et al., 2000). Using the same criteria as in the two initial studies, none of the P-items was answered in a realistic fashion by more than a small percentage of students (except for two problems; see below), sometimes to the great surprise and disappointment of these other researcher(s) who had anticipated that the “disastrous” picture of the Irish and Flemish pupils would not apply to their students.

While the results were remarkably consistent across nationalities, there is increasing evidence, both from these replication studies and from several other studies with a
somewhat different scope and methodology, that the tendency to respond to school arithmetic word problems in a stereotyped and non-realistic way is related to various kinds of task, subject and context characteristics.

With respect to task variables, P-items about the interpretation of a division with a remainder (i.e., the buses item and a similar item about sharing balloons) elicited considerably more realistic answers than the other kinds of P-items in the problem set in every study mentioned above.

With respect to subject variables, research evidence suggests that students’ tendency to ignore plausibly relevant and familiar aspects of reality in answering word problems, is associated with age, gender, and social class. Children with less years of experience with (traditional) schooling (Radatz, 1983; Yeping & Silver, 2000), girls (Boaler, 1994) and working-class children (Cooper & Dunne, 1998) seem more likely to remain within an “everyday” frame of reference when doing application problems in a school context, leading to less appropriate answers if scored from a traditional point of view.

Finally, several follow-up studies have tested the effectiveness of variations in the experimental setting. A first group of studies assessed the effectiveness of making students more alert to consider aspects of reality and to legitimize alternative forms of answer produce. For instance, Yoshida, Verschaffel and De Corte (1997) gave half of the pupils an explicit warning at the top of their test sheet (a translation of Verschaffel et al.’s (1994) test) that some of the problems in the test were problematic, and invited them explicitly to write down and explain these unclarities or complexities. This manipulation did not result in a significant increase in the number of realistic reactions to the P-items in the test. In other studies too, this kind of manipulation provided, at best, only very weak effects (see Verschaffel et al., 2000). In a second set of studies, one or more categories of P-items were presented in a more authentic, performance-based setting. For instance, DeFranco and Curcio (1997) confronted sixth-graders with a version of the buses item in the context of a typical paper-and-pencil math test and, afterwards, asked them to make a telephone call to order minivans to take sixth-graders to a class party. The more authentic setting elicited a much greater percentage of appropriate responses than the restrictive school setting. In contrast to the studies about the effect of alerting pupils mentioned earlier, increasing the authenticity of the experimental setting, as done in the study of DeFranco and Curcio (1997) but also in other related studies (see Verschaffel et al., 2000), yielded much greater improvements in students’ inclination to include the real-world knowledge they were so reluctant to activate and use under the previous, more restricted, testing conditions.
Besides deriving how students think about word problems from their responses to word problems in a paper-and-pencil test, it is, of course, possible to ask them directly.

Interviews carried out by Caldwell (1995) and Hidalgo (1997) suggest that, while unfamiliarity with the contexts involved in the problems and lack of appropriate heuristic and metacognitive skills may provide contributory explanations, (mis)beliefs about school arithmetic word problems constitute the major reason why so many students solve the P-items in a non-realistic way. For instance, a 10-year-old interviewed by Caldwell (1995, p. 39) commented as follows in response to the interviewer's question as to why she had answered a P-item in a non-realistic way: "I know all these things, but I would never think to include them in a math problem. Math isn't about things like that. It's about getting sums right and you don't need to know outside things to get sums right".

In a recent pilot study by Inoue (2001), upper elementary school children failed to give realistic answers to problems similar to the P-items from Verschaffel et al.'s (1994) test, but in the later clinical interview these answers were found not to be so unrealistic if they were judged based on the children's idiosyncratic interpretations of the problem situation. For instance, a student who had ignored the fatigue factor in solving a problem about finding how long it takes to finish a data-entry job based on the given rate (a problem very similar to the running item mentioned above), said that she ignored that fatigue factor since the calculational answer gives us the baseline information to judge how long it takes "theoretically". Her point was that such information is often useful for managing people calculating salary etc. in real life practices. Almost half of non-realistic answers given during the paper-and-pencil test were found to be of such type. This kind of "sensible unrealistic answers" (Inoue, 2001, p. 31) reminds also of Selter's (1994) findings with the infamous how-old-is-the-captain problem, wherein some students came up with highly ingenious explanations for their answers. For example, having responded to "There are 20 sheep and 5 goats on a boat. How old is the captain?" with the answer 25, one child suggested that may-be the captain's parents gave him an animal on each birthday so he would always know how old he is. Unfortunately, it is extremely difficult to distinguish solutions based on idiosyncratic interpretations that took place during problem solving from post-hoc rationalizations in defense of that response.

LOOKING FOR AN EXPLANATION: GOING BEYOND THE COGNITIVE

The results from the above-mentioned studies suggest that it is not a cognitive deficit as such that causes students' general and strong abstention from sense-making when doing arithmetic word problems in a typical school setting, but rather that they are acting in accordance with the "rules of the game" of the interactive ritual in which they are involved, or, as others would call it, in accordance with the "didactical
Several authors (e.g. De Corte & Verschaffel, 1985; Gerofsky, 1996; Kilpatrick, 1985; Lave, 1992; Reusser & Stebler, 1997) have carried out analyses of the hidden rules that seem to be used (implicitly, tacitly) by elementary school pupils (and by their teachers!) to make the “game of word problems” function efficiently, and have come up with rules such as the following:

- Any problem presented by the teacher or in a textbook is solvable and makes sense.
- There is a single, correct, and precise numerical answer.
- This single answer must be obtained by performing one or more mathematical operations with the numbers embedded in the text.
- The task can be achieved by applying familiar mathematical procedures.
- The text contains all the information needed and no extraneous information may be sought.
- Violations of your knowledge about the everyday world should be ignored.

De Corte and Verschaffel (1985) introduced the term “word problem schema” to refer to the system of beliefs about word problems shared by students and teachers, involving the perceived intent of word problems, interpretation of stereotyped semantic structure, and a complex network of implicit rules and expectations that govern playing of the “word problem game”.

The above interpretation of students’ non-realistic responses to word problems like the how-old-is-the-captain problem or the P-items from the test of Greer (1993) and Verschaffel et al. (1994), is in line with Schoenfeld’s (1991, p. 340) suggestion that the children who produced such bizarre responses were not irrational but were engaged in sense-making of a different kind: “Taking the stance of the Western Rationalist in mathematics, I characterized student behavior... as a violation of sense-making. As I have admonished, however, such behavior is sense making of the deepest kind. In the context of schooling, such behavior represents the construction of a set of behaviors that result in praise for good performance, minimal conflict, fitting in socially, etc. What could be more sensible than that? The problem, then, is that the same behavior that is sensible in one context (schooling as an institution) may violate the protocols of sense-making in another (the culture of mathematics and mathematicians)”. At a more general level, these children’s seemingly meaningless behavior can also be interpreted in terms of Vinner’s (1997, p. 97) particularly rich and relevant notion of “pseudo-analytical thought processes” in mathematics learning, wherein the person is looking for a satisfactory reaction to a certain
stimulus and the thought process is guided by uncontrolled associations and superficial similarities, without any serious cognitive involvement.

THE CLASSROOM CULTURE AS EXPLANATORY FACTOR

This brings us to the question: How do these superficial strategies for and beliefs about the solution of school arithmetic word problem develop? As with most other “pseudo-analytical thought processes” (Vinner, 1997), the development of students’ tactics for and conceptions about word problem solving is assumed to occur implicitly, gradually, and tacitly through being immersed in the culture of the mathematics classroom in which they engage. Putting it another way, students’ strategies and beliefs develop from their perceptions and interpretations of the didactical contract (Brousseau, 1997) or the socio-mathematical norms (Yackel & Cobb, 1996) that determine(s) (explicitly to some extent, but mainly implicitly) how to behave in a mathematics class, how to think, how to communicate with the teacher, and so on. More specifically, this enculturation seems to be mainly caused by two aspects of current instructional practice, namely (1) the nature of the problems given and (2) the way in which these problems are conceived and treated by teachers.

Let’s first have a look at the first of these two explanatory factors. In an attempt to summarize the characteristics of traditional word problems that appear in classrooms and textbooks and which lie at the basis of students’ beliefs about and strategies for solving word problems as discussed above, Reusser and Stebler (1997, p. 323) wrote: “Only a few problems that are employed in classrooms and textbooks invite or challenge students to activate and use their everyday knowledge and experience. Most word problems used in mathematics instruction are phrased as semantically impoverished, verbal vignettes. Students not only know from their school mathematical experience that all problems are undoubtedly solvable, but also that everything numerical included in a problem is relevant to its solution, and everything that is relevant is included in the problem text. Following this authoring script, many problem statements degenerate to badly disguised equations.” If the vast majority of the textbook and test problems have these characteristics, it should not be a surprise that many students develop gradually but inevitably strategies for and beliefs about word problem solving that are characterized by a lack of sense-making.

A second plausible explanatory factor for the development of the observed student beliefs about and tactics for word problem solving is the way in which these problems are conceived and actually treated by teachers in the mathematics lessons. A study that sheds some light on this second factor is an investigation by Verschaffel, De Corte and Borghart (1997), wherein (future) elementary school teachers were asked, first, to solve a set of P-items themselves, and, second, to evaluate four alternative answers from (imaginary) pupils to the same set of P-items as “absolutely correct answer, “partly correct and partly incorrect answer”, or
"completely incorrect answer". For each P-item, the four response alternatives always included the typical non-realistic answer and the most reasonable realistic answer. Only half of the student-teachers' own answers to the P-items in test 1 were scored as realistic, and, with respect to test 2, their evaluation of the non-realistic pupil answers to the P-items was considerably more positive than for the realistic answers based on realistic considerations!

In sum, the available evidence suggests that students' beliefs about and tactics for word problem solving do not develop as a result of direct teaching, but rather emerge from the nature of the textbook and test problems with which they are confronted and from the permanent interaction between teacher and students around these problems.

TAKING THE MODELING PERSPECTIVE SERIOUSLY

Based on the results of the above-mentioned theoretical and empirical work, several authors have put forward suggestions for improving the quality of the applied part of the mathematics education curriculum.

A minimal and rather easily achievable goal is to improve the quality of word problems as applications in numerous ways that have been suggested over many years such as:

- Break up the expectation that any word problem can be solved by adding, subtracting, multiplying or dividing, or by a simple combination thereof.
- Eliminate the flaws in textbooks that allow superficial solution strategies to be undeservedly successful.
- Vary problems so that it cannot be assumed that all the data included in the problem, and only those data, are required for solution.
- Weed out word problems in which the numbers do not correspond to real life.
- Accept forms of answer other than exact numerical answers.

However, on top of such a list of recommendations, which together constitute a minimal response to the identified flaws in traditional teaching of word problems, we propose in our book (Verschaffel et al., 2000) a more radical solution, namely to reconceptualize word problems as genuine exercises in mathematical modeling. In contrast to the truncated caricature of the multiphased and multidimensional model of mathematical modeling that underlies many traditional lessons in applied problem solving, at the basis of our approach is a much more elaborated version of the model of solving application problems, wherein all phases of the genuine modeling process are equally important and wherein

- knowledge about the phenomenon is not suppressed but considered as a valuable component in the initial stage of the solution process,
the nature and the outcome of the mathematization act is influenced by the goals implicit in the situation, imposed by the teacher, or negotiated,

the solver can make use of a rich variety of resources (including software modeling tools) in the stages of mathematical modeling and analysis,

the interpretation and evaluation phase involve comparison and discussion of alternative models, and

the task requirements may involve a communication phase that goes far beyond the bald reporting of the result of the calculation.

Starting from the above criticisms on the traditional practice surrounding word problems in schools and from the modeling perspective described above, researchers have set up design studies wherein they developed, implemented and evaluated experimental programs aimed at the enhancement of students' mathematical modeling and problems solving along the lines mentioned above. To mention just a few: several developmental research projects from the Freudenthal Institute in The Netherlands (see e.g., Gravemeijer, 1997), the Jasper studies of the Cognition and Technology Group at Vanderbilt (1997), wherein mathematical problem solving is anchored in realistic contexts using new information technologies, Lehrer and Schauble’s (in press) experimental curriculum for mathematics and science teaching in young children built upon the modeling approach, and our own study about the design and evaluation of a learning environment for mathematical modeling and problem solving in upper elementary school children (Verschaffel, De Corte, Lasure, Van Vaerenbergh, Bogaerts & Ratinckx, 1999).

Characteristics common to these experimental programs include:

- The use of more realistic and challenging tasks than traditional textbook problems, which do involve some, if not most, of the complexities of real modeling tasks (such as the necessity to formulate the problem, to seek and apply aspects of the real context to proceed, to select tools to be used, to discuss alternative hypotheses and rival models, to decide upon the level of precision, to interpret and evaluate the outcome, etc.).

- A variety of teaching methods and learner activities, including expert modeling of the strategic aspects of the modeling process, small-group work, and whole-class discussions; typically, the focus is not on presenting and rehearsing established mathematical models, but rather on demonstrating, experiencing, articulating, and discussing what modeling is all about (see also Mason, 2001).

- The creation of a classroom climate that is conducive to the development of the elaborated view of mathematical modeling and of the accompanying beliefs.

In most of these design experiments positive outcomes have been obtained in terms of performance, underlying processes, and motivational and affective aspects of
learning. After reviewing the available research evidence, Niss (2001, p. 8) concludes that “application and modeling capability can be learnt, and according to the above-mentioned findings has to be learnt, but at a cost, in terms of effort, complexity of task, time consumption, and reduction of syllabus in the traditional sense”.

To some extent, these characteristics of the modeling approach are beginning to be implemented in mathematical frameworks, and tests in many countries. However, according to Niss (2001), it is still the case, in general international terms, that genuine and extensive applications and modeling perspectives and activities continue to be scarce in the everyday practice of mathematical education.

PROMISES AND PITFALLS OF THE MODELING PERSPECTIVE

When putting the modeling perspective forward for serious consideration, it must be recognized that it is not without major difficulties and challenges.

A first critical issue is: how far can and should we go in our efforts to make the modeling tasks realistic? How much reference to the complexity of reality is possible and appropriate in the classroom context? I agree with Gravemeijer (1997) that there is, and always will be, an insurmountable difference between solving problems in the out-of-school reality and solving word problems in a mathematics lesson or test. But if we accept that there will always remain some gap between mathematical modeling in a school and an out-of-school context, what is the appropriate level of “reference to the real” that should be established in the mathematics classroom? And is encouraging students to use their real-world knowledge not opening a Pandora’s box? I don’t think that there is one appropriate level of realism nor that the non-existence of such a clearcut level forms an impassable didactical problem. It only suggests that the question about the model’s degree of abstraction and precision may be regarded, not as a difficulty, but as a part of what we want students to learn to make deliberate judgments about, as one crucial aspect of a disposition towards realistic mathematical modeling. Such difficulties with respect to the level of realism and precision are most serious, I believe, when word problems are presented in a context that precludes discussion, such as a student working alone on a textbook problem, or sitting a written test. Within the context of discussion and collaboration, the degree of precision, the reasonableness of plausible assumptions, and so on, may be negotiated (Verschaffel et al., 2000).

Second: does the modeling perspective exclude traditional word problems? I would contend that it does not rule out mathematical teaching and learning activities around classical word problems wherein students learn to apply powerful schemes for identifying, understanding, and solving certain categories of problems. For example, the schemes of addition, multiplication, direct proportionality, etc. are very powerful, and applicable to a wide variety of situations. So, it is important that students (also) learn to master these schemes and to apply them in various contexts during their
mathematics lessons. However, the problem arises when such a schema is automatically triggered by superfluous cues, i.e., when students are given no training in discriminating between those cases where it is appropriate and those in which it is inappropriate or, in the extreme sense, nonsensical (Hatano, 1997). So, there should be room for different kinds of word problems with distinct instructional goals. At one time they may be used mainly to create strong links between mathematical operations and prototypically “clean” model situations (with little room for timeless discussions about the situational complexities that might jeopardize this link), whereas at other times they may be used primarily as exercises in relating real-world situations to mathematical models and in reflecting upon that complex relationship between reality and mathematics. Both roles are important in a balanced math curriculum, but they have quite different characteristics and priorities, which must be clear to the student as well as the teacher (Burkhardt, 1994). In this respect, Galbraith and Stillman (2001, p. 301) propose an interesting problem classification, consisting of four categories, with essential differences in terms of the kind of thinking processes they elicit in students, as well as in terms of their underlying assumptions about word problems and their relation to solving problems in the real world:

- **injudicious problems**, wherein realistic constraints are seriously violated;
- **context-separable problems**, wherein the context plays no real role in the solution and can be stripped away to expose a purely mathematical question;
- **standard application problems**, where the necessary mathematics is context-related and the situation is realistic, but where the procedure is (still) rather standard;
- **genuine modeling problems**, in which no mathematics as such appears in the problem statement, and where the demarcation and formulation of the problem, in mathematical terms, must be (at least partly) supplied by the modeler.

Whereas, I would agree with these authors, injudicious problems are to be avoided, because they strongly reinforce the belief that mathematics has nothing to do with the real world (expect if they are purposely used in the context of making students, or in-service or pre-service teachers, aware of this problematic relationship!), context-separable and standard application problems do have a meaningful role in mathematics education. However, when using them, one should be cautious for the risk that students will tend to overgeneralize the validity and relevance of familiar modeling notions (e.g. addition, multiplication, proportionality) and transfer these to settings to which they are neither relevant nor valid (Niss, 1991), as argued by Hatano (1997) and as amply evidenced, for instance, in a study of De Bock, Verschaffel and Janssens, (1998) for proportionality. Moreover, we should not labor with the latter two types of problems under the illusion that such problems will foster the ability to apply mathematics to solve realistic problems. Only in the fourth type of Galbraith and Stillman’s (2001) categorization do we find the need to invoke...
assumptions integrating mathematical development with the real context as a key to progress.

A final important issue I want to address is whether teaching and learning mathematical applications according to the modeling perspective is important, and feasible for, all students. Over the past few years several authors, such as Keitel (1989) and Mukhopadhyay and Greer (2001), have made strong pleas for engaging all students in the modeling perspective, both for the empowerment of the individual and for the betterment of society. For Mukhopadhyay and Greer (2001), this “political aspect” can be considered as a third perspective from which mathematics education in general, and teaching and learning mathematical modeling in particular, should be analyzed critically, besides the (purely) cognitive and the social/cultural perspectives. In relation to this political aspect, the most important reason for introducing the modeling perspective to all students is to help as many people as possible “to become critical thinkers who can use mathematics as a tool for analyzing social and political issues, and can reflect on that tool use, including its limitations” (Mukhopadhyay & Greer, 2001, p. 310). Evidently, once mathematics educators start applying this modeling perspective on a larger scale and allow students to bring in their personal experience when trying to make sense of all kinds of technical, social and cultural issues and phenomena, they will be confronted quickly and inevitably with the diversity of these experiences in terms of gender, social class, and ethnic diversity (see also, Boaler, 1994; Cooper & Dunne, 1998; Tate, 1994). I endorse Mukhopadhyay and Greer’s (2001) claim that engaging students in such modeling activities, with careful attention to the relevance of the problem contexts and all the diversity in views and approaches that they elicit, is the best way to prevent students from becoming alienated by mathematics and its authority, and to help them using mathematics as a powerful personal tool for the analysis of issues important in their personal lives and in society. Given the multiphased, multidimensional and non-straightforward nature of the modeling process, it is often viewed as an activity that is only within the reach of older and/or more capable students. The evidence from several recent design experiments reviewed in this paper suggests that it is not only important, but also feasible, to start applying the modeling perspective successfully in mathematics education of all students already from a (very) young age on and with a diversity of learners.

INTRODUCTION – JOÃO FILIPE MATOS

When looking closely at everyday activity it is difficult to avoid the conclusion that learning is ubiquitous in ongoing activity. Nevertheless, societies came to forms of pedagogical practice that conform with the idea that social arrangements can be made up to provoke specific learning effects in some of the participants in a certain practice. Schooling is perhaps one of the most apparent examples of how societies create and maintain stable social practices. As soon as one enrols in school, at any level, one is positioned and labelled as a learner. This is not surprising but it strikes me the fact that as soon as one is positioned as a teacher, at any level, one tends to suspend or forget our condition of learners.

This paper is the reflection of the preparation of the PME26 Panel aiming to discuss the issue of ‘learning from learners’. When addressing the topic of Learning from Learners, one of the key issues is what it implies to be a learner. Sinha (1999) frames this issue asking how the developing human is being constructed and positioned in particular and specific kinds of practices, in such a way that they become a learner of the kind required by the culture within which teaching-learning activities occur. This question is asked implicitly in most studies addressing mathematics learning. But within this paper it is formulated in order to reflect on the way we as teachers and/or researchers learn from learners—pupils, teachers, researchers.

The panellists invited to address this topic—Joop van Dormolen, Susie Groves and Rosetta Zan—accepted the challenge of producing a short narrative and a brief analysis of an episode that each one found relevant for their own learning as a teacher and/or as a researcher. They were also asked to comment on each other episode and combine their own analysis with the others’. The result was a joint paper putting together the reflection of the three.

From my point of view, the very idea of conceptualizing the notion of ‘learning from learners’ contains in itself a rethinking of learning in terms of framing it by context,
communication and social practice abandoning traditional views which focus upon *isolated and individual subject* in confrontation with a cognitive or learning task. This implies, for example, the abandonment of the universalistic idea that learners, in all essentials, are the same in all times and places. These notions are reflected in different ways in the several parts of the paper.

**EPISODE I: HOW KARIN DISTURBED HER TEACHER’S LINE OF REASONING - JOOP VAN DORMOLEN**

**The episode**

The episode that I want to describe happened during a mathematics lesson in grade 7 that I observed. I was sitting together with a student teacher, let us call him John, in the back of the class, while the lesson was given by John’s mentor, let us call him Wilbur. The episode took place in the end of September, four or five weeks after the start of the school year. Wilbur, the teacher, had a 15 to 20 year experience with teaching grades 7 to 12. Students liked him and trusted him as a teacher.

This was the first day that John had started his teaching practice period. It was decided that he should not right away start giving lessons, but first observe lessons given with his mentor. I was there as the John’s university teacher. Wilbur and I had agreed that I would be in his class the first time that John was there and that after the lesson the three of us would sit together to analyze the lesson. This analysis in itself was meant to be a learning experience for John.

At the time of this story I had 20 years experience in the same kind of school as Wilbur and for about 6 years had been a teacher educator for secondary school mathematics at the university.

**The students**

The school was a typical Dutch school in which students would follow either a six years course that prepared for university studies or a five years course that prepared for higher non-university studies. Grade 7 is the first class of such schools. Decisions of which of the two courses the students would follow were not to be made before the end of the second year.

**The subject matter**

The lesson was about basic algebra rules: the commutative rules $a + b = b + a$ and $a \times b = b \times a$, and the distributive rule $a \times (b + c) = a \times b + a \times c$. During the weeks before the lesson the students had learned the concept of a variable and had had exercises with substitutions of numbers for variables and solving simple first degree equations with one variable.
The event

Wilbur had explained the fact that it does not matter whether you add 3 to 2 or 2 to 3, you end up with the same result, and this not only for the numbers 2 and 3, but for any two numbers. We can express this with \( a + b = b + a \) in which \( a \) and \( b \) stand for any number one can think of. This is not only for additions. Also in multiplication we have the same kind of rule: \( 3 \times 2 \) means \( 2 + 2 + 2 \) and \( 2 \times 3 \) means \( 3 + 3 \). These are two completely different multiplications, but their product is the same. So for any pair of numbers, hence we can say \( a \times b = b \times a \).

Most of the time Wilbur was speaking and explaining with occasional questions to students. The class was attentive and seemed to be willing to learn.

Then Wilbur started with examples of the distributive rule. He had been working on this for some time, say 8 to 10 minutes, when one of the students, let us call her Karin, put up her hand. Wilbur, thinking that she wanted to comment on what he was discussing, asked her what she wanted to say.

She said: “Two times three is six because two times three is one plus one plus one … (here a slight pause) plus one plus one plus one. And three times two is one plus one … (slight pause) plus one plus one … (slight pause) plus one plus one. In both cases you have the same number of one’s.”. While she spoke she moved her finger as if writing down in the air what she was saying.

In a friendly way Wilbur dismissed Karin’s remark with something like: “Yes, you are right, but we saw that already, we are now doing something else.” and went on with talking about the distributive rule.

What did I learn from Karin’s remark?

Sitting in the back of the classroom I had not Wilbur’s preoccupation of having to go on with the lesson, I could reflect on what Karin had said and I decided to make that one of the subject of the discussion with John and Wilbur after class. In that discussion Wilbur said he felt a little irritated, because Karin had said something that had nothing to do with what he was talking about at the time. He also told John and me that Karin was in his opinion one of the weaker students and therefore assumed that she just had been a little slow in following his reasoning. After some discussion he said he was sorry not to have realized that in fact Karin showed a deeper understanding of the commutative rule than just a formal acceptance.

Karin showed that she was really amazed. For many years as a teacher and in my discussions with my student teachers I felt that it is almost impossible to teach young children the commutative and the distributive rule as important mathematical properties. For most of them they are natural phenomena and I feel that making a big fuss about it is pretentious and only shows that mathematics is about making simple things difficult. Only when we are more sophisticated in understanding what mathematics is about, we learn that formally mathematics has to be built up from scratch and to do so we have to formulate axioms. These axioms are not just
concoctions that somebody dreams up. They are based on practical experiences. In
other words: the commutative and the distributive rules are not, as Wilbur and I and
many other teachers had been trying to teach for a long time, explanations of
phenomena, but indeed formalizations of such phenomena. I think that this is just
what Karin felt: Karin's amazement was not that you can explain the phenomenon
$2 \times 3 = 3 \times 2$ with help of the rule, but that you can explain the rule with help of the
phenomenon.

I am pretty sure that Karin did not realize this, but for me, as a teacher I learned from
it that it pays to present situations to students in which they can get amazed as a
starting point for learning to generalize. If Wilbur had realized this during the lesson
he could have used Karin's remark in this way.

The same language, different meanings
There are several approached to reflect on this episode. I have chosen one that I found
in an article (Klaassen & Lijnse, 1996) of two ex-colleagues of mine. They describe an
episode in which a teacher did not succeed to convince a student. They give five
different viewpoints from which one can analyze the episode. First, the view that an
error was made and thus the student has to learn what was wrong and to repair it.
Second, the view that there is a misconception and the teacher should work on that to
help the student to get the correct conception. Third, the view that the idea of
misconception is not an acceptable way of analyzing. Better is to recognize student's
previous learning and talk about pre-conception. It is the teacher's job to find ways to
confront that pre-conception and the 'correct' conception so that the student
can change. Fourth, the view that the student and the teacher are living in a different
world. "In each world, different concepts are used, being part of different kinds of
knowledge, with different characteristics and problem-solving procedures" (ibid. p.
121).
The fifth view comes from the authors themselves. They argue that teacher and
student do not live in different worlds. In fact they agree with each other, at least as
one looks at the language they use from the outside. However they use the same
language in a different way, giving the words a different meaning.

Interestingly in our case there was no mistake, so the first three viewpoints are not
relevant here. We even cannot think here in terms of different worlds. The last view,
however is enlightening.

We have to be clear that in our case the issue was not something about the
commutative rule. In fact this rule was not relevant at all; it was just a means to get to
the more general concept that certain kinds of rules are formalizations of certain
phenomena. Following the line of Klaassen and Lijnse we can say that the language
spoken by Karin and Wilbur was the same: Both talked about the fact that $2 \times 3$ is
equal to $3 \times 2$, that this was so for every pair of numbers which could be
expressed by $a \times b = b \times a$. They agreed about that, but each of them gave a different
meaning to it. Wilbur did not recognize that. He thought that Karin was just a bit slow
in taking up his ideas and therefore in a friendly way dismissed her remark as not relevant any more.

Reflecting on how I learned and its implications

From Karin I learned to distinguish between formalization of phenomena and explanation or a rule. In both cases one can use the same examples but in different contexts: in the context of formalization the examples are paradigms, in the context of explanation they are instances (Freudenthal 1978, pp. 201; Van Dormolen 1986).

Reflecting on my learning experience I found the same-language-different-meaning approach highly illuminating and useful in analyzing other episodes in which there is some sort of teacher-student conflict.

What I learned is interesting and illuminating. I used that later many times in my own classes of pre- and in-service teachers. More general is, however, the question of how I learned. Why was it that I could learn from Karin, while Wilbur and John did recognize her intentions only after I brought the matter up in our after-lesson discussion?

One essential element is (as ever so often) the role of the context. For me the situation was open, I had no restraints for attaining goals, like Wilbur. I was not on edge like John who had to cope with many new experiences. I had no responsibility like Wilbur to keep as many students as possible attentive and motivated. I could start to think about Karen’s remarks without paying attention what was happening after that. Wilbur’s context generated for him a situation that made him, experienced teacher as he was, react automatically. His experience with Karen’s not so bright performances in the past made him, without realizing it - assume that her remarks would again be on the poor side. In the after-lesson discussion he realized and deplored this automatic-pilot-attitude and he had every intention to be more attentive in the future to unexpected interventions of his students.

There is more to say about context. It is noteworthy that in the descriptions of all three episodes, Groves, Zan and I apparently wanted to tell much more than – on first sight – seems necessary to describe the case. After writing down the first draft of my episode, I wondered if I had written too much. Could I not delete, for example, all what I wrote about John? On first sight the presence of John seemed to be irrelevant. Yet I could not bring myself to take him out of the story. Realizing this I found that, intent as I was on finding subjects to discuss in the after-lesson talk, I might not have noticed the importance of Karin’s intervention without John’s presence. I see similar situations in the episodes of Groves and Zan. Apparently the total context was crucial for the three of us as an opportunity to learn.

Last remark: All this came from reflection (Van Dormolen 1998, 2000), both in the classroom, in the after-lesson discussion and in the composition of these notes for the panel discussion. Crucial as elements such as context, attentiveness, open mindedness, teaching experience etc. are for learning, without conscious reflection I would not have learned at all.
Comments on Joop’s episode - Rosetta Zan

The episode described by Joop can be read and generalized both by centering on the various actors present, and also by viewing it from a different perspective: one possibility, suggested by Joop, is to focus on the epistemological positions (either conscious or unconscious) of the teacher and the researcher. My reading of the episode comes from a different perspective, which is also the one that comes most naturally to me given my area of research: I will focus my attention on the complexity linked to the presence of two different subjects, pupil and teacher, and to their communication.

I tried to ‘put myself in Karin’s shoes’, and I’ll now describe her possible thinking process using a virtual monologue (Leron & Hazzan, 1997): this method, which originated from a researcher’s attempt to better see the world with the student’s eyes, provides us with an instrument for communicating our own way of seeing the pupil’s point of view to others. When Wilbur starts to introduce the distributive rule, I am still following the previous topic about the commutative rule:

It’s not like before, when maths was simply about doing calculations. No,... now we’re not just working with numbers to get a result ... Wilbur is teaching us something important, something ‘grown up’: we can describe things that seem simple in a more important way, it’s not enough any more just to do a calculation. Something that seemed so natural... that 2x3 and 3x2 give the same result ... Wilbur explained to us that this is a property that has a name! It’s important to be precise like this in mathematics: as we go on, we’ve got to learn to be even more precise! ...But... if we really want to be exact (and that’s what we’re learning to do, isn’t it?,) ... who’s telling me that 2+2+2 and 3+3 give the same number? Without calculating as we did before! Let’s see... If we write 2+2+2 as 1+1+1+1+1+1+1+1, yes, that’s it! and we write 3+3 as 1+1+1+1+1+1+1+1... there we are! Now, things are more precise!! I’m going to tell Wilbur... (and she puts up her hand)

Karin’s effort reminds me of many mathematics students that are learning to prove some results by starting from the Peano axioms and the definitions of the + and the x operations. It is the effort to distinguish between what can be assumed as true and what has to be proved when we are moving in an environment where everything already seems familiar. Even if this effort is not always successful, and the student’s solving processes highlight his confusion, it still testifies that the student is starting to approach mathematics in a new way: a more sophisticated way, linked to an evolving vision of the discipline, moving towards more mature epistemological forms.

Karin’s intervention was a missed opportunity for Wilbur, but Wilbur had his own project in mind: ‘to explain’ the commutative and distributive rules. This project is the result of a decision made before he started his interaction with the pupils. There are many of similar decisions to be taken: how to present the topic, what examples to make, how much time to dedicate to the various steps.... As time goes on, such decisions get easier and easier: after all, Wilbur has been teaching for many years, and this is a well defined task for him! But once he starts interacting with the class, Wilbur
finds himself having to manage situations that he hadn’t completely planned for when preparing the project. He has to deal with the pupils’ questions, and he has just a few seconds to decide how and whether to answer. Since the teacher’s decisions are not just influenced by his knowledge, but also by his beliefs and emotions, this influence is particularly strong when there is little time available for deciding what to do. While Wilbur is explaining the distributive rule, Karin intervenes. Wilbur, who is so focused on his attempt to make the students understand distribution, is ready to answer questions or deal with objections on that property. But Karin’s intervention moves away from the direction he wants to follow and puts him in difficulty: ‘Yes, you are right, but we saw that already.’

It becomes natural to ask ourselves: what idea was Karin constructing? And how could her teacher have discovered it? What consequences will Wilbur’s reaction have had on these new ideas? What consequences will this have had on Karin’s desire to understand what was new in this activity? Will Karin try again to ‘make sense’ of mathematics? Or will she simply conform to the demands and pace of Wilbur, to the demands and pace of the lesson, to the demands and pace of others?

But this is obviously a general problem: how can we understand what sense of mathematics the pupils are making for themselves? How many Karins do we distance from mathematics because we do not know how to listen to them? What consequences does a rigid and limited schedule have on the pupils? What idea of mathematics will be constructed by pupils who haven’t had an answer to their questions or haven’t been able to ask their questions? And what will be the resulting image that they construct of themselves?

What about Wilbur? Again, this is a general problem: how can the teacher learn to make quick decisions? How can he recognise the consequences that these decisions have had? How can he correct his mistakes if required? And how can he learn to respect the time needed by the students, and to respect their thinking processes?

**COMMENTS ON JOOP’S EPISODE – SUSIE GROVES**

In one sense it is difficult to go beyond Joop’s own analysis of this episode — in particular the discussion of the difference between *explanations and formalisations* of phenomena. However, for me, the most striking comment in Joop’s description is where he says that he learned that “it pays to present situations to students in which they can get amazed as a starting point to generalise”.

There are clear analogies with this view and the notion of creating cognitive conflict as a teaching strategy in science education. Vygotsky (1962) characterised children’s *scientific conceptions* as developing downwards, while their *spontaneous conceptions* develop upwards, stressing the importance of the interaction between these, with spontaneous concepts enriching scientific concepts with meaning and scientific concepts offering generality to the spontaneous concepts. This is sometimes described as the vine metaphor. Pines and West (1985) adopted the vine metaphor as a
framework, distinguishing different prototypes of learning situations by the extent to which the “upward and downward growing vines” clash or are congruent. From a constructivist viewpoint, they considered meaningful learning to take place when the two vines become intertwined, with the new scientific knowledge serving to make sense of the learner’s world of experience. In many ways this appears to describe what was happening when Karen “intertwined” the formal statement of the commutative property with her observation that two times three and three times two “have the same number of one’s”.

While Wilbur, the teacher in Joop’s episode, failed to capitalise on this opportunity — or even recognise it at the time — this is not surprising as he had a whole class to contend with and had already moved on to look at the distributive property. Moreover, if we are to take on board the notion of using students’ ‘amazement’ as starting points for generalising, we not only need to find appropriate situations with the potential to amaze students, we need to acknowledge the idiosyncratic nature of such happenings. For example, who could have predicted Karen’s reaction to a standard treatment of the commutative property, which presumably she had met many times before?

There are also implications for the organisation of teaching situations if teachers like Wilbur are to be able to capitalise on spontaneous situations such as the one described in this episode. In our Calculators in Primary Mathematics project — briefly described elsewhere in this paper — using the calculator, often in free play situations, prompted young children to be amazed. For example, one four year-old boy is captured on video spontaneously using his calculator to count by ones from a million. When asked whether he could count to one million one hundred he initially says he thinks there is no such number. However as he nears it he begins to have doubts and finally when he gets to 1,000,002 he is truly amazed to see he has “gone right past it”. The fact that the rest of the children in the class were absorbed in their own calculator explorations allowed the teacher to spend four uninterrupted minutes talking to this boy and his partner, during which time she was able to “learn” something about the boy’s understanding of very large numbers, spontaneously prompt him to try a potentially amazing activity, and engage him in discussion related to the outcome. This would not be easy to parallel in a secondary classroom.

Perhaps the real lesson from Joop’s episode however is that we are unlikely to learn from learners if we do not listen to them. A lot of time is spent in teacher education in teaching teachers to “teach”. Perhaps a lot more should be spent on teaching them to listen and learn from their students. In mathematics classes, this is particularly critical in terms of the type of communications we engage in with our students and the social and “socio-mathematical” norms (Yackel & Cobb, 1996) which operate.
EPISODE II: MARCO AND ANNA - EACH FOLLOWING THEIR OWN PATH – ROSETTA ZAN

The episode

The event that I’m about to describe happened during a meeting with teachers. Another University had invited me to give a lecture on the difficulties in mathematics: the audience was mostly teachers from higher education. In order to get them involved, I decided to give some examples that would be within their experience and ask them to perform an interpretative analysis. My first case was the incorrect use of brackets, a very common area of difficulty. I described the behaviour of a student, Marco, who had to multiply x+1 by x+2. He wrote: \( x + 1 \cdot (x+2) \), but he went on:

\[
x + 1 \cdot (x+2) = x^2 + 2x + x + 2 = x^2 + 3x + 2
\]

My intentions were: 1) To ask for their analysis of the case, start a discussion, etc. 2) If no other opinions had emerged, I would suggest a possible interpretation of this systematic error: maybe Marco interprets the presence of brackets as a sign that indicates the order of precedence for performing operations, but as a personal shorthand for his own use. He doesn’t therefore see them as signs to be used to communicate with others, with fixed and shared rules, but as notes to be ignored once the exercise has been completed; 3) to underline that, following this interpretation, Marco’s behaviour is completely consistent. Marco had possibly put brackets where he sensed they were needed to highlight a certain order, but didn’t use them when he felt there was no need because the order to be followed was easily apparent. In this interpretation, the fact that he performed the operations in the “correct” order shows that his use of brackets was correct.

The example caused an immediate reaction with all the teachers present. There was a chorus of: ‘It’s true! they do that!’ ‘Mine do too…’ When everyone had calmed down, one teacher raised her hand and asked to make a point: ‘It’s true: they often do this. But I always take off two points: one because they made a mistake in not using the brackets, there … [and indicates \( x + 1 \cdot (x+2) \)]; and the other point because they make a mistake in multiplying, here… [and she indicates the equal sign in the expression \( x + 1 \cdot (x+2) = x^2 + 2x + x + 2 \)]. The other teachers reacted noisily, many burst out laughing. The teacher who had spoken (let’s call her Anna) realised she was being derided by her colleagues and she repeated heatedly: ‘two mistakes: two points off. I explain to them that they have made two mistakes.’ Her colleagues looked at me before reacting, trying to understand what I was thinking. In order not to put Anna on the spot, I asked her without irony: ‘and in this way … do the students understand? Don’t they make any more mistakes using brackets?’ She replied with resignation, but still convinced: ‘No, they keep getting it wrong… but there are two mistakes.’

The incident finished there: I continued with my program.
What did I learn from Anna’s observations?

My first reaction to Anna’s intervention was disconcert and disappointment, even if I hid this behind my question. I had been talking about the constructivist model of learning and everyone (including Anna) had been following me with attention; I had talked about the importance of understanding what is behind a mistake if you are to overcome it, and everyone (including Anna) had agreed … and then that intervention! The other teachers were as shocked as I was: at least they seemed to have understood the message. Thinking back as I was on the train home that evening, even if my intervention had been useless to Anna, it had been of help to the others, so the balance of this exhausting day could be said to be positive. But even so, I couldn’t get over Anna’s intervention: remembering her expression, her conviction in defending her position, but also her dissatisfaction in recognising the uselessness of it! There was something important under all of this, something that I couldn’t grasp. But what?

When I thought back to my initial program in which I presented the case of Marco, what I wanted to do was to push the teachers towards ‘putting themselves in Marco’s shoes’, because in this way, they could begin to see the interpretative hypothesis I was making: to decide how to react, it is first necessary to ask yourself ‘Why has the student made this mistake?’ But after Anna’s observations, when I tried to put myself in the shoes of her Marco, I felt a total sense of estrangement: I had been corrected and penalised, though I hadn’t even made a mistake! My attention had moved from why Marco had made the mistake to the fact that it wasn’t possible for Marco to realise that he had made the mistake. But how could Marco modify his behaviour in a significant and definitive way, if he didn’t recognise he was wrong, if the consequences of his error didn’t lead to a failure? In that period the Pisa group was doing research about the evolution of attitude towards mathematics: we set an essay on mathematics (‘Me and mathematics: my relationship with maths up to now’) for students at all levels of school, and then we analysed the essays elaborated. It was a sentence of another Marco that came into my mind at this point: ‘…I constantly dedicated a lot of time, and I really wanted to succeed. But seeing that everything I did was wrong, I became resigned and came to the conclusion that maths and me weren’t meant for each other …’. Marco slowly distanced himself from a discipline that he couldn’t control: maybe because the things he did ‘well’ were corrected and penalised?

Anna and Marco: I couldn’t help but thinking of them ‘together’, as if there was just one Marco, the one with the brackets problem and who then went on to write the essay, and Anna his teacher. Together, but each one following their own path, and, in the end, both of them in difficulty, or rather -and Anna helped me understand this - their diversity was the reason why both of them were in difficulty: each had their own goals, their own criteria for evaluating whether they had been achieved, their own epistemology. But also Anna and I, in the end, had followed different paths: paths characterised by different goals, and different epistemologies. And in the end we didn’t manage to find each other either.
Analysis and comments

The sense of estrangement that we feel when we put ourselves in the position of a Marco whose teacher has just taken off two points highlights the possible rift that exists between the perception that the teacher and the student may have of the same situation. Such rift is particularly apparent in the case of Marco and Anna, not just because Marco’s result is correct, but also because the fact that the result is correct makes his personal use of brackets ‘correct’ (in the way we hypothesised before). But this episode was important to me because it forced me to focus my attention on the consequences that are usually generated when two different subjects, the teacher and the student, have to recognise an error or failure, a preliminary recognition that must occur before the recovery operation can start. This focus allowed me to reinterpret significant episodes that at first appeared separate, in a new single coherent perspective.

In the case of Anna and Marco, the rift is so large that Marco doesn’t recognise any of the errors that Anna identifies: in the end, Anna recognises incorrect solving processes, while Marco is probably convinced that he has given a correct answer with correct solving processes. But a similar rift can be observed in situations that at first seem very different to this case. For example, if the student sets himself the goal of finding the correct answer, and the error does not affect the outcome, the teacher’s perception of failure cannot be shared by the student. But if the student doesn’t realise his failure, or that that specific behaviour is causing the failure, how can he invest resources to change his behaviour? It is therefore not only important to ask ourselves why the student made a specific mistake before intervening, but also and in the first place, whether the student realises that his behaviour is at fault. But this is not the only point. The sense of estrangement that a student feels when he sees processes or products being corrected that he doesn’t recognise as being wrong can have extremely negative results in the long term. The student begins to feel he has lost control over his success / failure, and mathematics appears ever more as a discipline in which the only person who has any control is the teacher. The belief that mathematics is an uncontrollable discipline has very important and negative consequences. On the one hand, the student is constantly searching for what the teacher ‘wants’. On the other hand, negative emotional aspects appear such as anxiety, frustration, and even fear and panic, and in this way a fatalistic attitude takes over, with a consequential passive and resigned behaviour.

These considerations led me to change the perspective under which I approached the problem of learning difficulties in mathematics. The interpretation suggested by this episode allowed me to observe that some elements were common to other significant episodes that seemed to be completely separate problems up to then. It made me also reflect theoretically on the construction of a single coherent framework, which would provide instruments to observe and modify significant phenomena. A first partial and temporary result was the characterisation of difficulty, which also follows on from the comparison with other theoretical studies, and generates new problems and directions for research.

PME26 2002
Traditionally, the problem of recognising difficulties in mathematics relates to the recognition of errors. This doesn’t mean that the difficulties are identified with the errors: many researchers (see Borasi, 1996) underline the positive role of errors in the learning process. But even so, errors remain a strong indicator of difficulty. The reflections expressed above convinced me that a new explicit distinction must be made between errors and difficulty. The diagnosis of difficulty based on the recognition of error is apparently linked to objective elements (in fact the error is weighed and evaluated), thus risking to hide the intrinsic subjectivity of the observation/intervention process, caused by the presence of two different actors, the teacher and the student. Even if the teacher recognises the student’s error and intervenes, it is up to the student to modify his behaviour: but if the student is to significantly change his behaviour he first has to be convinced that a change has to be made, that the existing behaviour leads to failure. Talking about a failed process is different to talking about mistakes: it means making reference to a goal that has not been achieved. Therefore it is only by setting things up in terms of goals, rather than as ‘objective’ errors, that we can highlight the presence of two different subjects, student and teacher, and the complexity that derives from this. In the same way, we can consider managing this complexity only if we recognise explicitly that it exists.

All these considerations led me to conclude that it is better not to identify errors as indicators of difficulty: we should instead concentrate on failure, intended as not having reached the desired goal. The reference to goals takes us back to points underlined in some studies (Cobb, 1986): the problems that students face in the context of learning mathematics are ‘more social than mathematical’. We have to therefore consider the possibility that the goal set by the student is not necessarily ‘mathematical’: it can happen that when setting an exercise, the teacher sets a goal (e. g. find the area of a certain figure) which provokes a different goal in the student (e. g. give the right answer to the teacher). We should also consider that the points made here regarding the didactical value of errors suggest that only repeated failures and not a single one should be considered as a difficulty indicator. These observations bring me to the following temporary working definition of difficulty: the repeated failure in problems that the pupil encounters in the context of mathematics education. The effectiveness of this definition should be measured in practice, particularly in terms of its capacity to provide new instruments to detect and modify significant phenomena, opening up new directions for research.

LANGUAGE AND CONTEXT: COMMENTS ON ROSETTA’S EPISODE – JOOP VAN DORMOLEN

Anna and Marco

I would like to comment on the episode presented by Rosetta from the background of same-language-different-meaning approach that I wrote about in my comment on my own episode. Both used the same language, in this case the sequence:
Multiply \( x + 1 \) with \( x + 2 \)

\[
x + 1 \cdot (x + 2) = x^2 + 2x + x + 2 = x^2 + 3x + 2
\]

Both were using the same language but gave it different meaning: Marco considered it right, Anna said it was wrong. Rosetta did not write about this in these terms, but her remark that Anna and Marco followed different paths seems to agree in essence with the same-language-different-meaning approach. I would like to put forward that the language approach may give us a more promising possibility to get Anna and Marco to come to terms with each other. The different-paths metaphor makes us a little hopeless. How can they ever come together? That is the danger with metaphors: They make you understand, but they do not show how to go on. The language approach is not metaphoric at all. It describes real life situations. As such it helps us not only to understand the situation; it also might give us an indication how to repair the discord between the two speakers. How can we get them to speak the same language with the same meaning?

For that we have to analyze the situation a little more. That was what Rosetta had been doing. She wanted the teachers to try and understand “what is behind a mistake…”. Yet she did not convince Anna. Apparently Anna agreed as in general terms, but when she imagined that something like the example would happen in her class, she became uneasy and had the courage to give her opinion. What made her unhappy with the Marco example?

I would like to propose two reasons. One, as Rosetta points out, is the inability to put herself in Marco’s shoes. The other is the divergence between Anna and Rosetta.

Let me try and analyze the first reason first. I learned from Karen (see my own episode) that thinking in terms of analyzing mistakes is an asymmetric way of working. It is the I-know-better attitude. The same-language-different-meaning approach makes one realize that there are two sides in a conflict. Both sides are right when viewed from each owns standpoint. So let us try and find out what the different standpoints are.

Again I see a similar situation as in the Karen-Wilbur conflict that I described in my own episode. Marco’s path is formalisation of an experience, while Anna wanted to explain the procedure from the rules. Seen from this standpoint both are right in their conclusion: Marco thought he did the right thing, namely reply to the instruction to multiply \( x + 1 \) with \( x + 2 \) and for that he invented an ad-hoc formalisation, that helped him to find the solution, but is irrelevant for others. From his viewpoint his teacher had no business with the way he worked. He gave the correct answer to the task. Anna thought to explain what he did in terms of allowable rules and as such –from her viewpoint- he went wrong.

**Anna and Rosetta**

Much more important for the case than the Anna-Marcos conflict (they even did not know each other) is the Rosetta-Anna conflict. Analyzing it with the same-language-
different-meaning approach one could say that Rosetta and Anna were using the same language when talking about what Marco did, but Rosetta (and the other teachers) were thinking about an explanation of his behaviour, while Anna was thinking in a for her more direct practical direction: What to do about it? At that moment she could not find another solution but the one she was used to. Putting myself in Anna’s shoes I would say something like: “All this talk is good and interesting, but it does not tell me how I can make Marco aware of what he has done and why I cannot accept that”.

Rosetta, in her reflections, takes a wider approach, which brought me to think about the different contexts in which Rosetta had put herself (and most of the teachers with her) and Anna’s context.

Rosetta’s context was the constructivist model of learning. As long as this went in general terms it was also Anna’s context, but the example of Marco changed that. Just as the other teachers she recognized the situation from her own experiences. Maybe because of that, the situation became more realistic for her than for the others and she wondered what she had to do when she had had Marco in her class. She could not understandingly just accept Marco’s work. She knew she had to do something. She asked herself how she had to react. That changed her context completely. She had to make Marco aware that this is not done and therefore she had to punish him.

Anna’s context made her say things that – in her fellow teacher’s eyes – transformed her in the stereotype of the old fashioned teacher that wants her student just do what they are told. In a way this is similar to Wilbur’s generalization of Karin’s abilities in my episode. (From reading Rosetta’s analysis I am sure that this was not how she saw Anna!). Anna apparently was not aware of her other context and therefore expressed herself rather crude and cruel, but maybe what she said was a clumsy way of asking for help: “Tell me what one can do in such a situation”. Was this a (rather extreme) instance of same-language-different-meaning?

**What did I learn from Rosetta?**

I learned nothing new, but am grateful for her description and her reflection on it, because I saw the same elements as in my and Susie’s episode:

- The reason of a discord can often be analyzed with the same-language-different-meaning approach. It makes the situation symmetric. There is no I-know-best situation any more.

- In mathematics teaching-learning such different meanings can sometimes (often?) be explained as difference between formalizing experiences and explaining rules.

- The same-language-different-meaning approach may also prevent us from generalizing other people’s abilities.
COMMENTS ON ROSETTA’S EPISODE - SUSIE GROVES

For me the most striking observation about the episode presented by Rosetta is the critical importance of people’s beliefs about the nature of mathematics for their behaviour as learners and as teachers of mathematics.

The first of the two Marco’s referred to in the episode appears to (not uncommonly) view mathematics as a set of procedures to be mastered in order to obtain correct answers to problems which of themselves appear to have no meaning and over which they have no ownership. Having obtained the correct answer of $x^2 + 3x + 2$ for the product of $x + 1$ and $x + 2$, Marco presumably was not concerned by the fact that his use of notation in the process of obtaining the answer was unorthodox. In my experience, students when asked what they mean when presenting a written or verbal solution often answer “You know”. When pressed further they still repeat “You know” as often as needed. This is not surprising because usually the teacher DOES know and is only asking for confirmation from the students that they too “know” whatever it is the teacher knows. Students have very little experience of being asked to solve problems where it is possible that the teacher does NOT know the solution strategy or thinking used by the students — that is situations where they genuinely need to explain their thinking to someone else. They have little idea that mathematics needs to be communicated to other people, both within the community of mathematicians and when applying it to problems in the real world — and of course that this is why mathematical conventions and their correct use are important.

By way of contrast, Anna in this episode has a very strong sense that mathematical conventions are important. But there is no sense that she sees these as important because of the need to communicate mathematics to others. In fact, she appears to share Marco’s view of mathematics as a possibly meaningless, but nevertheless rigid, set of rules and procedures which it is her task to transmit to her students, however unsuccessfully. A constructivist model of learning mathematics is by and large irreconcilable with such a view of mathematics, so it is not surprising that both she and Rosetta felt confronted by the mismatch between Anna’s response to the Marco scenario and her apparent acceptance of the constructivist model. While I realise that constructivism refers to how knowledge is constructed by humans, regardless of the context or the discipline, I have italicised the word mathematics in the previous sentence because I wonder what we believe might be the implications of adopting a constructivist model of learning for teaching someone, for example, how to fly an aeroplane — which I am assuming here is strictly a set of skills. Would holding Anna’s view of the nature of mathematics simultaneously with a constructivist model for the learning of mathematics lead to an impossible notion somewhat akin to “discovery learning”?

The second Marco in Rosetta’s episode presents a sad story of really trying to succeed, but seeing “everything I did was wrong” and coming to the conclusion that he and maths “weren’t meant for each other”. This story appears to illustrate that this Marco also saw mathematics as a set of rules and procedures which need to be learned
verbatim and mimicked in response to an appropriate cue. Again there is no sense of mathematics as a living, evolving discipline, with intrinsic underlying meanings which can be explored and personally constructed into a web of knowledge.

In her description of the episode, Rosetta, while seeing Anna and the two Marco’s together, sees them all following their own paths, with their own goals and criteria. In my reading of the episode, I was much more struck by the similarities of their goals and criteria and their common, mechanistic view of the nature of mathematics.

**EPISODE III: CALCULATORS – THE FIRST DAY - SUSIE GROVES**

**The episode**
The event I have chosen to describe occurred ten years ago when Jill Cheeseman and I were producing the video *Young Children Using Calculators* (Groves & Cheeseman, 1993) to disseminate some of the findings from the *Calculators in Primary Mathematics* project.

**The context**
The *Calculators in Primary Mathematics* project was a long-term investigation into the effects of calculator use on the learning and teaching of primary mathematics. Kindergarten and grade 1 children in six schools in 1990 were given their own calculator to use whenever they wished in class. The project followed these children through to grade 3 and 4 in 1993, with new children joining the project each year as they started school. The project was based on the premise that calculators, as well as acting as computational tools, are highly versatile teaching aids which can provide a mathematically rich environment for children to explore. Teachers were not provided with classroom activities or a program to follow, instead they were regarded as part of the research team investigating the ways in which calculators could be used in their mathematics classes.

At the time when this event occurred, video footage had been obtained in a number of classrooms and we were ready to edit it to produce the final videotape. However, we were alerted to the fact that we had missed an important aspect when a teacher at one of our regular teacher meetings showed her “home video” of children in her kindergarten class being given their calculators on the first day of school. For technical reasons we could not include her video footage and it was too late to capture the first day of school in any of the project classrooms. However, for reasons which no one could remember, one of the six schools had decided that the project would commence at grade 1 rather than kindergarten. We approached the school and asked whether they would be prepared to include their kindergarten class in the project and allow us to videotape the lesson in which the children would be given their calculators. The school and the kindergarten teacher, who we will call Clare, agreed.
The event

A week before the videotaping was to occur, we visited the school with the technical producer to discuss what would happen in the lesson, space constraints, etc. For reasons of space it was decided that the class would be split into two and each have a 20 minute session. Unlike the other lessons videotaped (and all other lessons taught in the project) where we left it entirely up to the teachers to plan their lessons, on this occasion we particularly wanted to capture footage similar to what we had seen on the “home video” and in many other project classrooms over three years — i.e. children being given their calculators and asked to explore them and then report back to the class what they had found. Clare, who at that stage had had no previous connection with the project, readily agreed to the proposed plan.

Just before we left, the producer asked me to recap with Clare exactly what would be happening the following week. Clare thought for a while and replied that as it was a Thursday, she would be dealing with number and that as it would be the ninth week of the school year, she would be dealing with the number nine. The children would be doing some colouring and other activities based on the number nine and five or ten minutes before the end of the lesson she would hand out the calculators and ask the children to enter some nines on it. This was not what we had expected and we asked her whether she would consider devoting the entire 20 minutes to the plan we believed had previously been agreed. This time she agreed somewhat reluctantly, saying that she did not believe that children would be productively engaged for such a long period.

During the two 20 minute sessions, extracts of which appear on the final videotape, children excitedly explored what they could do with their calculators, while Clare engaged them in purposeful discussion about what they were doing. One boy opened his calculator and exclaimed: “Ooh, now I can tell the time!” One child entered the numbers 12345678 and was disappointed when he had to clear the display in order to continue with 9101112. Another child showed the teacher a display which included a negative sign and then demonstrated, at Clare’s prompting, how to “take the sign away”. A girl entered 98765432 and answered Clare’s question regarding the significance of the numbers by saying that “that’s when a rocket ship blasts off”. Most remarkable was the child who entered 92430 and explained that this was the date the teacher had recorded the date on the board for the first time that morning. But of course it was recorded as 30/4/92.

What we learned

The most striking thing that I learned was the fact that I could not take for granted that each of the parties in a discussion took away the same understanding of what had been discussed — on my part, I “took as shared” the understanding that the children would freely explore their calculators and then report back to the class, while Clare framed the discussion in terms of her previous understanding of what a lesson at this stage of the year would look like.
More importantly, I also learned what an excellent teacher Clare was. Although unwilling at first to follow the proposed plan for the lesson, she did so with enthusiasm on the day and her questioning of the children both during the exploration time and the sharing time resulted in high quality discussion. She was very good at listening to the children and asking probing questions in order to understand the purpose of their often surprising uses of the calculator.

Clare also learned what a wide range of number knowledge was present in her class and how by lock-stepping the whole class into the same, relatively low-level activity, she was only catering for a very small minority of the children. Not only did Clare acknowledge this, but the role of the calculator in revealing this common feature was reported frequently by many teachers throughout the project’s duration.

Both Clare and I also learned from the children new ways in which the calculator could be used not just as a computational tool but also as a tool to facilitate mathematical exploration and reflection. In fact, in much the same way as illustrated here, the project had already found that very young children frequently used the calculator as a “scratch pad” to quickly and easily record numbers and number patterns which they found particularly significant. None of us had anticipated this use of the calculator. Once teachers noticed this spontaneous use, many devised innovative learning activities based on using the calculator as a recording device.

**Students as learners and teacher professional growth**

Since Clare joined the Calculators in Primary Mathematics project at the stage when kindergarten classes only continued to be part of the project for a little over six months and she was not one of the seven teachers who were part of our case study investigating the effects of calculator use on classroom practice, I am unable to comment further on what happened to Clare after the event reported here. However, from the wealth of data collected in the project, I believe that Clare’s experience was shared in many ways by many of the teachers in the project. In particular, I chose this event because in my opinion it highlights the way in which teachers’ learning from their students’ learning experiences can play a powerful role in their professional growth. I will try to elaborate on this below.

The two major aims of the project were to investigate the effects of children being given ‘their own’ calculators to use freely from kindergarten onwards on firstly the classroom practice of teachers and secondly the long-term learning of children. While funding for these two ‘investigations’ came from separate sources, they were nevertheless seen as inextricably linked from the outset. In particular, an underlying assumption of the project was the belief that teachers would observe children using their calculators – presumably in ways which challenged their existing beliefs about the nature of young children’s learning of mathematics – and that reflection on the ‘classroom experiment’ of calculator use and the consequent observations of children would lead to a change in their teaching practice.
This assumption was originally based on Guskey’s (1986) model of teacher professional growth, which proposed that the major motivation for teachers to change is the desire for improvement in student learning outcomes and that changes in teachers’ classroom practice need to precede changes in their beliefs and attitudes. Thus teachers learning from children’s learning was a central thrust of the project from the beginning.

Later in the project, we adopted Clarke and Peter’s (1993) dynamic model of teacher professional growth, which traces its origins to Guskey’s model. The Clarke-Peter model (see Figure 1) identifies four domains: the personal domain (teacher knowledge and beliefs); the domain of practice (classroom experimentation); the domain of inference (valued outcomes); and the external domain (sources of information, stimulus or support). It further identifies reflection and enaction as two mediating processes which are used to explain how growth in one domain is translated to another. In recognition of its dynamic nature, the model allows for entry at any point in the cycle.

In terms of the Clarke-Peter model, the stimulus of the presence of the calculator, together with the support provided by the project, were changes in the external domain.
domain. This was translated into action in the domain of practice through classroom experimentation, which, in this case, took the form of using calculators on a regular basis. As well as their own observations of children learning in the calculator environment, teachers received feedback from the members of the project team who reported their observations of individual children’s learning during regular classroom visits. These visits therefore acted as a further stimulus by giving teachers access to a much wider range of observations of children than would otherwise have been possible. This in turn provided teachers with enhanced opportunities to engage in the reflective process in order to bring about change in the domain of inference — that is the valued outcomes. The reflective process was also supported by the discussion which took place at project meetings. This reflection on changes in both the external domain and the valued outcomes mediated change in the personal domain.

Most of the seven teachers who were part of the case study investigating effects of calculator use on classroom practice claimed to have made substantial changes to their teaching of mathematics, with all seven commenting that their mathematics teaching had become more open-ended, and four teachers describing their mathematics teaching as having become more like their teaching of language (Groves, 1993). While it is not possible to determine the long-term effect on Clare of the event reported here, it appears highly likely that Clare’s teaching also became more open-ended as a result of her experiences that day and also when subsequently working with calculators with children in her class. Certainly the findings from the project in general support the notion that placing teachers in experimental situations which challenge their existing beliefs by focusing attention on their students’ learning has the potential to support teachers’ own learning and professional growth.

**COMMENTS ON SUSIE’S EPISODE – ROSETTA ZAN**

Reading this episode gives us the possibility of reflecting on some significant aspects of the teaching process. Even though the information that can be extracted from a single episode are limited, Clare’s behaviour reminds me of behaviour and decisional processes observed in other teachers, and of possible interpretations of these processes.

In a first instance Clare refuses the work proposal of Susie and Jill: she thinks that the children cannot be left for 20 minutes to perform that type of activity, and that a more structured activity under the teacher supervision would be better. I seem to recognise in Clare’s behaviour, but above all in her decisions, the influence of her beliefs and emotions. Her beliefs regard both her class and their capacity (the children cannot be left working for a long time on a single activity), and the teaching of mathematics (if we want the children to learn, we have to provide them with structured activities). But I also recognise a strong emotional component in all of this: the fear of losing control of the situation, and the anxiety of not completing a pre-established program.

The importance of the theme of teacher’s beliefs in the research on teaching is linked to the shift of this research from the only observable phenomena such as teacher’s
behaviour, to studies about the teacher’s decision processes. In the more recent studies teachers are seen as thoughtful professionals, who make judgements and carry out decisions in a complex environment. The teacher’s decisions are influenced (just like the decisions made by a subject involved in a problem posing or solving activity) both by their knowledge and by their beliefs. In particular, the beliefs regarding the capacity of their pupils can push the teachers towards making low demands, and can end up in low results, as suggested in pioneering studies by Rosenthal and Jacobson (1968) on the so called Pygmalion effect. However, research on problem solving highlights that decisions made by a subject who is solving a problem are also influenced by his/her emotions (McLeod & Adams, 1989): therefore the teachers’ emotions, which are currently studied less than their beliefs, have just as important a role in explaining their decisional processes (Malara & Zan, 2002).

These factors (beliefs and emotions) also have a great influence on the relationship between teachers and researchers, and can be an obstacle to the implementation of the researchers’ project. Even if Clare declares, and is convinced that she wants to participate in the project, her co-operation is held back by her resistance to allowing the children to work freely for a longer period of time. This phenomenon has also been analysed in mathematics education with respect to the reproducibility of a teaching experiment (Arsac et al., 1992): even when the teachers’ behaviour has been programmed down to the finest detail, some of their non programmed decisions at a micro level are enough to make the activity not reproducible.

Reflection on this type of episode can lead both the researcher and the teacher to modify their practices. As a teacher these reflections convinced me of the importance of being aware of my decision-making processes, and of the deeper motives that bring them about. As a researcher, reflection on the role of the teacher convinced me that the reproducibility of a teaching experiment depends on the training given to the teachers involved in the experiment. Such training cannot simply be limited to communicating the spirit of the project to the teachers, but has to try to work not only on their knowledge but also on their beliefs and their emotions.

Analysis of episodes like this one also gives the opportunity to reflect on the importance of allowing pupils to explore, and not to limit their mathematical experience to very structured tasks. If problem solving is a crucial activity in the development of pupils’ abilities and knowledge, the task of problem posing is no less so (Silver, 1993). In particular, the fact that during problem posing the subject solving the problem is the same as the one proposing it, has important implications. It allows certain cognitive obstacles to be overcome, such as those linked to the comprehension of a text, which are often exasperated by the stereotypical nature of school problems. As well as this, since exploration stimulates the production of conjectures, problem posing provides an ideal context for constructing the first steps in proving processes that are crucial to mathematical activity. But above all, problem posing guarantees active involvement of the pupil, reducing the risk that mathematical activity loses its sense and that the pupil loses control, thus generating a negative and fatalistic attitude.
Concluding remarks

What I presented here is certainly only one of many possible interpretations of Clare, Karin and Wilbur’s behaviours, but it is also the result of other experiences and analyses performed on other pupils and teachers. What I want to underline is the plausibility of this interpretation and NOT its correctness! Such plausibility is sufficient to highlight that the lack of communication between teacher and pupil (that I see as common to the three episodes) can be or become cause of difficulties. But I think that highlighting the complexity linked to these aspects takes us towards having instruments to make it manageable. The pupil/teacher relationship is asymmetrical: in my opinion managing to listen to and observe the pupils, talk to them, monitor the vision of both mathematics and themselves that they are building up, are all components of the teacher’s role. This raises new issues which researchers will have to face: the need of developing a theoretical framework providing teachers and researchers with tools for observing and interpreting pupils’ behaviour, and the need of adequate teacher education, in order to develop teachers’ knowledge, but also their sensitivity and awareness (Mason, 1998). Theoretical tools, sensitivity and awareness can help the teacher recognise that the pupil is following a different path from the one he or she was expected to follow, and consequently make adequate decisions to reduce the distance between reality and expectations. But knowledge and metacognition are not enough without a crucial emotional aspect: the desire of communicating. Hence it is also on such desire that researchers need to work, in order to make teacher education act upon and affect such emotional factor.

Similarly, in my opinion, theoretical tools and metacognitive abilities are also the instruments that allow teachers and researchers to learn from learners: but, again, no tools are sufficient without the desire of learning.

WHAT I LEARNED FROM KARIN, ROSETTA AND SUSIE – COMMENTS ON SUSIE’S EPISODE – JOOP VAN DORMOLEN

I started with my own episode, and then I worked on the Rosetta Zan’s. Susie Groves’s episode is the last of the three on which I have to comment. I cannot but see several common elements in all three descriptions and therefore, next to commenting on her episode I use this, for me last, scribbling for a sort of summing up.

Same language, different meaning

The three episodes of Susie Groves, Rosetta Zan and me have several common elements. One of them is the phenomenon that people can talk with each other, using the same language and yet give different meaning to it. In Susie’s story there is the agreement that “the class would be split into two and each have a 20 minute session.” These 20 minutes meant for Susie that the whole period would be devoted to exploration of calculator, while for Clare the splitting up was meant just for technical reasons as there was not space enough for the camera crew in a full classroom. For the
rest she though she could go on with her planned lesson, be it that five or ten minutes before the end would be devoted to the calculator. The intervention of the producer made it clear that there was indeed a difference in meaning. As ever so often this shows again the usefulness, if not importance, of conducting an evaluation after a meeting in which, between other issues, participants look back on their decisions: Are they clear for everybody? Does everybody attach the same meaning to it? (Johnson & Johnson 1997, Van Dormolen 2000).

The same-language-different-meaning is also clear in the actions and explorations of Clare’s children. The language of the numbers in the display was indeed for them very different from the language in which the calculator is a computational tool.

Susie rightly points out Clare’s willingness and ability to learn her children’s language and to talk with them in that language in order to give them more and deeper experiences.

The context

Another element that is strongly apparent in all three episodes is the influence of the context on learning. All three of us found it necessary to go into detail about the circumstances that leaded to our learning. Each of us could have given the incident about which we wanted to write in less than half a page, but we decided not to do that. The context helped us to learn, so we were compelled to describe the context. For the children it was the context of being able to freely explore the new instrument. For Clare it was the context of being in the classroom with her children and noticing their excitement. For Susie it was the context of having the class as part of her project which gave her the opportunity to observe and learn.

Like ever so often the three episodes showed us again the importance of creating a rich context in order to provoke meaningful learning (Freudenthal 1978, pp. 178-185). The ideas of realistic mathematics education are based on this assumption (or should I say: law?).

Formalization and explanation

Explanation is about rules, formalization is about experiences. Both are elements in language and may help to determine if there is a case of same-language-different-meaning and if yes, to describe the different meanings.

From Susie’s description I get the impression, that neither she, nor Clare wanted to explain rules about how to use the calculator. It is not clear what they expected what could happen if there was no explanation, but both of them were open minded to give children the freedom to find their own formalizations. One could ask if the word ‘formalization’ is a bit heavy in this case. I think not. Formalization is for me the result of some generalization. The children in Susie’s episode, at least the children that she mentions, generalized and by telling Clare what they found, they formalized their findings.
Never generalize on another person’s abilities

In my episode Wilbur had certain experiences with Karin’s abilities to learn mathematics. Unconsciously he generalized these experiences and that prevented him to recognize her intervention as constructive. In Rosetta’s episode something similar happened to the teachers who seemingly stereotyped Anne as a rigid teacher. Wilbur’s context was not a favourable one in which he could recognize his own bias. The same can be said about Anna’s fellow teachers. Rosetta, Susie and Clare were in a different position. Their context was different, which allowed them to be aware that the situation should not be understood automatically. Clare was convinced that her children could not very well cope with the calculator and therefore did not want to spend more than 10 minutes to it. She was however open minded enough to try something else and, in contrast to Wilbur, she had all the time to make a decision to change her plan. Susie might have been shocked by Clare’s intentions and did what she could to change Clare’s mind. Yet she seemed to allow Clare to act as she looked fit. Susie’s context was a very favourable one: an important goal of her project was just to be open and see what happens. Rosetta was shocked by Anna’s remarks, did not allow herself to act accordingly. In this case she could not decide on the most favourable reaction. Her context restrained her in the time to find that reaction. Only later in the train she could reflect on the incident.

EPILOGUE – JOÃO FILIPE MATOS

When people find out that they have competing versions of ambiguous events, they often try to negotiate a kind of commonly agreed upon definition of the situation. This we can find in all three episodes just presented and analysed.

One of the features that seem to be equally relevant in the three episodes and subsequent analysis is that authors report learning within a certain situation reconstructing the conditions where it occurred and re-contextualising the learning within their actual frame. It is not surprising that all three authors do believe that learning occurred in the episodes shown and that they are able to identify the sources of learning in interaction with others.

There are also some aspects that emerge from the several analysis presented and that can help us to formulate relevant research questions regarding the issue of learning from learners.

Firstly, learning is seen as a phenomenon inherent to human nature and therefore an ongoing and integral part of everyday life. In fact, it doesn’t seem possible to see learning as a special kind of activity separable from the rest of our life. This brings us to questions such as the definition of the unity of analysis in research on learning — focusing on people acting in the world versus focusing on cognitive processes.

Secondly, learning is conceptualized as an ability to negotiate new meanings, involving the whole person in dynamic participation in practices. Learning in general (and
learning mathematics in particular) is viewed as a constructive activity that is developed more in a process of socialisation rather than one of instruction. It is during this process—which is socially mediated by language and other communication tools—that patterns of thought and action develop and are considered to be (mathematically) legitimate. This brings along for example the question of the contrast that is established between the concerns arising when we intend to teach children to do mathematics (emphasis on knowledge as a way of doing) and the concerns arising when we intend to educate them mathematically (highlighting a concern with a form of knowledge).

Thirdly, learning transforms one identity, by transforming one’s ability to participate in the world and it does this by changing who we are, our practices and the communities we belong to. This very fact makes emergent issues such as the way the participant in the practice develops a sense of belonging and therefore construction of identity becomes a key element.

Finally, learning involves an interplay between the local and the global. The three episodes help us to realize how learning takes place in practice as it defines a global context for its own locality. Learning occurs whatever the educational form that helps to create the context for learning (including the absence of an intentional educational form) pointing to a fundamental distinction between learning and intentional instruction. Obviously this idea does not deny that learning may occur where there is teaching, but it does not make intentional teaching to be the source or the cause of learning.

All these features of learning need to have the attention of researchers in mathematics education. This paper aims to be a contribution for a first step towards an ethnography of learning from learners.

ACKNOWLEDGEMENTS

The Calculators in Primary Mathematics project was funded by the Australian Research Council, Deakin University and the University of Melbourne. The project team consisted of Susie Groves, Jill Cheeseman, Terry Beeby, Graham Ferres (Deakin University); Ron Welsh, Kaye Stacey (Melbourne University); and Paul Carlin (Catholic Education Office).

INTRODUCTION

Tommy Dreyfus and Eddie Gray

Since there is no universally accepted research paradigm in mathematics education, theories and terminology tend to multiply. It is therefore one of the tasks of the research community to critically compare theories that deal with closely related issues and have similar aims. The setting of a research forum at PME conferences is one of the few opportunities where attempts at such comparison can be undertaken in public by a large group of researchers.

Several theories for processes describing the emergence of mathematical knowledge structures (abstraction) have been put forward recently. While these theories differ in many respects, they have a common goal: they aim to provide a means for the description of processes during which new mathematical knowledge structures emerge. Thus, they have the potential to provide insight into one of the central aspects of learning mathematics and inform instructional practice.

Three theories of abstraction have been selected for discussion in the Research Forum on the basis of their similar aims but different approaches. The selection was made so as to achieve, within the limited space and time available, a wide variety with respect to the theoretical underpinnings of the approaches, the formal or informal nature of the emergent knowledge, the role of context in the process of abstraction, the importance the theories attribute to contextual factors, and the degree to which they are anchored in instructional design. While a main aim of each of the three theories is to describe processes (rather than outcomes) of the emergence of knowledge during learning activities and a secondary aim is to contribute to the design of learning, the assumptions of the three theories differ considerably. For example, the theory by Tall & Gray is predominantly cognitive (with links to neuro-physiology), while context is accorded a limited role; on the other hand, the theory by Gravemeijer is predominantly contextual. Similarly, instructional design interacts with the theories in very different ways: For Tall & Gray, instructional design is a result of the research undertaking, for Schwarz, Hershkowitz & Dreyfus, it is the location of the research undertaking (in the
sense that the research takes place in an environment designed for instruction), and for Gravemeijer instructional design is at the origin of the research undertaking.

A theory cannot possibly be presented appropriately in the limited space allotted to each group of contributors within this written presentation of the Research Forum. Therefore, the following contributions by the three presenting groups only give a summary overview over each of the theories, and provide the reader with ample references for further reading. Many of these references are accessible from the conference website. They are also available from the authors. The papers included hereafter have been written following a set of fairly detailed guidelines. The aim of these guidelines was to define a number of dimensions for comparison of the theories. Specifically, each paper

(i) Gives a description of what their theory is about,
(ii) Identifies the assumptions being made by the theory,
(iii) States the theses of the theory (what does the theory say?), including a detailed discussion of the meaning of the terms that are used,
(iv) Discusses the aim(s) and applications of the theory,
(v) Gives evidence concerning the validation of the theory (for example empirical research).

Authors have been asked to be specific about the meaning of their terminology to enable the identification of cases where either the same term is used with different meanings or where different terms are used to describe closely related phenomena. First and foremost, the term 'abstraction' is likely to mean different things to different people; similarly, the term 'context' may be given a rather narrow or a very wide interpretation. In addition, each theory uses its own idiosyncratic terms.

The two papers by the reactors stress commonalities and differences between the three theories, for example with respect to the underlying definitions of abstraction, the domains of applicability of the theories, the empirical evidence validating the theory, and the role which context plays in the process of abstraction.

Whilst our theme examines from a contemporary perspective theoretical issues that have been of interest to PME members over the past quarter of a century, two broader issues are also relevant to our discussions.

First, there is an issue associated with "having abstracted". Though we are examining theoretical perspectives of the role of abstraction, its contribution and influence on different modes of thinking displayed by mathematics students leads us to ask to three general questions, which can and should be expected to arise for discussion out of the reaction papers are:

- When do we know students have abstracted and what student behavior attests to this?
- What happens if students do not abstract?
- How do we encourage abstraction?
Secondly, there is an issue associated with coherence and unification. In the opinion of the presenters and the reactors, the domain of theoretical physics has no exclusive right to yearn for a unified theory. Even though mathematics education as a scientific discipline is a few centuries younger than physics, we believe that this is the time to start the work of combining, merging and fusing our theories, and thus to make them more widely known, applicable and applied. One milestone on this road will be the use of different theories to analyze the same data set and thus to directly confront the theories. We hope that the discussions of the research forum will give rise to such undertakings, as well as to some speculation on a possible unification of the theories into a larger framework. It is this hope for progress in the direction of fewer, more widely known, more widely agreed, and more widely applied theories that has motivated this research forum.

ABSTRACTION AS A NATURAL PROCESS OF MENTAL COMPRESSION

Eddie Gray & David Tall

Introduction

The term ‘abstract’ has its origins in the Latin ab (from) trahere (to drag) as:
- a verb: to abstract, (a process),
- an adjective: to be abstract, (a property),
- and a noun: an abstract, for instance, an image in painting (a concept).

The corresponding word ‘abstraction’ is dually a process of ‘drawing from’ a situation and also the concept (the abstraction) output by that process. It has a multi-modal meaning as process, property or concept. Piaget distinguished between construction of meaning through empirical abstraction (focusing on objects and their properties) and pseudo-empirical abstraction (focusing on actions on objects and the properties of the actions). Later reflective abstraction occurs through mental actions on mental concepts in which the mental operations themselves become new objects of thought (Piaget, 1972, p. 70). In Tall et al, 2000, we reviewed ideas in the literature and concluded that elementary mathematical thinking uses reflective abstraction both by focusing on objects (for instance, in geometry) and on operations on objects represented as symbols (in arithmetic, algebra, etc). In the latter case we see symbols used dually as process and concept and have formulated this in terms of the notion of procept (Gray & Tall, 1994, see also below). At a later stage, in advanced mathematical thinking, the focus changes to properties (of objects and operations) formulated as fundamental axioms for mathematical theories.

Our hypothesis is that different forms of abstraction lead to different type of cognitive development and in turn, to differing cognitive problems. Empirical and reflective abstraction in shape and space lead to a van Hiele type development that we see as the growing dominance of verbal description over visual perception, as language refines our imagery and leads to increasingly sophisticated forms of mathematical structure.
and proof. Pseudo-empirical and reflective abstraction in arithmetic, algebra and calculus naturally focus on our notion of procept. Increasing focus on properties and deduction lead to a property-based axiomatic theory where the process of proof leads to the concept of theorem which may then be used as steps in building up a systematic formal theory.

We have a great empathy for the notion of different modes of operation as proposed by Bruner (1966) and, more particularly, in the SOLO taxonomy of Biggs and Collis (1982). For instance, it is possible to build a holistic embodied mode that relates to the enactive/iconic modes of Bruner or the sensori-motor/ikoncic modes of Biggs and Collis, before gaining an insight in proceptual (concrete-symbolic) terms; or, at a later stage in advanced mathematical thinking, in formal-deductive terms. Tall (1999) considers the distinct forms of proof available in these various modes as the child develops cognitively into a mathematical expert. Tall (2002) reviews calculus in terms of an enactive-iconic approach manipulating graphs, symbolic-proceptual representations (manipulating formulae) and formal proof (in analysis).

In this short paper we do not have space to attend to our full theoretical perspective. We focus only on the abstractive processes occurring in constructing procepts in arithmetic, algebra and symbolic calculus and how differing types of symbol (whole numbers, fractions, algebraic expressions, (infinite) decimals, limits) give rise to distinct problems of concept construction and re-construction.

Five Aspects

The research forum is designed to focus on five aspects, given in (a)-(e) below.

a. What is the theory about?

Our theory grows as a result of our quest to understand not only what students do in constructing symbolic mathematics, but how they do it. We believe that abstraction is a natural consequence of human brain function. At any given time human thinking occurs dynamically as a process, whereby items evoked in the focus of attention are manipulated mentally as concepts. It is the duality of symbols in arithmetic, algebra, etc as both process and concept that is the basis of our theory.

b. What assumptions are being made?

We assume that abstraction is a natural product of human mental activity, in which a complex parallel-processing organ solves the problem of complexity by focusing on essential structures that enable decisions to be made. Sometimes this process of abstraction is a conscious reflective act, but much of it does, and must, occur unconsciously to enable the brain to focus only on essential elements. There is physical evidence that over time routinising tasks uses less brain capacity:

As a task to be learned is practiced, its performance becomes more and more automatic; as this occurs, it fades from consciousness, the number of brain regions involved in the task becomes smaller. (Edelman & Tononi, 2000, p.51)
There is also a compression in the nature of the symbolism being used:

I should also mention one other property of a symbolic system – its compactibility – a property that permits condensations of the order $F = MA$ or $S = \frac{1}{2}gt^2$, ...in each case the grammar being quite ordinary, though the semantic squeeze is quite enormous.

(Bruner, 1966, p. 12.)

We do not have the data to link mathematical activity in a one-one mapping to neurophysical phenomena, steps in this direction (eg Dehaene, 1997) are still in their early stages. However, the underlying biological basis of mathematical thinking in a brain ill-built for numerical computation and formal logic, is a vital underpinning for our own reflections on how mathematical thinking develops.

c. What does the theory claim? What terms are used and what do they mean?

The notion of procept (as given in Gray & Tall, 1994) is seminal in what follows.

An elementary procept is the amalgam of three components: a process which produces a mathematical object, and a symbol which is used to represent either process or object.

... A procept consists of a collection of elementary procepts which have the same object. (Gray &

We follow Davis (1983, p. 257) in defining a procedure as an explicit step-by-step algorithm for implementing a process and see a spectrum of increasing power through the usage of procedure, process and procept. We do not agree with Sfard or Dubinsky that the development invariably proceeds in a sequence we describe as procedure-process-procept. In particular, as students become more sophisticated, they may sense an intuitive holistic grasp of the overall ideas in, say, an embodied mode before concerning themselves with the specific procedures that may be seen to occupy a particular role within a symbolic or formal mode of operation.

We do not have a theory that tells us how all individuals can be helped to move through all of these modes. (Indeed, no-one has such a theory at this moment in time.) Instead, in the growth of symbols, we find a bifurcation between those who concentrate more on the procedures associated with symbols, who have a greater cognitive strain to overcome, and those who develop a proceptual system switching flexibly between process and concept to construct a more powerful generative mental structure. This does not mean that students necessarily remain in a fixed part of the spectrum. However, we do have considerable evidence that there is a bifurcation in performance between those who remain entrenched in procedures and those who develop more flexible proceptual thinking, so that progress to greater sophistication is more difficult for some and easier for others.

d. What are the aims of the theory and what are its applications?

The initial aim of our theory of the proceptual growth of symbols is to try to explain why some students are so highly successful with symbols, whilst others are procedural at best and could, at worst, be overwhelmed by the complexity of mathematics. To
move towards this overall goal we focus on the different ways that procepts arise in cognitive development. These include

1. **arithmetic procepts**, $5+4$, $3\times4$, $\frac{1}{2} + 0.3$, $1.54 \div 2.3$, all have built-in algorithms to obtain an answer. They are *computational*, both as processes and even as concepts. **Fractional procepts** behave differently because the focus moves from sharing procedures (e.g. divide into 4 equal parts and take 2) to equivalent fractions, which from our viewpoint are seen as processes that have the same effect (divide into 4 equal parts and take 2, has the same effect as divide into 6 equal parts and take 3).

2. **algebraic procepts**, e.g. $2+3x$, can only be evaluated if the value of $x$ is known and so involves only a *potential process* (of numerical substitution) and yet the algebraic expressions themselves represent manipulable concepts (manipulated using algebraic rules of equivalence).

3. **implicit procepts**, such as the powers $x^2$, $x^0$ or $x^{-1}$, for which the original meaning of $x^n$ no longer applies but the properties need to be deduced using the power law $x^m \times x^n = x^{m+n}$ (which also no longer has its original meaning!)

4. **limit procepts**, $\lim_{x \to a} \frac{x^3 - a^3}{x-a}$ or $\sum_{n=1}^{\infty} \frac{1}{n^2}$ etc, have potentially infinite processes ‘getting close’ to a limit value that may not be computable in a finite number of steps.

5. **calculus procepts**, such as $\frac{d(x^3e^x)}{dx}$ or $\int_0^\pi \sin nx \cos nx \, dx$ focus again on finite operational algorithms of computation (the rules for differentiation and integration).

This reveals that each of new form of procept has its own peculiar difficulties that makes abstraction qualitatively different in each case. We believe that knowledge of these specific difficulties is essential to help a wider spectrum of students to succeed in the longer-term process of successive abstractions:

*e. How has the theory been validated?*

Our data (summarized in Tall, Gray, *et al*, 2001) reveals both general themes and specific information on cases (1)-(5) above. The general themes illustrate diverging approaches from procedural to proceptual in a spectrum of students from elementary arithmetic (Gray & Tall, 1994), through algebra (DeMarois, 1998; McGowen, 1998; Crowley, 1999), symbolic calculus (Ali, 1996), and on to formal mathematical theory (Pinto, 1998). In addition, qualitative differences in imagery emerge from different forms of abstraction (Pitta, 1998; Gray & Pitta 1999), leading to differing levels of success in the longer term, depending on whether children continue to focus on real-world situations and imagery, or move on to a more flexible proceptual hierarchy (Gray *et al*, 1999). The data from the above-mentioned studies reveal how differing contexts pose significantly different kinds of cognitive problems in both the nature of
the procepts concerned and the procedure-process-procept spectrum of student activity. We believe that these difficulties are best handled by the learner supported by a mentor who is aware not only of the mathematics but of the underlying cognitive structures.

This aspect of learning is complementary to the desire of Schwarz et al (this forum) to theorize about a general strategy for encouraging abstraction in context. We suggest that it is a laudable aim to have a general theory of construction, but we observe that specifics often overwhelm the broad sweep of such a theory. From the learner's point of view, different obstacles occur in different contexts. The acquisition of mathematical knowledge from early years to undergraduate level involves a variety of reconstructions. Each new reconstruction refines that which was established earlier so that effective reconstructions contribute to the organic nature of growth in the embodied and proceptual modes of operation and on to a close harmony between wider aspects of concept image and concept definition in advanced mathematical thinking. Our central concern is not just how we can encourage students to make abstractions, but also to find why some students succeed so effortlessly and others can fail so badly at making the necessary reconstructions. Our empirical evidence provides an insight into a possible answer—inappropriate abstraction from mathematical activity.

ABSTRACTION IN CONTEXT: CONSTRUCTION AND CONSOLIDATION OF KNOWLEDGE STRUCTURES

Baruch Schwarz, Rina Hershkowitz and Tommy Dreyfus

The construction of abstract knowledge structures is central in human learning, including mathematics education. As practitioners who are informed about recent theoretical research, we have been deeply involved in curriculum design, development, and implementation. Our approach to abstraction is thus a product of our interest both in theory concerning abstraction and in experimental observations of activities in schools in which we judged that a process of abstraction has been evidenced.

Many researchers have taken a predominantly theoretical stance and have described abstraction as some type of decontextualization. For example, Piaget has proposed that abstraction consist in focusing on some distinguished properties and relationships of a
set of objects rather than on the objects themselves. Abstraction is thus a process of decontextualisation. According to Davydov (1972/1990), on the other hand, abstraction starts from an initial, undeveloped form of knowledge and ends with a consistent and elaborate knowledge structure.

A Definition for Abstraction, the Nested RBC Model, and Consolidation

Leaning on ideas of Davydov and other researchers, and in view of our experience in classrooms and our need for an operational definition, we translated our theoretical principles into the following more applicable definition:

Abstraction is an activity of vertically reorganizing previously constructed mathematics into a new mathematical structure.

The term activity in our definition is directly borrowed from Activity Theory (Leont'ev, 1981) and emphasizes that abstraction is an activity, a chain of actions undertaken by an individual or a group, and driven by a motive, which occurs in a specific context. Context is a personal and social construct, which includes the student’s social and personal history, conceptions, artifacts, and social interaction. The term previously constructed mathematics refers to two points: One, that outcomes of previous processes of abstraction may be used during the present abstraction activity; and two that a process of abstraction leads from initial, unrefined abstract entities to a novel structure, as posited by Davydov. These two points show the recursive nature of abstraction. The phrase reorganizing into a new structure implies the establishment of connections, such as inventing a mathematical generalization, proof, or a new strategy of solving a problem. The novel structure comes about through reorganization and the establishment of new internal and external links within and between the initial entities. We very intentionally used the word new to express that, as a result of abstraction, participants in the activity perceive something that was previously inaccessible to them. Finally, we borrowed the term vertical from the Dutch culture of Realistic Mathematics Education, in which researchers relate to vertical mathematization as to an activity in which mathematical elements are put together, structured, organized, developed etc. into other elements, often in more abstract or formal form than the originals. It is mainly this integration that comes about by the establishment of new connections during processes of abstraction, which we wanted to express by means of the term vertical.

According to this definition, abstraction is not an objective, universal process but depends strongly on context, on the history of the participants in the activity of abstraction and on artefacts available to the participants. In this sense structure is internal, "personalized".

The study of abstraction raises a methodological challenge. Whichever its definition is, abstraction implies mental activity, which is not observable. Since we want to empirically investigate processes of abstraction, we need to devise a way to make them observable. Put otherwise, we need to use (theoretical) spectacles, which let us see
processes of abstraction, as they occur during students’ activities. And it is precisely this view of abstraction as activity, which provides us with the desired spectacles: Activities are composed of actions – and actions are frequently observable. The question, which actions are relevant for abstraction, we answer with reference to Pontecorvo & Girardet (1993): Epistemic actions are mental actions by means of which knowledge is used or constructed. Epistemic actions are often revealed in suitable settings. Therefore, settings with rich social interactions are good frameworks for observing epistemic actions. Coming back to our experimental research we were able to identify three particular epistemic actions, which are constituent of abstraction, and provide a strong indication that a process of abstraction is happening: Recognizing, Building-With and Constructing, or RBC. In summary, we consider these epistemic actions because they characterize abstraction and because they are observable. In other words, they provide us with an operational description of processes of abstraction.

**Constructing** is the central action of abstraction. It consists of assembling knowledge artefacts to produce a new knowledge structure to which the participants become acquainted. **Recognizing** a familiar mathematical structure occurs when a student realizes that the structure is inherent in a given mathematical situation. **Building-With** consists of combining existing artefacts in order to satisfy a goal such as solving a problem or justifying a statement. The same task may thus lead to building-with by one student but to constructing by another, depending on the student’s personal history, and more specifically on whether or not the required artefacts are at the student’s disposal.

The three epistemic actions are the elements of a model, called the dynamically nested RBC model of abstraction. According to this model, constructing incorporates the other two epistemic actions in such a way that building-with actions are nested in constructing actions and recognizing actions are nested in building-with actions and in constructing actions. Moreover, constructing actions may themselves be nested in further constructing actions.

On the basis of observations reported below and elsewhere, we postulated that the genesis of an abstraction passes through (a) a need for a new structure; (b) the construction of a new abstract entity; (c) the consolidation of the abstract entity through repeated recognition of the new structure, building-with it in further activities with increasing propensity, and using it in further constructions.

Stage (c), the consolidation of the newly knowledge structure, seems a priori to be linked to the following behaviors: (i) the reconstruction of the new structure or its actualization by recognizing it in different contexts, (ii) its use with increasing facility for building-with in different contexts, (iii) its use in the construction of further structures for which it is a necessary prerequisite, (iv) its verbal articulation, possibly during or after an activity of reflection such as reporting or summary discussion in class. Thus the term consolidation denotes a progressive familiarization and further
use observable through recognizing and building-with actions in these four types of situations.

The validation of the theory through empirical research

We characterized abstraction as a process taking place in a complex context that incorporates tasks, tools and other artifacts, historical background of the participants, as well as the social and physical setting. Abstraction processes are then context dependent. However, we claim that the ways in which these processes are taking place and become operational have a universal structure. This structure was elaborated and partially confirmed in Hershkowitz, Schwarz and Dreyfus (HSD, 2001). Further studies were partially designed for confirmation of the model and partially designed for extending it.

In HSD we showed that the dynamically nested RBC model fits the genesis of abstract scientific concepts acquired in activities designed for the purpose of learning. A first validation of stage (a) and (b) of the genesis of abstraction according to the model was obtained in a case study with a single ninth grade student who was interviewed while solving a problem, a suitable computer program being at her disposal.

We showed that the model describes the mechanism of processes of abstraction. As such it contains the main invariant features of abstracting as a thinking process. Moreover, the model is apt to take context into account.

HSD also revealed a methodological problem: the occurrence of processes of abstraction cannot be ensured; rather, students can only be presented with opportunities for abstraction. The creation of such opportunities presents a challenging design problem since it depends on the contextual factors mentioned above. We tried to elicit strong motives such as the need to justify a just discovered claim, the need for solving a problem as well as conflict situations in order to augment the opportunities for abstraction. This corresponds to stage (a) of the genesis of abstraction according to the model.

Dreyfus, Hershkowitz and Schwarz (2001a; 2001b), tested stages (a) and (b) of the model in a richer context, in which two peers interacted to construct new knowledge. The study focused on the social dimension of the process of abstraction. Two parallel analyses were carried out on the same protocols: the analysis of epistemic actions according to the model of abstraction as well as an analysis of the interaction. The study showed far-reaching parallels between the two analyses. In other words, we enhanced the RBC model of abstraction so as to describe processes of abstraction by interacting pairs of students and patterns of distribution of abstraction between collaborating peers. The parallel analyses led to the identification of types of social interaction that support processes of abstraction.

While research concerning stages (a) and (b) can be done within one activity, investigation of consolidation processes requires at least a medium term research, where one can analyze processes occur among successive activities. Such an analysis
demands the elaboration of powerful methodologies with the help of which individual
history of individuals evolving in changing learning environments should be traced. A
small number of studies in this direction have already been undertaken (Dreyfus &
Tsamir, 2001; Tabach, Hershkowitz & Schwarz, 2001; Tabach & Hershkowitz, 2002).
A first attempt at an empirically based theory for consolidation emerged from a
sequence of interviews about the comparison of infinite sets with a single talented
student. It showed that consolidation may occur both as a result of problem solving
activities and as a result of reflective activities, and that it can be identified by means
of the psychological and cognitive characteristics of immediacy, self-evidence,
confidence, flexibility and awareness.

The significance of our theory of abstraction concerns theoretical, psychological and
educational issues: Since our research is empirical, it has the potential to yield insights
on processes of abstraction and consolidation as they develop, and to confront these
empirical insights with the theoretical constructs of the model. Abstraction and
consolidation as the central components of construction of knowledge are investigated
in relation to the history of the participants, and to series of activities in a social
context. On the basis of the theory, we also expect to articulate educational design
principles for sequences of activities that are intended to lead to abstractions and their
consolidation.

historical topics. Cognition and Instruction 11, 365-395.
In general, mathematics is thought of as abstract, formal knowledge. Within this view, the key problem for mathematics educators is to shape mathematics instruction that helps students in bridging the gap between informal, situated knowledge at one hand, and abstract, formal mathematical knowledge at the other hand. A rather common view is that students have to abstract from their informal knowledge; they have to decontextualize, or to cut the bonds with reality. In this paper, an alternative view is presented that does not take its point of departure in the metaphor of a gap between abstract, formal knowledge and informal knowledge, but in an emergent approach, within which formal mathematics grows out of the mathematical activity of the students. The latter view is part of work in the area of instructional design.

Abstraction as the Creation of New Mathematical Reality

The deliberations on the issue of abstraction that will be presented here grew out of an effort to further explicate and elaborate the domain-specific instruction theory for realistic mathematics education (RME) (Treffers, 1987). As part of this effort, this domain-specific instruction theory has been recast in terms of instructional design heuristics (Gravemeijer, 1994). The elaboration of one of those design heuristics—concerning emergent models, or emergent modeling—created the need to further investigate the underlying, implicit, notions of abstraction (Gravemeijer, 1999). The emergent-modeling heuristic assigns a role to models that differs from the classical role of models in mathematics education: instead of trying to concretize abstract mathematical knowledge, we try to help students model their own informal mathematical activity. In doing so, we attempt to foster a process, within which a model of their own informal mathematical activity gradually develops into a model for more formal mathematical reasoning for them. In contrast with the gap metaphor, formal mathematics is not seen as something separate, existing independent of a knowing agent. Instead, formal mathematics is seen as emerging alongside with the model-of/model-for transition.

When speaking of formal mathematics, we hasten to say that in RME, formal mathematics is not seen as something “out there”. Instead, formal mathematics is seen
as something that grows out of the students’ activity. For us, the notion of “abstraction” is tied to a progression from informal to more formal mathematical reasoning, which in turn is tied to the creation of new mathematical reality. So instead of “cutting bonds with (everyday-life) reality”, we want to stress “construction”. Informal, situated knowledge is the basis upon which more formal, abstract mathematical knowledge is build.

Our claim is that the emergent-modeling design heuristic helps instructional designers in developing topic-specific instruction theories and corresponding instructional activities that support learning processes in which students construe new mathematical reality. In order to clarify the emergent modeling heuristic, we will briefly describe an exemplary instructional sequence.

This exemplary sequence, which concerns linear measurement and flexible arithmetic, was developed in connection with a teaching experiment carried out at Vanderbilt University (Cobb, Stephan, McClain, and Gravemeijer, in press; Stephan, 1998). The underlying idea is that measuring by iterating measurement units can give rise to the construal of a ruler and that the ruler can subsequently support arithmetical reasoning about problems concerning incrementing, decrementing and comparing measures.

After a series of preparatory activities, the students start measuring with stacks of ten unifix cubes. They first iterate units of ten, then adjust by adding or subtracting ones. In this manner, measuring with tens and ones helps the students in structuring the number sequence up to 100. Next, the students create their own paper strip that is ten unifix cubes long. With that, a basis is being laid for the construction of a measurement strip that comprises ten units of ten; each subdivided into ten units of one cube. The idea is that, thanks to the history, measuring with the measurement strip is grounded in the imagery of measuring with units of ten and one. Thus, for the students, measuring with the strip signifies iterating a unit of ten cubes and a unit of one cube. Next, a shift is made from actually measuring items to reasoning about lengths when solving tasks around incrementing, decrementing and comparing measures that are not physically present (i.e. comparing the measures of the heights of sunflowers in the context of a sunflower contest). These tasks offer opportunities for developing solution methods based on curtained counting—using the decimal structure as a framework of reference. Numbers close to a decuple, for instance, can be identified by using that decuple as a referent, e.g. 64 = 60 + 4; 40 = 35+5. These relations can be exploited when analyzing patterns that correspond with jumps of 10. An empty number line is introduced as a means for symbolizing measurement strip-specific, arithmetical solution methods that are grounded in reasoning with “tens & ones” (see fig. 1). A jump on the number line describes a move on the measurement strip that in turn can be seen as corresponding with iterating unifix cubes or smurf bars.
Finally a generalization is made from magnitudes to numerical quantities in general; the students are asked to solve various addition and subtraction context problems, while using the empty number line as a means to record and support their thinking.

**Emergent Models**

We will use this example to explicate the emergent modeling heuristic. We may start by noting that the label “model” is used in a metaphorical sense. There is an overarching model that takes on various manifestations. We may characterize the series of symbolizations within which the model manifests itself as a chain-of-signification (Stephan, 1998). In the exemplary sequence the ruler is conceived as the overarching model. The idea is that the ruler emerges as a model of iterating a measurement unit (or measurement units). In this sense, the ruler is grounded in the activity of measuring. Gradually, however, the ruler changes character, as the attention shifts from measuring to reasoning about the results of measuring. Finally a schematized ruler becomes a model for reasoning about arithmetical relations between numbers up to one hundred.

Key for us is that the shift towards more formal mathematical reasoning is connected with the creation of a new mathematical reality. In the example sequence, we may conceive this new reality as constituted by numbers up to 100 as entities in a framework of number relations. What is expected is, that in the course of the sequence, a shift is taking place in which the student’s view of numbers transitions from referents of distances to numbers as mathematical entities. This shift involves a transition from viewing numbers as tied to identifiable objects or units (i.e. numbers as constituents of magnitudes; “37 feet”) to viewing numbers as entities on their own (“37”). For the student, a number viewed as a mathematical entity still has quantitative meaning, but this meaning is no longer dependent upon its connection with identifiable distances, or with specified countable objects. In the student’s experienced world, numbers viewed as mathematical entities derive their meaning from their place in a network of number relations (see also Van Hiele, 1973). Such a network may include relations such as 37=30+7, 37=3\times10+7, 37=20+17, 37=40-3. The critical aspect of this network is that the students’ understanding of these relations transcends individual cases. That is, when students form notions of mathematical entities, or mathematical objects, they come to view relations like the above as holding for any quantity of 37 objects (including a magnitude of 37 units). We would denote this conception of numbers as mathematical objects that derive their meaning from a framework of number relations as new mathematical reality.
As an aside, we want to remark that we prefer to limit the use of the model-of/model-for terminology to those more encompassing shifts where one can speak of the creation of new mathematical reality. We may further note that this creation of new reality is reflexively related to the model of to model for transition. On the one hand, the students’ actions with “the model” foster the constitution of new mathematical reality (in our example, a framework of number relations). On the other hand, through the students’ development of this new mathematical reality, “the model” can take its role as a model for mathematical reasoning.

**Aims and Applications**

The emergent modeling heuristic may guide instructional designers by asking them to think through the endpoints of a given instructional sequence in terms of new mathematical reality; to describe what mathematical objects the students are expected to construe, and how these relate to some framework of mathematical relations. They are further advised to think through the model-of/model-for transition, which for instance means, to indicate what informal situated activity is being modeled, and what a potential chain-of-signification might look like. In connection with the above, the heuristic suggests points of attention for the enactment of the instructional sequence. It highlights that formalizing is not equal to, and cannot be forced by, the use of formal notations. Instead formalizing grows out of a shift of attention towards mathematical relations. The aforementioned considerations will indicate what those relations are, what the mathematical issues are that are to become topics of discussion, and what role the various tools/symbolizations may play.

The emergent modeling heuristic implicitly or explicitly plays a role in various RME designs (e.g. Streefland, 1990). The role of emergent models is older that the explicit characterization presented here. However, more recently this heuristic has explicitly guided design and analysis in a number of developmental research (or design research) projects. In this respect, we can claim that this heuristic is validated in a number of teaching experiments. Next to experiments at the primary-school level, like the aforementioned numberline experiment, we want to mention research in data analysis (Cobb, in press), and research on differential equations (Rasmussen, 1999).

REACTION

Anna Sierpinska

This "reaction" will be about my rather unsuccessful attempts at understanding the three proposed theories. Words were familiar, all right. But they were put together in strange juxtapositions and concatenations. I could recognize the words or parts of them - activity, perception, abstraction, procedure, process, concept, proCEPT, PROcept, object, structure...- but I couldn't build-with them, never mind construct anything remotely resembling a structure with them.

I was taught in school that "meaning belongs first of all to the world of objective-historical phenomena" (Leont'ev, 1959, p. 223), and that the content of an individual mind is a result of "an assimilation of the experience of the previous generations of people" (ibid.), but here I was, confronted with the meanders of individual consciousnesses of several "Robinson[s], making [their] own independent discoveries on a desert island" (Leont'ev, 1959).

Take, for example, ABSTRACTION. I am used to thinking of abstraction as a dual mental activity whereby some aspects of the object of thought are ignored while other
are highlighted. For example, if the object of my thought are integers and I decide to ignore multiples of 2, then all that is highlighted are the remainders, 0 or 1, and I end up with the even/odd distinction (or the concept of even and odd numbers, if you will). If I now highlight the mental process which led me to the construction of the even/odd numbers construction, and disregard the fact that I was ignoring multiples of 2, and decide to now remove from the field of my attention multiples of 3, 4, or any number n, for that matter, then I end up with the concepts of Euclidean division, and congruence modulo n. I can further ignore the specific nature of particular integers, look at the whole arithmetic of integers from afar, highlight only its ring structure and ask myself if I could not do something similar with other rings as well. I may fancy taking R[x] and decide to ignore multiples of $x^2 + 1$. Then what is highlighted forms a structure strikingly similar to the field of complex numbers. This chain of ignoring and highlighting is usually called generalization: a process of abstractions which starts from some object of thought $O_1$ and arrives at an object of thought $O_2$ such that $O_1$ is a special case of $O_2$. If abstraction is understood this way, as an act of ignoring/highlighting, then it appears as an "elementary particle" in the process of mathematical thinking. One would hardly want to call the whole process of theory building in mathematics "abstraction". Even the processes of single concept construction involve more than a few acts of abstraction. This concept of abstraction is too elementary to capture what happens in processes of mathematical thinking. It is also not specific to mathematics nor any scientific knowledge for that matter. Abstraction is an elementary operation in any kind of thinking. For example, we engage in abstraction when we move from saying that our neighbors seem to be a happy couple to thinking about happiness in general. Therefore, in speaking about mathematical thinking, we need more specific concepts such as generalization and concretization, formalization and de-formalization, algebraization and geometrization, axiomatization and modeling, etc.

The above socio-cultural notion of abstraction appeared not to satisfy the authors of the RBC theory presented in this forum. SHD (here and in the sequel, G, GT, and SHD will indicate the three groups of authors, according to the initials of the family names of their authors) were inspired by Davydov's definition of abstraction, which they interpreted as, "abstraction starts from an initial, undeveloped form of knowledge and ends with a consistent and elaborate form. It proceeds from the idealization of the basic aspect of practical activity involving objects to cognitive experimentation characterized by the fact that one (a) mentally transforms objects during the activity and (b) forms a system of connections between these objects". I didn't quite see how this description would exclude mental activities such as fantasizing. Imagine a poor man sitting there in his boat with a fishing rod and idealizing the basic aspect of his activity as dreaming about a big catch. Cognitively experimenting with his vision of a big catch, and dreaming about how this would impress his wife upon his return home, his vision was suddenly transformed into a half-fish/half woman. This way, the notion
of mermaid has been proved to be a socio-cultural consequence of the division of labor in the poor man's household, and fantasizing – a special case of abstraction.

SHD's own definition of abstraction was as follows: "Abstraction is an activity of vertically reorganizing previously constructed mathematics into a new mathematical structure". Now, this was very confusing because the statement was at the same time very restrictive (restricted to mathematical abstraction) and very general. It was general because it seemed to identify all construction of mathematical knowledge with mathematical abstraction. It was confusing also because it was circular. The circularity was, in particular, in the definition of the genesis of abstraction as "passing through (a) a need for new structure; (b) the construction of a new abstract entity; (c) the consolidation of the abstract entity...". Thus the product of abstraction should be an "abstract entity", but I was not informed what the authors understood by "abstract entity".

While SHD stressed that, for them, abstraction was a mental activity, GT assumed that it is was a product of mental activity, "in which a complex parallel processing organ solves the problem of complexity by focusing on essential structures that enable decisions to be made". GT's notion of abstraction had the properties of the notion I was used to, namely those of ignoring some aspects while focusing on some other aspects, and I felt quite comfortable with it. I was less at ease with the rest of the theory and especially with the interpretations of the students' mathematical behavior that this theory afforded. The focus was entirely on the biology of cognition, in abstraction from the social and institutional situation, in which the learning of mathematics normally takes place. For GT, "essential structures" of the problems they presented to the students were always certain mathematical structures, those structures they were themselves most familiar with. In the experiment with children being shown five red cubes and asked what would be worth remembering about them, children who chose to remember that there were 5 cubes happened to belong to the group of high achievers; those who chose to remember the color, the pattern or configuration were from the low achievers group. But who decided that remembering the number of the cubes was the right thing to do? Isn't this a matter of didactic contract? In a mathematics class, numbers are important. In communication or arts class, color and arrangement could have tremendous importance. Aren't some children failing because they have not figured out what is the didactic contract in each particular class? Because they have not figured out how school works and what one is rewarded for?

It is extremely dangerous to explain success and failure in mathematics at school by cognitive factors alone. We must take the didactic system as a whole and the student as a "perfinking" person (perceiving, feeling and thinking, David Krech cited in Bruner, 1987) in it as a whole. "Success in mathematics" is an institutional measure, not a measure of cognitive progress or capacity.

The examples of the contrasting behavior between high and low achievers in the area of algebra again suggest that low achievers are those who are bad at noticing what are
the rules of the game; in this case – what are the formal conventions of writing algebraic expressions, and when two functions are to be considered the same. They are strangers in the school mathematics culture. They would rather use a different syntax to express things, and how you get a result is important for them. How you get a result is important in programming computers; \(a(u + v)\) and \(au + av\), where \(u\) and \(v\) are vectors and \(a\) is a scalar are different functions in a CAS. The first involves \(n\) additions and \(n\) multiplications; the second - \(2n\) multiplications and \(n\) additions. How do you know that in this particular algebra class this does not matter? How do you know what is important and what is not in a particular culture? This is not mathematics thinking; this is socio-cultural thinking and some people are better than others in assimilating into a foreign culture. Some keep their terrribel forrreyn akzent for ever.

G, representing RME (realistic mathematics education) defines abstraction as an activity, which is comprised in the processes of mathematizing and seen as a two-way process: from less formal to more formal and the other way round. As in GT, abstraction is not an important concept in RME. More important is the assumption that, for the purposes of mathematics education, mathematics should be seen as a human activity and not as a library of accomplished and polished theories. RME is a project of curriculum development, not a theory, although the developers have started formulating their epistemological assumptions and principles in view of building techniques (heuristics), technologies and theories of mathematical instruction. SHD claim that their theory is also an outcome of curriculum development activities but their focus in the papers is on a theory of learning. RME researchers focus on the design of tasks embedded in long term curriculum activities. They describe the activities and try to justify the design. Little is said about the classroom experimentations and the notion of "success" of an experiment is not defined.

What are the criteria of success? What have been the proofs of success? Results on TIMSS? G claims that in RME the developmental research is "evolutionary in the sense that theory development is gradual, iterative and cumulative. There is no theory with which to start. The initial, global theory is elaborated, refined and explicated during the process of designing and testing" (G, 1998, p. 282). This suggests the hope that the law of the "survival of the fittest" will guarantee progress in the long run. However, the law of the survival of the fittest does not imply that the best curricula and best conditions for learning mathematics are eventually going to be achieved. What is "the fittest" is often governed by the law of least resistance or the tendency of the educational system to short-circuit all scholarly activities that are costly in managerial effort and time and are not directly related to the preparation of students for passing the final examinations.

ABSTRACTION: WHAT THEORY DO WE NEED IN MATHEMATICS EDUCATION?

Paolo Boero

I will divide my reaction into two parts. In the first part I will follow the grid (“what is the theory about”, etc.). In the second part I will discuss the need for a theory of abstraction in mathematics education, and the requirements that, in my opinion, such a theory should meet, then I will reconsider the three theories from this personal point of view. In the sequel, G, GT, SHD will indicate the three theories (according to the initials of the family names of their authors).

According to the Grid...

Most of suggested reading criteria (What is the theory about? What assumptions are being made? What does the theory claim? What terms are used and what do they mean? How has the theory been validated?) are related to minimal, necessary requirements that each theory (as a “scientific theory”) must meet in human sciences (psychology, anthropology, sociology, etc.). The second part of the last reading criterion (What are the aims of the theory and what are its applications?) refers to a specific challenge for theorists in mathematics education.

More or less explicitly each presented theory satisfies the first and the third requirement. Here it seems to me that theories G and SHD deal with subjects that are rather close to each other (a common title might be “abstraction in context”, yet with a different meaning of the word “context” – see later), while in the case of GT the theory deals with mathematical content and related individual learning processes.

Different ways of satisfying the second requirement are followed within the above presentations of the three theories. In the case of GT, “assumptions” are intended as general assumptions derived from other theories in order to create an environment where the theory can develop and be better understood; in the case of G and SHD, general assumptions are internal to the theory and constitutive of the core of the theory itself. We can observe how G aims at self-sufficiency in the presentation of the theory, while SHD refers to existing general theories (especially “activity theory”). The second criterion poses some problems: in the case of G, what meanings may be attached to crucial terms in a self-sufficiency perspective? (See later). In the case of GT and SHD, what relationships to establish with related theories?

Concerning the latter problem, we can identify different attitudes in mathematics education research as well as in the GT and SHD presentations. In the GT case, an
autonomous elaboration (the procept theory) is linked to existing general theories in the field of psychology (Piaget's "Pseudo-empirical and reflective abstraction in arithmetic, algebra and calculus naturally focus on our notion of procept.") and used to reinterpret some other theories in the field of mathematics education: "We do not agree with Sfard or Dubinsky that the development invariably proceeds in a sequence we describe as procedure-process-procept". In my opinion the legitimacy of these links and re-interpretations should be carefully discussed. As concerns the specific section "What assumptions are being made?" in the GT presentation, in my opinion the need for this kind of discussion becomes ever stronger: for instance, beyond heuristic hints, what are the precise relationships between the "semantic squeeze" in Bruner's quotation, the "reduction in brain area involved", considered in neurophysiology studies, and the construction and functioning of procepts? In the SHD case, activity theory is taken as a fundamental reference. In my opinion, the adoption of an activity theory reference paradigm needs to consider the teachers' role as constitutive of the "learning" process (in our case, of the "abstraction" process). Indeed in Vygotsky's seminal work it is well known that a crucial, recurring term is "obucenie", that means "teaching and learning". Yet I see (in the article as well as in the SHD forum presentation) that this "joint activity" aspect is not sufficiently developed.

Let us come now to the most critical criterion: What terms are used and what do they mean? It is clear that the danger for a person like me, who was educated as a mathematician, did research in mathematics for some years and still teaches mathematics at the University level, is to apply such criterion in the strict way he generally uses when dealing with his students' mathematical performance. It is true that in the human sciences domain it is very difficult to give "definitions" in the same, strict sense. In most cases, definitions are reduced to some evocative words that suggest a meaning, and then the context provides the full meaning. But I think that within the same theoretical construction (a theory), or the presentation of a theory, a crucial term must have a rather precise meaning (in order to establish whether or not an object or a situation falls within its semantic domain) and keep it. From this point of view, I find that in G and SHD the meaning of some crucial terms is not sufficiently clear, while the meaning of other terms seems to change during the presentation of the theory. In particular, I refer to the following terms:

"Formal mathematics" (in G): "formal" according to a high level of formalisation? And/or according to a social (or academic) consensus about ways of presenting relevant concepts, validating statements, etc.?

"Mathematical reality" (in G): what is its psychological and epistemological status? A subjective construction (or re-construction)? A historically shared and inheritable production, rooted in mankind's needs and experiences? A set of shared conventions?
“Structure” (in SHD): one part of the axiomatic organisation of mathematical knowledge (e.g. “the structure of group”)? And/or the overall organisation of mathematical knowledge? And/or the organisation of mathematical thought?

“Context” (in SHD): in mathematics education, like in psycholinguistics, the word “context” takes different meanings:

- that of “situation context”: those factors affecting the mathematical performance that are related to the situatedness of the students’ activity (including social relationships in the classroom, environmental factors, etc.);
- that of “task context”: the task evokes specific “realities” and constraints; as a consequence, behaviours, schemes, etc. related to those “realities” are activated;
- that of “inner context”: in this case the attention is focused on the (internal) representation of the subject’s past and present experience.

These different meanings of the word “context” suggest different perspectives under which teaching and learning mathematics in the classroom can be considered. For instance, in the case of abstraction the second perspective suggests to choose peculiar tasks suitable for it, while the first perspective suggests to take into account the social interactions that the teacher must “orchestrate” in the classroom.

Concerning the **aims** and the **applications** of the three theories, they are very different. Here again there are strong analogies between G and SHD (the theories are intended to provide useful tools to plan and/or improve teaching projects, and better interpret what happens in the classrooms where planned teaching is implemented). In the case of GT, the focus is on interpretative aims and in particular on explaining “**why some students are so highly successful with symbols, whilst others are procedural at best**” (etc.). In my opinion, in mathematics education we need both types of theories, bearing in mind that a theory of the second type can develop in (or support) a theory of the first type, and that a theory of the first type can provide interesting research questions for theories of the second type.

Concerning **validation of theories**, it seems to me that (in relationship with their specific aims) each theory meets this requirement. However I must say that it is met not so much in the above papers as in the articles included in the references: this is an unavoidable, necessary consequence of the space limitations of presentations.

**Do we Need a General Theory of Abstraction in Mathematics Education? What Kind of Theory?**

Let us consider the following examples:

- a right-angled triangle is drawn on the blackboard; students draw right-angled triangles on their copybooks; the teacher illustrates Euclid’s theorem;
- the teacher writes on the blackboard: \((uv)'=u'v+uv'\), then \(\int xsinx dx\), then illustrates and justifies the well known method of integration of the \(xsinx\) function based on the law of derivation of products of functions;
the teacher draws a square on the blackboard, then one diagonal, then he proves (by the usual "reductio ad absurdum" proof) that the diagonal and the side of a square are incommensurable: \[ d^2 = 2s^2, \quad (d/s)^2 = 2, \] etc.

the teacher establishes a 1-1 correspondence between the set of even numbers and the set of all natural numbers, then defines "infinite sets" as those sets which are equivalent to a proper subset.

In each of these cases mathematicians recognise some specific aspects of "abstraction". Mathematics educators have tried to deal with these aspects in different ways. For instance, C. Laborde and B. Capponi define a (geometric) figure as the set of couples \((O, d_i)\), where \(O\) is the geometric object (e.g. the right-angled triangle) and \(d_i\) is one of the drawings that constitute the 'material representation' of the geometric object. Therefore the figure is the product of the abstraction process performed by the subject when, starting from a drawing (signifier) he or she thinks about the represented geometric object”. This definition of figure is useful to deal with some difficulties that students meet when they approach geometrical reasoning (for instance, the reference to the peculiarities of a drawn right-angled triangle, or the stereotyped representation of the height of a triangle). These considerations are specific to the kind of abstraction inherent in the first situation. For the second situation an entirely different theoretical approach to abstraction is needed. Indeed, the ‘material representation’ is related to the represented mathematical object in a completely different manner: on one side the ‘material representation’ is much more distant from the mathematical object, on the other it becomes the starting point for a chain of transformations performed on the written expressions according to general syntactic rules. The third example shows some partial similarities both to the first example and to the second. Let us consider the fourth example: the idea of “epistemological obstacle” was elaborated in order to cope with students’ difficulties inherent in "accepting" some cultural, “abstract” constructions like the “equivalence” between a set and a proper subset, which contradict our usual experiences about the sets of objects that we can describe extensively (i.e. by listing all their elements).

I add, as explicitly quoted in GT and in SHD, that general theories of abstraction already do exist in psychology.

A recurrent question for me, when reading the contributions for this panel, was: do we need a general theory of mathematical abstraction in mathematics education, i.e. a general theory suitable for describing and interpreting many typical phenomena of "abstraction” that intervene in teaching and learning mathematics and, possibly, controlling them (i.e. planning teaching in order to get the best results) by selecting pertinent variables and coming to predict the effects of actions on them?

In my opinion, a general theory of mathematical abstraction that would be of interest for mathematics education purposes should:

- cover most forms of abstraction currently met in teaching and learning mathematics at different school levels;
— interpret difficulties met by students in tackling abstraction in their approach to mathematical knowledge;
— point out relevant variables accessible to educational intervention;
— take into account relevant research in the field of epistemology of mathematics (as concerns reflection on abstraction) and cognitive sciences (as concerns general theories about abstraction, or specific theories about mathematical abstraction).

According to the first three requirements that I propose, each of the three theories offers some relevant contributions but also shows important weaknesses. G shows (through the example sketched in the PME contribution and other evoked examples) how some processes of abstraction can work, helping both the designers of teaching projects and teachers to plan and manage suitable classroom situations. But it seems to me that G does not cover processes of abstraction that are needed when a "break" is unavoidable in the transition from mathematical experience in real contexts to "formal mathematics". Moreover, the role of mediation played by the teacher, which is particularly crucial in this case, is not explicitly dealt with. GT is suitable to cover many "abstract" mathematical objects, but it seems to me that in my first example it does not provide much help in dealing with students' difficulties in managing the "abstract" notion of right-angled triangle (e.g. in the case of stereotyped images). And (being mainly a theory about mathematical objects in their relationships with generating processes) I see it might have some difficulties in dealing with the "abstraction" inherent in the activities (e.g. students' mathematical argumentation). SHD is a very general theory and it surely covers abstraction in a wide sense, but its current generality implies that some peculiarities are lost in specific cases. Perhaps in the future this theory will become suitable to deal in a productive way with all the examples provided at the beginning of this Section, but then the subject's individual processes should be better investigated in relation with the "situation context", the "task context" and the teacher's mediational strategies.

As concerns the fourth requirement that I propose, it seems to me that the three theories do not take sufficiently into account important, new streams of research in epistemology of mathematics, psychology and neurophysiology that are developing in different research communities. Recent joint studies in the fields of epistemology and neurophysiology (for an example the project "Geometry and cognition" at the ENS, in Paris) show the possibility of a convergence on the idea that even at the highest level of "abstraction" productive reasoning relies upon very "concrete", body related intuitions. This approach puts again into question, but within a new perspective (neurophysiology investigation), the idea of a purely conventional character of axioms and axiomatic theories; the anti-logicist positions have opposed this idea during the whole XX century under different perspectives (mainly philosophical or ideological or based on introspection). This approach also draws an almost entirely new picture of how high level professional mathematical activities are performed. It seems very interesting and promising that this stream of research goes in the same directions of
some other streams of research in different disciplines (in particular, "embodied cognition", in psycholinguistics and psychology).

If it is true that "thinking abstract objects as if they were concrete" is possible, but "thinking in an abstract way" is impossible (as far as productive thinking is considered), then a theory of abstraction suitable for educational purposes should take charge of the whole complexity of the relationships between mathematical objects, the thinking processes concerning these objects, their "situatedness" in the classroom environment (the mediational role of the teacher being a crucial issue), and the most suitable "task contexts" for meaningful mathematical abstraction (both as concerns the mathematical content involved and the body-rooted processes). From this wide and very demanding point of view I think that the presented theories offer some important contributions, but we are still far from a comprehensive theoretical answer to the challenge of mathematical abstraction in mathematics education.

THE NATURE OF MATHEMATICS AS VIEWED FROM MATHEMATICS EDUCATION RESEARCH

Introduction

Lyn English, Queensland University of Technology
Gerald A. Goldin, Rutgers University

How we conceive of mathematics has a major bearing on our educational efforts. The nature of the mathematical ideas we consider essential for success in the new century, and the ways in which these ideas are conveyed during the school years, can facilitate or impede students' lifelong mathematical understanding, learning, and communicating. Though we have made significant advances in mathematics education research, fundamental issues of intellectual importance having political, social, and economic ramifications, continue to be debated. These issues include: (a) What counts as mathematics? (b) What is the nature of mathematical ideas? (c) What is the relative importance of these ideas to society? (d) What is the nature of the various representations these mathematical ideas may take (both internal and external to the student)? (e) What are the processes by which these ideas are understood by students? (f) How might we maximize students' understanding of these mathematical ideas?

Among the viewpoints are those that consider mathematics and the direction of its growth to be shaped by a complex system of cultural, social, and political forces (e.g., D'Ambrosio, 1999; Skovsmose & Valero, 2002). Lerman (2000) refers to the "social turn" in mathematics education, which came into being towards the end of the 1980s. The social turn saw the emergence of theories that view mathematics and mathematical meaning and reasoning as products of social activity. Social constructivists, for example, emphasize the processes through which consensus develops in determining the nature of mathematical knowledge and how it is constructed.

Complementing the sociocultural perspectives are those that draw on advances in cognitive science to explain aspects of the structure of mathematics and its development. Included here are analyses of external mathematical representational systems (e.g., mathematical symbolism, computer microworlds, structured analogues, diagrammatic structures) and internal systems (e.g., verbal/syntactic systems, imagistic systems, conceptual metaphors, mental models). The nature of the interactions within and between these representational systems is considered to play a powerful role in learners' mathematical growth.
Theories that lie within the broad sociocultural framework, along with the more cognitively oriented theories, are contributing to current debates about what mathematics students should learn, how they should learn it, and the extent to which school mathematics curricula should capture the essence of workplace mathematics (e.g., see Stevens, 2000).

A comparatively recent and controversial cognitive perspective on the nature of mathematics is that of "mind-based mathematics" (Lakoff & Nunez, 2000). Here mathematics is not inherent in the universe, nor is it merely a cultural artifact; rather it is shaped essentially by the nature and structure of human brains and minds via "conceptual metaphors."

There are varying perspectives among both mathematicians and mathematics educators on the aforementioned issues. It is important for educators to consider mathematicians' points of view, especially in light of the current curriculum debates highlighted by the media in several nations. Will mathematics educators and mathematicians find intellectually sound ways of connecting differing perspectives, or will existing gaps widen further?

The papers in this Forum provide critical debate on the issues we have addressed. Brian Greer argues that mathematics, mathematics education, and mathematics education research are situated in "sociohistory, culture, and politics." On a somewhat different note, Laurie Edwards presents a "personal journey" on the nature of mathematics, where she illustrates the perspective that mathematical ideas are shaped in fundamental ways by our embodied experience in the world. The importance of communication is emphasised in Anna Sfard's paper, where mathematics is seen as a discursive activity, that is, "a special way of communicating." Within her communicational framework, thinking is regarded as a special case of communicative activity. Another interesting perspective is presented by Shlomo Vinner who addresses boundaries, identities, and mathematical objects in his discussion of mathematics and mathematics education. Hartwig Meissner, on the other hand, explores the distinctions among "Einstellung" (attitude), "Vorstellung" (internal image) and "Darstellung" (external representation) in addressing mathematics and the processes of mathematics learning. Gerald Goldin extends Meissner's ideas in his discussion of representational systems, and provides critical thought on the sources of the "widening chasm" between mathematics and mathematics education.
Complexity of Mathematics in the Real World
Brian Greer, San Diego State University

Perception of the relationships among mathematics, mathematics education, and mathematics education research used to be simple.

Mathematics was seen as a relatively well-defined, hierarchically structured, body of knowledge. Mathematics education meant transmitting this body of knowledge to each student up to an appropriate level in the hierarchy. Psychological research was expected to provide general theories of cognitive development and learning, with the assumption that these theories could be applied to the learning of mathematics as a domain and the improvement of (mathematics) education through generating hypotheses testable via standard experimental designs. Many mathematicians and psychologists taking a more or less informed interest in mathematics education feel comfortable with this simplicity (for example, in the context of the Californian Math Wars, see the analysis of the unholy alliance between psychologists and mathematicians by Jacob and Akers (1999)).

However, the situation has become more complicated.

First, mathematics continues to grow fast and computers have changed both its content and its methods. Consequently, questions of selection and arrangement arise — what parts of mathematics should be chosen and how should they be reorganized for education? Typically, curricula are largely the result of tradition and inertia and, insofar as growth occurs, it is mainly through accretion without radical restructuring. There is very little by way of principled design — consider the limited adaptation to the new representational systems afforded by computers, for example.

Second, the first wave of the cognitive revolution generated disequilibrium when it became clear that there was "de-emphasis on affect, context, culture and history" (Gardner, 1985, p. 41). The outcome was the "second wave" (De Corte, Greer, & Verschaffel, 1996, p. 497) which mathematics education research both contributed to, and was influenced by, in major ways. Methodologies became interpretative rather than scientific, with results that are liberating or anarchical, depending on your point of view. The work of some researchers now exemplifies Engestrom’s proposed methodology for activity theory that puts it to "the acid test of practical validity and relevance in interventions that aim at the construction of new models of activity jointly with the local participants" (Engestrom, 1999, p. 35).
Inevitably, mathematics education researchers' views of mathematics have been complicated by their immersion in activity systems, including exposure to the culture of the classroom, the nature of schooling, and the politics of mathematics education. Mathematics, mathematics education, mathematics education research are all situated in sociohistory, culture, and politics.

To illustrate the foregoing comments, I offer sketchy outlines of three key characteristics of mathematics (revealing my own biases, naturally) and how they play out in mathematics education and mathematics education research.

**The Two Faces of Mathematics**

On the one hand, mathematics is rooted in the perception and description of the ordering of events in time and the arrangement of objects in space, and so on ("common sense -- only better organized", as Freudenthal (1991, p. 9) put it), and in the solution of practical problems. On the other hand, out of this activity emerge symbolically represented structures that can become objects of reflection and elaboration, independently of their real-world roots. In the process, common sense is soon transcended, yet, time and again, the results of such elaborations have proved (often after a considerable lag in time) useful in theoretical descriptions of real-world phenomena and solution of real-world problems. (De Corte, Greer, & Verschaffel, 1996, p. 500).

The link between the two faces of mathematics is the activity of modeling. Typically, the modeling of a real-world situation leads to a range of solutions that need to be judged in terms of human criteria such as utility, purpose, and complexity. Introducing pupils early to this perspective may be considered part of the process of enculturation into the practices of mathematicians, yet until relatively recently, it has not received much attention (Niss, 2001; Verschaffel, 2002).

**The Developmental Nature of Mathematics**

"Mathematics grows ... by its self-organizing momentum" (Freudenthal, 1991, p. 15). In the course of the sociohistorical construction of mathematics, several developmental mechanisms may be identified:

(a) The disequilibrium that comes from lack of closure. The obvious example is the extension of the concept of number from its origins in natural numbers. (It seems to me that there is a clear parallel with Piagetian theory but I am not aware of anyone who has explored this idea in depth).
(b) Metaphorical extension, which has been elaborated in the recent book by Lakoff and Nunez (2000) (and see Edwards). Why are all those different things all called “numbers”? (Poincare defined mathematics as the art of giving the same name to different things).

(c) Variations on the theme of reification (e.g. Sfard, 1991, and see Vinner).

(d) Mediation by cognitive tools, as illuminated by the Vygotskian tradition—language (see Sfard), symbols, representational systems (see Goldin, Meissner).

(e) Systematization, including the development of axiom systems. The history of attempts to teach mathematics on this basis is well known.

It has been pointed out that a major reason for the difficulty of mathematics education is that children are expected to master in a few years concepts that took humankind millennia to develop. All of the above developmental processes have ramifications at the ontological level. In particular, analyses of developmental obstacles represent one broad focus for the continuing relevance and usefulness of cognitive analyses (Greer, 1996).

Mathematics as Cultural Construction

“Mathematics as a human activity” has become a principle cutting across developments in mathematics education, new directions in the philosophy of mathematics education (e.g. Hersh), and influences on mathematics education from critical pedagogy, ethnomathematics, feminist critiques, historical perspectives, and so on.

For balance, it should be remembered that the proof of Fermat’s last theorem, and the pages of complex formulae that Ramanujan sent to Hardy also represent human activity and require an account of the coherence and continuity of cognitive processes within an individual brain over an extended period of time however mediated by social environments (Greer, 1996).

Mathematics as a Form of Communication

Anna Sfard, The University of Haifa, Israel

Many different answers have been offered to the question What is mathematics? throughout history, but the definition given by Henri Poincare is the one which I find particularly useful. According to the French mathematician, mathematics is the science of calling different things the same name. This deceptively simple statement, if interpreted in a way not necessarily intended by Poincare himself, can be seen as a forerunner of the communicational vision of mathematics. In what follows, I outline this special
approach in general terms. The presentation is organized as a series of questions and answers.¹

Q1. What is mathematics?

A1: It is a kind of discourse (a way of communicating)

The first thing to notice in Poincare’s definition is that by putting the issue of naming in the center of our attention, it implies that mathematics is, in principle, a discursive activity. In other words, mathematics is a special way of communicating. One can oppose saying that it is thinking rather than communicating that should be given prominence in the definition. My answer to this is that thinking is already included in the term communication. Indeed, according to the basic tenet of the communicational framework, thinking can be regarded as a special case of communicative activity.

Q2. What renders mathematical discourses their unique identity?

A2. Their use words, their visual mediators, and their special routines.

After bringing the discursive activity to the foreground, Poincare gives a hint as to what makes mathematical communication distinct: It is the mathematicians’ special propensity for unifying many different things under the same name which is the hallmark of the mathematical discourse. True, using the same word as a signifier for many different signifieds is not unique to mathematics – this activity is the very essence of conceptualization, and as such it is a vital ingredient of any communication. Mathematics, however, exceeds all the other types of discourse in the range of things included under each of its terms. This special tendency of mathematicians to speak of sameness even when what reveals itself to their eyes (and ears) appears different, is known as their propensity for abstracting.

Please note that within the communicational approach, the adjective ‘abstract’ refers to the way words are being used in the discourse, and not, as is often the case within other conceptual frameworks, to a special property of objects that are being talked about. More generally, the use of words is the first of several properties that one has to consider while trying to decide whether the given discourse can be called mathematical. While becoming a participant of the mathematical discourse, the learner often modifies her uses of known words and then introduces new words which from now on will serve as common names for sets of things that until now were never considered as “the same”.

Two additional dimensions along which mathematical discourse can be distinguished from other types of communication are their special mediating
tools (or simply mediators), that is, visual means with which people help themselves while communicating; and their distinct discursive routines with which the participants implement well-defined types of tasks. Let us say a few words about each of these special discursive features.

Mediators. Unlike in the less abstract, more concrete discourses which can be visually supported with objects existing independently of the discourse itself, mathematical communication is mediated also, and sometimes exclusively, by symbolic artifacts specially designed for the sake of communication. Contrary to what is implied by a common understanding of a tool in general and of symbolic tools in particular, within the communicational framework one does not conceive of the communication mediators as mere auxiliary means that come to provide expression to pre-existing, pre-formed thought. Rather, one thinks about them as a part and parcel of the act of communication and thus of cognition.

Discursive routines are patterned discursive sequences that the participants use to produce in response to certain familiar types of utterance expressing a well-defined type of request, question, task or problem. In the case of mathematical discourses, the routines in question are those that can be observed whenever a person performs such typically mathematical tasks as calculation, estimation, explanation (defining), justification (proving), exemplification, etc. The routines with which interlocutors react to the given type of request (e.g. “estimate” or “justify”) may vary considerably from those employed in response to a similar question asked in everyday setting. One of the special characteristics of full-fledged mathematical discourse is that its routines are particularly strict and rigorous.

Finally, let me explain why the question I am answering now speaks of “mathematical discourses”, with the plural form implying that there is more than one type of communication that can count as mathematical. Although the same words can be used on many occasions, the rules that regulate this use may vary from one setting to another. Similarly, although seemingly speaking of the same things (quantities, geometric shapes) discourses may differ in their mediators and in their routine interpretation of what appears as the same tasks. Thus, we have a good reason to speak of different types of mathematical discourse, distinguish between everyday mathematical discourses, school mathematical discourse, and the discourse of professional mathematicians (cf. Rittenhouse, 1998).

Q3. Why do we need mathematical discourse?
A3. For the sake of economy of communication, for its maximal effectiveness, and to solve problems that could not be solved before.

The brief answer A3 above points to three reasons because of which mathematical discourses came into being and developed the way they did. The last of these reasons seems quite obvious, so I will elaborate here only on the other two.

The economy of communication is attained by the very property Poincare was talking about: By calling different things the same name, mathematical discourse subsumes several former, independently existing discourses, turning them into discourses “about the same thing” and making it possible to express in the new language everything that can be said in any of them with their own special signifiers. For instance, while saying that “three and two equals five” we simultaneously express a truth about fingers, dollars, kilograms, and infinity of other countable objects. The successive discursive “squeezing” exists also within the mathematical discourse itself. For example, the discourse about functions subsumes discourses about graphs and the discourse about algebraic expressions.

The issue of effectiveness must be considered when one asks why the meta-rules of mathematical discourse developed the way they did. It seems that it has always been an undeclared hope of the mathematicians to create a discourse that would leave no room for personal idiosyncrasies and would therefore lead to unquestionable consensus. Such consensus would imply certainty of mathematical knowledge. The exacting rules of the modern mathematical discourse are the result of unprecedented efforts of 19th- and 20th-century mathematicians to attain this unlikely goal.

Q4. What is mathematics learning?

A4. To learn mathematics means to change one’s discourse

Learning mathematics may now be defined as an initiation to mathematical discourse. It is important to note that the introduction to a new form of communication never starts from zero. Whether the discourse to be learned is on fractions, triangles, functions or complex numbers, it will be developed out of the discourses in which the children are already fluent. If so, to investigate learning means getting to know the ways in which children modify and extend their discursive ways in the following three respects: in vocabulary they use, in the mediators they employ, and in the discursive patterns (routines) they follow.

Q5. How does the learning occur and what can we say about teaching?
This is the very central question math ed researchers are asking. The issue is extremely complex and it would be imprudent to try to summarize it in a few sentences. I thus leave this last question without an answer. Here, let me just say a few words about the expected impact of the communicational conceptualization on the vision of learning and teaching mathematics.

Perhaps the most dramatic difference between the more traditional, cognitivist vision of mathematical thinking and the one discussed in this paper lies in their conception of the origins of mathematical learning: The traditional approaches assume that learning results from the learner's attempts to adjust her understanding to the externally given, mind independent truth about the world, and thus imply that, at least in theory, the learning could occur without the mediation of other people. In contrast, the idea of mathematics as a form of discourse stresses that individual learning originates in communication with others and is driven by the need to adjust one's discursive ways to those of other people.

What is the added value of this conceptual shift? First, if we agree that the site of mathematical learning is between people rather than beyond them, we also realize that social and cultural factors are those that enable the process of learning in the first place. Second, the communicational conceptualization helps us to see an inherent complexity of learning: The idea of thinking as a form of communication and of mathematics as a kind of discourse, if taken seriously, makes us realize that in the process of learning mathematics, the students' awareness of the proper use of words and symbols must precede their ability to account for this use. This vision of learning is bound to entail a revision of some popular interpretations of the idea of learning-with-understanding. Finally, the communicational approach brings second thoughts about many other pedagogical believes as well. As has been argued in many places, some of these beliefs must be modified, while some others would better be abandoned altogether. Much work is yet needed to examine the practical value of this theoretical change.

The Nature of Mathematics: A Personal Journey
Laurie D. Edwards, St. Mary's College of California

What counts as mathematics? What is the nature of mathematical ideas?

The questions that frame this Research Forum are clearly foundational to the practice of mathematics education. I would like to address these questions not by proposing definitive answers, but by reflecting on my own experience as a researcher over the past 18 years. During this time, my own thinking about the nature of mathematics has evolved, in parallel with the emergence of the
theoretical frameworks discussed in this Forum. I hope that the examination of a particular "case" of changing theoretical perspectives in a single body of research may be instructive.

My first major research project involved the creation of a computer-based learning environment for a specific mathematical domain, transformation geometry. As with many studies of students' mathematical thinking, the research revealed "errors" in the children's thinking, interpretations that differed from accepted mathematical truth. An example of such an "error" is described in this passage:

The rotate bug...is an error in conceptualizing a transformation...Instead of imagining the entire plane rotating around the center point...these students thought that the shape would first slide over to the specified point, and then turn around it in place." (Edwards, 1989, p. 107-8).

The characterization of the students' interpretation of rotation as an error, as well as the entire framing of the research, reflected an objectivist view of mathematics (Edwards & Núñez, 1995); indeed, it exemplified what Lakoff and Núñez call "the Romance of Mathematics" (Lakoff & Núñez, 2000). According to this view, "Mathematics is an objective feature of the universe; mathematical objects are real; mathematical truth is universal, absolute, and certain" (ibid., p. 339). In other words, mathematics has a transcendent existence, apart from any human knowledge of it. The implication of this view is that our role as educators and researchers is to design more effective instruction about, and representations of, this mathematical reality.

Lakoff and Núñez acknowledge that there is no way to determine, empirically, whether mathematics indeed has such a transcendent existence. However, it is clear that the teaching and learning of mathematics always takes place within specific social contexts, and that simply characterizing students' understandings as "correct" or "incorrect" does not go very far in helping to improve learning. Thus what Lerman has called "the social turn" in mathematics education has come to the fore (Lerman, 2000). This change in focus from evaluating the adequacy or inadequacy of individual cognition to investigating the irreducibly social nature of learning and teaching emerged in my own research as well, One specific area in which this framework became important was in the investigation of mathematical explanation and informal proof. I first used the transformation geometry microworld with 11-year-olds. In addition to the occasional "bug" in the students' understanding of the transformations, I also found that few students were able, independently, to generate explanations or informal proofs for the patterns they were guided to discover in the
microworld. At the time, I attributed this to the students' age and level of intellectual development. I expected that when I used the microworld with older students, they would be able to, fairly spontaneously, notice and explain these informal theorems that seemed so obvious in the microworld. This turned out not to be the case: the older students behaved very much like the younger children with regard to their mathematical explanations – neither group was able to produce such explanations without some degree of scaffolding and interaction with the researcher. This led me to reconsider the nature of mathematical explanation and proof. Rather than expecting that, given a dynamic and accurate representation of a domain, students would be able to discover and explain pre-existing mathematical truths, I came to think of proving as a social process, one which needs to be explicitly modeled and scaffolded (Edwards, 1997).

Thus, in my own personal journey in thinking about the nature of mathematics, I moved from assuming that mathematical ideas were "out there," waiting to be discovered, to thinking of mathematics as a product of social interaction, a kind of language, a human practice with norms that must be learned over time. Yet the fact that mathematics is learned and practiced within social contexts begs an important question: within a given social context, why is it that mathematical ideas take the form that they do? And how is it that humans, as cognizing creatures, are able to co-construct systems of mathematical knowledge that are mutually intelligible? One answer, of course, might be that mathematical ideas take the form they do simply because of their objective, transcendent reality, that human beings are simply "perceiving" the way things are, mathematically. I found this answer unsatisfying, in part, because it seemed to set mathematics apart from all other products of human history and cognition. Instead, I found work on conceptual metaphor (Lakoff, 1987; Lakoff & Johnson, 1980) and embodiment (Varela, Thompson & Rosch, 1991) to be evocative, in pointing to a deeper level of cognitive structure upon which much of human thought and language is constructed. The reason that mathematical ideas take the form that they do, and the reason they are mutually intelligible, is because they are, at a foundational level, built upon the common experience of being humans, with the same kinds of minds and bodies, living and growing in the same physical world (Lakoff & Núñez, 2000; Núñez, 2000, Núñez, Edwards & Matos, 1999).

A concise statement of the implications of embodiment for understanding mathematics can be found in the work of Lakoff and Núñez:

- Mathematics, as we know it or can know it, exists by virtue of the embodied mind.
• All mathematical content resides in embodied mathematical ideas.

• A large number of the most basic, as well as the most sophisticated, mathematical ideas are metaphorical in nature.

(Lakoff & Núñez, 2000, p. 364).

I would like to offer an example of the application of this perspective by returning to the "rotate bug," described above. This interpretation arose after the students were introduced to what was, for them, a new mathematical idea – they had never been taught about geometric transformations before. Yet the "idea" of turning was not new to them – indeed, the embodied experience of moving through the world, from a very early age, includes innumerable instances of turning one's own body. However, this experience of turning is different in an important way from the mathematical version of rotation instantiated in the microworld. This general transformation, or mapping of the plane, could take place around any arbitrary center point, whether this point was part of, or distant from, the block letter L used to show the transformations.

The conceptual construction that the students made of the new mathematical idea of rotation of the plane was shaped by their embodied experience of turning in the physical world: the rotate "bug," in which rotations always take place around a point on the L-shape, can be seen as a metaphorical mapping from the experience of turning one's own body in place. It is worth pointing out that this metaphorical mapping was unconscious: there was no socially-communicated introduction of the metaphor; instead, the physically-grounded source domain existed prior to the introduction of the mathematical idea, and shaped its assimilation in the children's minds.

In fact, the researcher did introduce an explicit metaphor or image to help the students extend and generalize their understanding of rotation. I asked the students to think about an object at the end of a string, which could be turned, with the other end of the string being fixed in place. This explicit, socially communicated metaphor helped, I believe, to bridge students' initial "local" interpretation of rotation to the more general or global mathematical one.

These remarks are intended to communicate aspects of a personal intellectual journey, yet this journey is not one in which prior theoretical commitments are left completely behind. Putting aside the question of the objective existence of mathematics (which seems to be something of a religious question), I still believe that much of mathematics is socially constructed, and that in understanding teaching and learning, we must attend to particular social and cultural contexts. However, what is constructed, within these contexts is not
arbitrary: mathematical ideas, as they exist within, and are shared between, actual human minds, are shaped, in fundamental ways which we are still in the process of understanding, by our embodied experience in the world.

**Boundaries, Identities and Mathematical Objects – Should we bother?**

Shlomo Vinner, University of Israel

The proposal for this research forum raises the question whether mathematics educators and mathematicians will find intellectually sound ways of connecting their differing perspectives and reinforce each other’s ideas, or whether the existing gaps will widen further. I assume that the mathematicians mentioned here are the university mathematicians who teach tertiary mathematics. Some of them are not interested in teaching mathematics since their main interest is mathematical research. Others, in case they care about teaching, have their own views on how to do it and do not believe that mathematics educators have useful advice for them. Usually, mathematicians have vague ideas about who we are and what we do (there might be some exceptions). So, who is going to listen to us? One answer is that we can listen to each other. This is quite common for academic circles. A parody about such circles appears in Davis and Hersh (1981) where a handful of devoted mathematicians who work on the decision problem for non-Riemannian hypersquares is described (pp. 34-39). If we do not want to stay like them in the isolated ivory academic towers the alternative is to look for communities who can use our research findings. Such a community, and perhaps the only one, is the community of mathematics teachers. However, if we want to approach them it should be done within their intellectual frameworks and in their language. The nature of mathematics is undoubtedly an issue with which they have to be involved. But to what extent? Thus, this forum, whose title is *The Nature of Mathematics as Viewed from Mathematics Education Research*, is a good opportunity to raise some questions about mathematics education research that deals with the nature of mathematics. To be more specific, my question is the following: What aspects of the nature of mathematics are relevant to the community of mathematics teachers, and what aspects should be kept for our closed circles where we can discuss any subject at any level of sophistication. Asking that, I am, in fact, raising two questions. One is about boundaries and the second one is about identity. The one about boundaries is: What are the boundaries of mathematical education research that are relevant and meaningful to mathematics teachers. The one about identity is: What is the purpose of mathematical education research? In fact, this is an identity question about our group and it has been
raised in the past several times by several people. One of them was in Ballachev’s letter from 1996. Questions about boundaries and identity have more than one answer. So, what I suggest here is only one possible answer out of many. I suggest trying to define a restricted domain of mathematical education research which I will call the core and which will have an immediate simple application to the practice of teaching. Some other issues, which imply a level of sophistication that teachers do not have, will be considered as peripheral.

The nature of mathematics has many aspects. One of them is the nature of mathematical objects. Some time ago, a student of mine (she is a junior high mathematics teacher) came to me complaining: “You sent us to take a course in the philosophy of mathematics,” she said, “and the lecturer spent three weeks discussing the question: what are objects and what are mathematical objects? What is the point of it?” I was quite irritated by the question but as a teacher, I have trained myself to control my reactions and to try to tolerate and to understand my students’ views. “Isn’t this question relevant to our research forum?” I asked myself and decided to discuss it here. First of all, I would like to explain why the question of mathematical objects is such a crucial question in the philosophy of mathematics. According to mathematical logic and model theory, mathematics is a collection of theories about mathematical systems. A mathematical system is a set of abstract objects with relations and operations that fulfill certain primary conditions. The mathematician’s task is to discover some interesting claims about the mathematical systems implied by these primary conditions. Whether you accept this or not, it can explain why the problem of mathematical objects is so crucial for the philosophy of mathematics. But is it also so crucial to mathematics education research? Even a short literature survey will show us that many mathematics educators are involved in investigations about this issue. In a paper by Tall et al. (2000), there is an attempt to draw certain boundaries between some approaches to mathematical objects in mathematical education research. When one speaks about boundaries one has to speak also about territories, but Tall et al. (p.233) speak about scopes, not about territories. Hence, what I say here is my interpretation of their formulation. Their paper discusses three approaches to mathematical objects: In the first two, an attempt is made to explain how mathematical objects come into being in the human mind: it is either by encapsulation (Dubinsky, 1991) or by reification (Sfard, 1991). The third one (Gray and Tall, 1994) does not bother with the question of how mathematical objects come into being. It assumes that people think and speak about mathematical objects. However, it draws our attention to the fact that some
mathematical terms and mathematical symbols are ambiguous. These terms and symbols denote both processes and objects or, if you wish, both processes and concepts. This led Tall and Gray to invent the notion of procept. If you look at it this way, the discussion in the above paper (Tall et al, 2000) is, in fact, about boundaries. If you agree to accept mathematical objects without trying to ask how they are formed then some controversies are moved from the core to the periphery. A serious objection to excluding the mathematical objects from the core might claim the following:

People fail in mathematics because they have not constructed in their mind the mathematical objects required in order to perform the mathematical tasks imposed on them. We should lead them through well-designed activities in order to construct in their mind the required mathematical objects. Therefore, these activities should be an essential part of the mathematical education research core. More specifically, we should make our students go through many processes that will eventually become (by encapsulation or reification) mathematical objects.

Since I wish to avoid controversies I will not argue with this claim. I would only suggest, as an alternative working assumption, a different view. Mathematical objects are a special case of abstract objects. The problem of abstract objects is widely discussed in the philosophy of language. There is the classical distinction between concrete nouns and abstract nouns. Please, note that we are speaking here about nouns and not about objects. Some nouns or noun phrases denote well-defined concrete objects. For instance: The dog of my mother in law. On the other hand, many nouns do not denote any object. For instance, is there any object in our world that is denoted by the noun milk? The question becomes even more embarrassing when abstract nouns are discussed. Are there objects in the world denoted by love, peace or compassion? Surprisingly enough, in our thoughts we relate to these nouns as if they denote objects. This is reification. The Webster’s Ninth New Collegiate Dictionary suggests that the word “reification” is in use at least since 1846 and it is the process or result of reifying. To reify is to regard something abstract as a material or concrete thing. Thus the working assumption which I suggest claims the following:

(1) There is a tendency in languages to introduce nouns even when no objects are involved (it probably facilitates talking about certain things.)

(2) Reification occurs spontaneously the moment a noun is introduced.

Because of time limitation I will bring only two short examples to support the above claim. 1. When teaching limits in Calculus, many of us use the term
"infinity" instead of saying "increasing unboundedly." However, in calculus (contrary to set theory), there is no object the name of which is infinity. In spite of that, many calculus students think of infinity as an object. 2. Even languages of primitive cultures have abstract terms. Levi-Strauss, the famous French anthropologist, in his book The Savage Mind (1966) illustrates this by some examples. Two of them are the following: In Chinook, a language widely spoken in the north-west of North-America, the proposition "The bad man killed the poor child" is rendered as: "The man's badness killed the child's poverty." And for "The woman used too small a basket" they say: She puts the potentilla-roots into the smallness of a clam basket" (p.1). The issue of reification is widely discussed in the major works of Quine (1960), 1981, 1995)). Finally, I would like to relate again to the claim that people fail in mathematics because they fail to construct the mathematical objects involved in their mathematical tasks. There are so many potential reasons for failure that it is impossible to isolate one factor and to claim that it is the cause for failure.

The way I suggest to understand the procept paradigm by Tall and Gray allows us to speak about processes, objects and concepts as primary notions. Namely, we do not have to explain what processes, concepts and abstract objects are. On the other hand, the procept theory points at a major obstacle in the learning of mathematics - ambiguity. Ambiguity is a serious obstacle in communication. On the other hand, it also enriches communication immensely. I suggest, however, that this issue will not be included in the core of mathematical education research.

Einstellung, Vorstellung, and Darstellung

Hartwig Meissner, Westf. Wilhelms-Univ. Muenster, Germany

Einstellung, Vorstellung, and Darstellung are keywords to describe the process of learning and understanding mathematics. Analyzing this process we do not rely on philosophical theories (Kant's ontology). We base our theory of learning and understanding mathematics on the following assumptions:

(1) Mathematics is "something" which exists independent from human beings or from human brains like trees, birds, genetic codes, time, space, electricity, gravity, infinity, ...

(2) There are external representations of mathematical ideas, Darstellungen, which we can read, or see, or hear, or feel, or manipulate, ... These Darstellungen can be objects, manipulatives, activities, pictures, graphs, figures, symbols, tags, words, written or spoken language, gestures, ... In a Darstellung the mathematical idea or example or concept or structure is
hidden or encoded. There is no one-to-one-correspondence between a mathematical idea, concept, etc. and a Darstellung.

(3) Human beings are able to "associate" with these objects, activities, pictures, graphs, or symbols a meaning. That means each Darstellung evokes a personal internal image, a Vorstellung (cf. concept image, Tall & Vinner, 1981). Thus Vorstellung is a personal internal representation, which can be modified. Or the learner develops a new Vorstellung. A Vorstellung in this sense is similar to a cognitive net, a frame, a script or a micro world. That means the same Darstellung may be associated with many individual different internal representations, images. Each learner has his/her own Vorstellung. And again here, there is no one-to-one-correspondence between a Darstellung and a Vorstellung.

(4) The process of building up a Vorstellung depends very much on the basic mentality of the learner, i.e. on his or her Einstellung. The Einstellung includes affective components like attitudes, beliefs, emotions, values (Goldin). The Einstellung affects attitudes towards learning in general, towards mathematics in general, towards problem solving, or towards the specific learning "environment". The Einstellung is a product of social interactions (with parents, teachers, peers, etc.), of genetic factors, of cultural or historical impacts, etc. Positive Einstellungen in the class room are necessary for a successful teaching-learning process. A learner with a negative Einstellung probably will not be very successful. Einstellungen work like a filter or a catalytic converter in the transformation processes Darstellungen ↔ Vorstellungen.

In this paper I concentrate on Vorstellungen and Darstellungen. The process of building up a Vorstellung very much depends on the already existing internal representations ("assimilation, accommodation" according to Piaget, "coherence, connectedness" according to Greeno) and on the already existing "subjective domains of experiences" (Subjektive Erfahrungsbereiche, Bauersfeld). Learning mathematics now means that the learner has to build up a Vorstellung which "corresponds" (especially in the sense of Greeno) as much as possible to the mathematical idea / concept / structure. But the learner does not experience the mathematical idea / concept / structure directly, the learner only is confronted with (different types of) Darstellungen. Figure 1 presents a summary of these ideas.
We are interested in the cognitive processes\(^1\). What does "learning" mean? And when do we "understand"? Learning obviously is the process of building up an "adequate" Vorstellung of a given mathematical situation (by means of "appropriate" Darstellungen). But the Vorstellung is individual and cannot be inspected or evaluated directly. With other words, there is no direct way to evaluate "adequate" or, there is no direct way to evaluate the degree of "understanding".

![Diagram of mathematical concepts and Vorstellungen and Darstellungen](image)

Figure 1: Examples of Vorstellungen and Darstellungen

We only can judge a Vorstellung by a corresponding Darstellung, that means "communication" is necessary. To prove understanding the learner must transform the individual Vorstellung into a Darstellung. And when the learner's Darstellung corresponds with one of the expected Darstellungen we may assume that the learner did understand. The problem is obvious. We do not judge a Vorstellung but we interpret a performance.

---

\(^1\) Despite a suggestion from the IC to "facilitate greater insight and engagement" we will continue the paper with the German words which are more precise than English translations.
To distinguish the *Vorstellung* from the performance we will speak of a *conceptual understanding* when the learner has an adequate *Vorstellung*, i.e. his or her internal representation corresponds appropriately to the given situation. A conceptual understanding also may be intuitive or unconscious. And of course, a conceptual understanding only can be demonstrated indirectly up to a certain degree, consciously or unconsciously, see examples.

To detect the student's conceptual understanding we still need *Darstellungen* from the student. But we must allow flexibility in the use of *Darstellungen*. Not the *Darstellung* itself is important but the *Vorstellung* behind that *Darstellung*. When there are misunderstandings concerning a specific *Darstellung* just change the *Darstellung* to clarify if the misunderstanding originates from the *Vorstellung* or from the *Darstellung*. Of course also non-standard *Darstellungen* can be used. Clinical interviews with experienced interviewers - and also experienced classroom teachers - can identify the student's conceptual understanding. Written tests - like TIMSS or PISA - usually cannot help to prove conceptual understanding.

Skemp distinguished between instrumental understanding and relational understanding. *Instrumental understanding* is characterized by selecting and applying appropriate rules to solve the problem without knowing why ("rules without reasons"). In our terminology specific *Darstellungen* are expected and it is necessary to (re-)produce them: "Tell me what to do and I will do so". There is no adequate mathematical *Vorstellung* behind.

An understanding with more *Vorstellung* behind it, was termed a relational understanding by Skemp (1978): "knowing both, what to do and why". Here an adequate *Vorstellung* leads to an expected *Darstellung*. We want to call this a *communicable understanding*. It combines both, the conceptual understanding with the ability to communicate in a wanted or given format. A person with communicable understanding is able to communicate flexibly in those *Darstellungen* which are expected or - according to the specific problem - in *Darstellungen* which fit best to the problem. We will give some examples to illustrate these various aspects of understanding.

---

2 In earlier papers we called this a relational understanding (which is different to SKEMP's relational understanding).

3 HOSPESOVA and TICHA found through interviews examples for both, "good conceptual understanding, but no expected TIMSS-Darstellung" and "correct TIMSS-Darstellung, but no adequate conceptual understanding".

4 For more details on the role of communication and communicational conflicts see Anna Sfard and Gerald Goldin in this Forum-paper.
Example 1 (Sorting objects)
A teacher and about 25 students (age ~9) are sitting around a set of about 40 geometrical solids. Teacher: "I have a rule in my mind to sort these solids. These two solids follow my rule. Who can find other solids which follow my rule?" Only directed by the teacher's YES or NO without any further explanations the set gets sorted into the set of solids which follow the rule and a second set (of counterexamples). This non verbal process of sorting objects by guess and test may lead to an intuitive concept (of polyhedra or rectangular solid or rectangle or ...), i.e. an (partly unconscious) conceptual understanding develops. But during the process of sorting in the classroom also discussions start to guess the "rule", to verbalize the situation. The concept becomes more conscious and a communicable understanding develops.

Example 2 (Linear functions, discuss possible Vorstellungen)
To draw the graph of \[1.5x - \sqrt{8}y = -\sqrt{3}\] we get the following Darstellungen:

Example 3 (Interpreting functions, analyze the conceptual understanding)
Student A draws the correct graph of a given function and determines correctly by computation the maximum at x=5. Student B draws the same graph and determines the minimum at x=5 (by applying the correct algorithms with a computational mistake).

Example 4 (Procepts)
A keyword or symbol or tag as a Darstellung can serve as a stimuli to evoke proceptual thinking (Gray & Tall, 1994). Here the Vorstellung involves both, a
procedural and a conceptual aspect. E.g. \( y = f(x) \) may be seen as an assignment (process) or a function (concept).

**Connecting Understandings from Mathematics and Mathematics Education Research**

Gerald A. Goldin, Rutgers University

The perspective I bring to this discussion may be a controversial one, but I shall start noncontroversially by building on Hartwig Meissner's accompanying presentation. Meissner highlights differences among the notions of *Einstellung* (attitude), *Vorstellung* (internal representation), and *Darstellung* (external representation) as descriptors of processes in mathematical learning and understanding, and takes mathematics to be something that "exists independently" of these. Before considering aspects of the nature of mathematics, let me continue with two further, important ideas about representation.

First, I would emphasize that individual representational configurations, whether external or internal, cannot be understood in isolation. Rather they occur within *representational systems*. The latter are not mere collections of representations, but have complex structures that in practice may be ambiguously defined or context-dependent (Goldin, 1998). Thus words and sentences occur within natural language systems, having conventional grammatical and syntactic structural features that can be characterized as *external* to any one cognizing individual. *Internal*, verbal representational configurations also occur in each individual, within a personal system of linguistic competencies encoded in the brain that has its own structural features. All these depend on context in various ways. The "communicational approach" in Anna Sfard's accompanying presentation, at least tacitly, involves such structural features of language. Likewise in mathematics, we have conventional, external systems of representation including base ten numeration, rules for arithmetic operations, ways of denoting rational numbers, Cartesian graphs, a system of algebraic notation, etc., with accompanying verbal descriptions, all usefully regarded as external to the individual. And we have the visual imagery, notation-images, kinesthetic encodings, and so forth, occurring within personal systems that may be partially-developed and embody misconceptions, contradictions, and idiosyncratic structural features. We might use the terms *Darstellungsysteme* and *Vorstellungsysteme* to refer respectively to external and internal representational systems.
In my work I have found it useful to distinguish five different types of **Vorstellungsysteme** that come into play in learning and doing mathematics: (1) verbal/syntactic systems, referring to internal natural language competencies, (2) imagistic systems, including visual/spatial representation, kinesthetic representation, and auditory/rhythmic representation, (3) formal notational systems, referring to internal procedural/structural competencies associated with the conventional representations of mathematics, (4) a system of heuristic planning and executive control, including configurations for strategic decision-making that govern problem-solving activity, and (5) an affective system including rapidly-changing emotional states as well as more stable, multiply-encoded constructs such as attitudes, beliefs, and values. A psychologically adequate description of mathematical learning, development, and problem solving requires that we take account of all five types of **Vorstellungsysteme** in interaction with each other and with **Darstellungsysteme**. Here I think Meissner’s term **Einstellung** usefully distinguishes certain more stable aspects of affect and related cognition that individuals bring to mathematical situations.

The second idea I want to emphasize is the strong psychological role that the initial assignment of meaning, or semiotic step; plays in the individual’s developing **Vorstellungsysteme**. Understanding this is important not only to education, but to grasping how mathematics itself has evolved.

For example, children frequently learn that multiplication of natural numbers ("times") is an abbreviation for repeated addition: i.e. ‘3 x 5’ means ‘5 + 5 + 5’ (three fives). The formal notational and imagistic representational subsystems associated with the operation of multiplication then develop structurally, making use of this ‘meaning’. The usual multiplication tables are constructed, and patterns found in them. The commutative and associative properties of multiplication, and the distributive property of multiplication across addition, are verified and illustrated. As more structure is built on the initial meaning, its psychological persuasiveness increases. Repeated addition becomes for the learner what multiplication really is. But the moment comes when the meaning fails! A child may interpret ‘3 x ½’ as ‘½ + ½ + ½’, but ‘½ x 3’ is problematic—what does it mean to ‘add three one half of a time’? The structural commitment to the commutative property suggests a value for ½ x 3, but the absence of the original meaning leaves a gap in understanding—a cognitive obstacle. We have well-documented related misconceptions, such as the idea that “multiplication always makes larger,” which may persist until some reconceptualization has occurred.

Similar obstacles occur not only in individuals learning mathematics, but in the history of the mathematical field. They have their origins in the structural
extensions of mathematical systems that require relinquishing the necessity of
the original semiotic connections—so that the mathematical structures are
abstracted, and the ways in which the mathematical notations function as
representations of imagistic configurations are generalized. Mathematicians of
earlier eras struggled mightily with the concepts we today call irrational
numbers, imaginary numbers, negative numbers, and non-Euclidean
geometries, due in part to the psychological difficulty of abandoning the initial,
“real” meanings attributed to numbers, to points and lines, and so on. The
necessity for such reconceptualization is well understood now, and has
influenced our evolving notions of “mathematical existence” and
“mathematical truth.”

This brings me to the major point in my presentation—the notion of
mathematical truth, its recent unfortunate downplay in mathematics education,
and the consequent widening chasm between the fields of mathematics and of
mathematics education. I view the gulf that has developed as both damaging
and unnecessary. Although the divide has reached a depth that seriously
impedes our common educational goals, I do not think the sociological reasons
for rivalry are so strong as to generate inevitable conflict. For both
communities, and for the next generation of students, the value of achieving
meaningful improvement is extremely high, providing a powerful incentive for
real collaboration. I want to focus on what I perceive to be intellectual reasons
for division, intending my comments to be strongly critical.

At the root of the problem in each community is a willingness to deny or
dismiss the very integrity of the knowledge generated by the other. It is not
always apparent to mathematicians when they do this in relation to
mathematics education research, nor is it always apparent to non-
mathematicians when they do this in relation to mathematics. Sometimes,
however, it seems to be done consciously and opportunistically, as a way of
inviting attention and gaining a following—with a kind of wilfully-maintained
ignorance of the other discipline.

On the one hand, some in the mathematical sciences community insist on
imposing—with unwarranted confidence—tacit but naive models of what it
means to learn mathematics. It is straightforward for mathematicians to focus
on building powerful competencies in formal notational systems, as these are
culturally agreed to be part of mathematics, and competencies in them can
usually be tested straightforwardly. Powerful problem-solving strategies and
heuristic planning techniques that work in various mathematical domains
(Polya, 1954, 1962, 1965), including proofs, are likewise generally agreed to
be part of, or closely related to, mathematics, though techniques such as “work
backward from the goal" or "solve a simpler, related problem" are difficult to test. But for many mathematicians the traditional view of mathematics as consisting of abstract systems encoded formally accords only casual or unimportant status to all but the most standard of representations. The power of formal, logical reasoning when applied to abstract mathematical entities, together with the fact appreciated in mathematics that visual intuitions can mislead, creates a reluctance to place a high, explicit value on imagistic representation, especially non-standard representation with accompanying differences in individual learning styles, or on affect. Visualization, metaphor and metonymy, emotions, and the relation between feeling and mathematical imagination, are dismissed or relegated to incidental status, despite growing empirical evidence for their fundamental roles in the learning of mathematics.

One extreme position is to discretize, take as "given", and value very highly in defining the curriculum a collection of standard mathematical material, in disregard of the complexity of the processes through which mathematical understanding develops in students of diverse abilities and motivations. This view has energized the "traditionalist" side of the recent "math wars" in the United States. Skills are seen as prerequisites to conceptual understanding, and are thus to be taught first. Mathematical achievement manifests itself through speed and accuracy in answering test questions. Mathematical ability is seen as an innate, unitary characteristic of individual students, describing the rapidity with which they acquire formal notational competencies when trained in them. Of course I am not saying that all or most mathematicians adopt such dismissive positions, though some educators have sought to establish this stereotype. Some mathematicians do, and the fact that they do offers a convenient rationale for counterpart dismissive fashions in education.

Fundamental to the integrity of mathematical knowledge is the notion of "truth", which has evolved significantly by virtue of mathematical insights achieved over millenia (Kline, 1980). Let me use this term in a certain way that mathematicians typically use it. The field of mathematics has been characterized by many as the study of pattern (e.g. Sawyer, 1955). This includes pattern detected in the natural world, and pattern in systems invented by human beings. To study patterns, mathematicians seek to characterize them as precisely as possible. One way this is done is to formulate definitions and axioms or postulates that describe a system or class of systems incorporating a pattern. We then have a collection of mathematical statements taken from the outset as true. Further propositions (called theorems), often not at all obvious, can be proven from the axioms by means of well-defined rules of inference and are thus demonstrated to be true. Truths in mathematics occur within systems
of assumptions. In developing such systems, our concepts change and evolve. Some lines of reasoning turn out to be valid, while others are demonstrated to be invalid. Often our initial conceptions turn out to be too limited, or even self-contradictory. Sometimes imagistic thinking guides us to mathematical truths, and sometimes it misleads us. In short, there exist essentially objective answers to important mathematical questions. Furthermore the system we create is abstract, and not necessarily restricted to apply only to the original, motivating conceptual domain—other, unexpected models are likely to exist! And there are fundamental, logical limits—proven limits—to the possibility of demonstrating the completeness or consistency of mathematical axiom systems.

The fashionable but dismissive intellectual trends influencing mathematics education research have in the past two decades been ultrarelativist. Such views are ideological (in the sense of being nonfalsifiable), since a contrary argument can never be more than an alternative viewpoint. They include radical constructivism, radical social constructivism, and variations of postmodernism, each in its own way denying the very possibility of objective truth, knowledge, or validity, and thus dismissing from the outset the central construct of mathematical inquiry. These have energized extremes on the “reform” side of the “math wars.” Most recently we have the grand claim that mathematics consists entirely in “conceptual metaphors” (Lakoff, G. & Núñez, R., 2000), predictably attracting favor among some mathematics education researchers. Here there are only conceptions, no misconceptions. Ideas and visualizations (familiar to mathematicians) that underlie and motivate abstract constructions are renamed as metaphors, presented as if newly-discovered, and taken to be the mathematics—with those mathematicians who might disagree caricatured as Platonists, naive realists, or empty formalists. In this view mathematics cannot possibly “exist” independently of human metaphors, so the initial point in Meissner’s presentation is be rejected entirely.

Of course, the definitive characterization of mathematical truth and the validity of mathematical reasoning are far from a solved philosophical problem. We have a lot to learn about it, and many unanswered questions remain. However, we must distinguish between the assumptions, definitions, conventions, and rules of inference chosen to characterize some visualized or imagined patterns (socially constructed, subject to negotiation in their framing, and possibly “metaphorical”) and their logical consequences (now “true” in an important, “objective” sense). Denying or dismissing the very construct—replacing “mathematical truth” by “social consensus” or “stability of human metaphor”, replacing “validity” by “viability”, and so on—makes no contribution to our
mathematical understanding. Rather it seems to make deeper mathematical understanding unnecessary. Some version of ultrarelativism may be a tempting response to closed-minded or "absolutist" views among mathematicians. It may seem to justify our being open to students' various ways of thinking mathematically, to our emphasizing in education the ideas of mathematics, imagery and metaphor, open-ended problem solving, discovery processes, social and cultural environments, and various systems of belief—all that I strongly favor! But ultrarelativist "isms" undermine what should be central goals of mathematics education—conveying the nature of mathematical truth and the power of valid, objective mathematical reasoning, bringing learners to experience the processes of abstraction and proof, and helping students to identify the same abstract mathematical constructs in a variety of different conceptual domains.

In my studies of mathematics and of students' processes of learning and problem solving in mathematics, I have never found what we learn validly as mathematicians and what we learn validly as researchers in the psychology of mathematics education to contradict each other. Both sets of understandings are needed. Mathematicians who are "absolutists" nevertheless offer important mathematical insights. "Ultrarelativist" educational researchers have designed and reported on ground-breaking studies. Progress is made when mathematicians and educational researchers communicate effectively and learn from each other, so that our understandings of difficult notions are enhanced—not when we erase distinctions or dismiss centrally important constructs.

To conclude, then, it is time that mathematics education researchers exercise far greater discernment than we have in the past. Let us knowledgeably and thoughtfully abandon the dismissive fads, fashions, and "paradigms" in mathematics education, in favor of a unifying scientific and eclectic approach.

Concluding Points

Lyn D. English, Queensland University of Technology

The papers of this Forum have presented a range of perspectives on the nature of mathematics as viewed from mathematics education research. The authors have raised controversial and, at times, opposing viewpoints on the issues presented in the introduction. The ideas expressed by each of the authors provide a rich basis for tackling the numerous debates emerging within and beyond our discipline, debates that are being fuelled by the increasing scrutiny of mathematics education by the public, by governments, by mathematicians, and by school systems. Such debates include the nature of the mathematical
content we should teach, how and when we should introduce this content, how we can provide all students with access to powerful mathematical ideas, and how we can encourage more students to undertake courses in mathematics. We face many challenges as we attempt to deal with these concerns. The question remains as to how effectively we are meeting these challenges.

Although not denying the importance of diversity in our perspectives and the richness this brings to mathematics education, I believe we have become too divided and too insular in many of our beliefs, theories, and ideologies. We seem to be addressing only those questions that fall readily within our particular ideological stance while ignoring other important issues. While following a particular social-constructivist perspective in exploring children's mathematical learning, for example, we often overlook the inherent structure of the mathematical tasks or at least give it superficial treatment. So we might argue for the richness of children's learning through their classroom interactions, while failing to recognize the mathematical inadequacies of the tasks being explored.

As no one perspective can provide a satisfactory answer to all of our research and teaching issues, we need to be more cognizant of alternative viewpoints and incorporate the best of our own ideas with those of others. This Forum represents an important step in this direction. There still remain, though, many issues in need of attention as we continue to foster the growth of our teaching and research communities. Some of these issues are listed below for further debate.

- To what extent are our theoretical bases addressing the mathematical needs of society in the new millennium?
- How are our existing ideologies impacting on students, teachers, and on the community at large?
- How can we ensure a closer match between what we believe about mathematics and mathematics education and the goods we deliver?
- To what extent are we dismissing one another's perspectives and philosophies, both within our own mathematics education community and with our neighbours, the mathematicians?
- Mathematics continues to grow rapidly. How is this growth changing our views on the nature of mathematics and what we consider important to know and understand?

1 Needless to say, this extremely concise exposition cannot possibly count as a proper introduction of the comprehensive conceptual framework. The interested reader may turn for elaboration to Harre & Gillett (1995), Edwards (1997), and Sfard (2000 a, b; 2001a).

2 Two discursive sequences will be regarded as being instances of the same discursive routine if they comply with the same set of meta-discursive rules. This latter term refers to principles that help the observer to account for the regularities she spots in the behavior of the interlocutors. Rather, than being prescriptions which the speakers follow in a conscious way, these are propositions that help the analyst encapsulate the discursive flow the way the formula of free fall helps physicist to encapsulate the movement of falling bodies (cf. Sfard, 2000b; Sfard & Kieran, 2001a).

RESEARCH FORUM
MEASURING MATHEMATICS LEARNING AND DESCRIBING GOALS FOR SYSTEMIC REFORM

Co-ordinators:
Peter Sullivan, La Trobe University, Australia
Dianne Siemon, RMIT University, Australia

FORUM OVERVIEW
In many countries, governments have initiated projects to evaluate and describe mathematical competence. Researchers within such projects make assumptions about what mathematics should be learned at particular ages, how learning goals are described, how learning is measured, and what findings may mean for curriculum and teaching. The forum is not critiquing whether this process is appropriate or necessary, but considers the solutions that researchers have sought and the rationale for those solutions.

Contributors to this forum describe their involvement in such projects, assumptions they made, the tensions they identified, and their resolutions of those tensions. Particular emphasis is on the contribution that such projects make to the mathematics education research.

Some of the decisions connected with this process include: What are the mathematical goals for students at particular ages? How can the learning of this mathematics be measured? What instruments and processes are appropriate for collecting evidence? What evidence would be characteristic of learning? Are there underlying assumptions about the way curriculum is described? Are there underlying assumptions about the way mathematics is taught? What are the tensions (e.g., suitability of instruments for all students, need for attention to have issues arising will be addressed) identified, and how are these reconciled?

MEASURING MATHEMATICS LEARNING AND DESCRIBING GOALS FOR SYSTEMIC REFORM: SOME ISSUES FOR CONSIDERATION
Stephen Lerman, South Bank University, London, UK

Large-scale projects to provide evidence for policy on developing mathematical competence are opportunities for mathematics education researchers to play a part in the improvement of students’ learning of mathematics. There have been too many
situations internationally where policy has proceeded without evaluative, descriptive or predictive research. Indeed in some countries educational researchers are deliberately ignored. It is most important, therefore, that such projects consider carefully as wide a range of issues concerning the quality of their project and its potential impact before commencement and as an on-going process throughout their work.

What follows is a non-exhaustive list of issues, expressed as questions, that I believe should be considered. These comprise methodological and ethical questions and one concerning engagement with the research community.

I invite the contributors to this Research Forum to respond to some or all of these issues, describing whether and how they feature in their projects. On the other hand you may have reservations about the necessity of responding to one or more of these issues. If so, I invite you to explain your point of view.

• Whose agenda is the project? Whose interests are served: students, parents, teachers, society, Government, the mathematics education community? Who owns the data? How will it be used?

• What are the theoretical frameworks (some of which may be implicit)? Are they drawn from psychological and/or sociological and/or other intellectual resources? What are the methodological justifications for the methods being used?

• What are the assumptions about the relationship between teaching and learning? What are the assumptions about the role of texts and other materials?

• What are the assumptions about the nature of curriculum?

• Where do the norms of student mathematical development come from (since both norm-referenced and criterion-referenced norms are actually norm-referenced)? Will tests be designed to measure actual development or proximal development (or both)?

• Does the sample size do justice to the research questions?

• Who benefits from the project, and how? Will there be any losers? Will the disadvantaged be further disadvantaged?

• How are insiders’ perspectives taken into account (students, teachers, parents, etc.)?

• What arrangements are there for gaining, then reviewing and revising the consent of participants?

• How will the findings be critiqued within the community of mathematics education research (or other academic communities)? Will the project be discussed with the research community at the design stage, the interim findings and/or the final outcomes stages? Will the findings be expected to be generalisable internationally?
MEASURING PROGRESS IN NUMERACY LEARNING

Margaret Brown, Mike Askew, Valerie Rhodes, Hazel Denvir, Esther Ranson and Dylan Wiliam
King's College, University of London

LARGE SCALE RESEARCH AND POLICY

We focus on the longitudinal assessment strand of the Leverhulme Numeracy Research Programme in the UK between 1997 and 2002. A broader report is presented in a Plenary paper in this conference (Brown, 2002): we have tried to minimise the overlap in content.

Steve Lerman is right in his challenge to be concerned about large-scale assessment of mathematical competence; there is no doubt that the results of studies such as SIMS and TIMSS (Robitaille & Garden, 1989; Reynolds & Farrell, 1996; Beaton et al., 1996; Mullis et al., 1997) have had a major influence on mathematics education in England, providing the justification for an ever-tightening centralised control of curriculum and teaching methods. Two English studies which one of us has previously managed (Concepts in Secondary Mathematics and Science (CSMS) (Hart (Ed.), 1981), and Graded Assessment in Mathematics (GAIM) (Brown (Ed.), 1992) has supplied data informing the structure and content of these reforms. While we regret some of the uses made of the results of these studies, these policies have nevertheless been developed by democratically elected governments and supported by the majority of teachers, parents and voters. We believe that it is part of the collective responsibility of mathematics education researchers in any country, and indeed internationally, to assist in the collection of reliable and valid large-scale data to inform international, national and local policies. We also of course regard critique as part of our collective responsibility and hence value large-scale data which can provide evidence on which rigorous critique of policy can be based (e.g. Brown et al., 1998). Large-scale research can also often provide a basis for and/or evaluation of design and development work, which is a third essential element of the collective responsibility of mathematics educators.

Our support for large-scale work is by no means in opposition to arguing the importance of case-studies; indeed we believe that insight gained from successful small-scale work is not only valuable in itself but also an essential preliminary to large-scale studies. We do not therefore have a problem in being associated with both types of work in a complementary way, as in the Leverhulme Numeracy Research Programme and in many other studies in which we have been involved.

In the next sections, we will try to answer the most relevant of Steve’s questions to our project. Sometimes the order is changed to assist the narrative; in some cases the pressure of space has forced rather briefer answers than we would like.
1. Origins and Purposes

The Research Programme is funded by the Leverhulme Trust, which is independent of Government and distributes the interest on profits from manufacturing to support charitable work. The research agenda was partly that agreed by the Trust, advised by academics; they announced in 1996 that they would donate £1 million to a study of low achievement in primary schools focusing on literacy and/or numeracy. The Core Project, one of six projects in the Programme, was proposed 'to obtain large-scale longitudinal value-added data on numeracy, in order: to inform knowledge about the progression in pupils’ learning of numeracy throughout the primary years; and to assess relative contributions to gains in numeracy of the different factors investigated in the programme.'

The sample would be all the children from two different cohorts in 40 schools, ten in each of four local education authorities in different and varied areas of England. One cohort would start in Reception (age 4 to 5) and progress to Year 4 (age 8 to 9); the other would start in Year 4 and progress to Year 8 (age 12 to 13), although test data would be collected only in Years 2 to 7.

2. Theoretical Background

In the full research team there are about 16 researchers, although only two work full-time on the programme. In addition to mathematics educationists the team includes a cognitive psychologist and a social anthropologist, since an aim of the research programme is to examine primary school numeracy from multiple perspectives. Most of the group working on the large-scale assessment project are educationists who espouse a broadly social constructivist view of learning, involving progressive generalisation from situated cognition sometimes experienced within overlapping communities of practice (Wenger, 1998), and a dialectic both between the social and the individual, and between the cognitive and the affective. However our separate theoretical positions vary along these continuums.

There are clearly problems about the concept of criterion-referencing which assumes an all-or-nothing capability. The tests are only loosely criterion-referenced in the sense that most items can be related to specific cognitively based skills. Justification for this lies in the fact that the original form of the tests was as part of a diagnostic interview which was developed iteratively as part of a study identifying important steps in learning (Denvir & Brown, 1986). Any inferences from success in items to specific understandings is highly dangerous, but the analysis of associated sets of items will involve some inferences about learning which we recognise as very speculative. But such speculation lays the foundations for science.

As part of the study we have observed teaching in all the classrooms and adapted an analytic framework first used by Saxe (1991) which relates to a broadly activity theory approach focusing on discourse, tools, tasks, relationships and norms.
3. Methods

In Steve’s terms the assessment is probably intended to be actual not proximate, although evidence suggests that items sometimes scaffold learning. We would all accept the crudeness of the method of assessing children’s progress which we use, i.e. tests with questions read out by the teacher and answered in printed test booklets. It is constrained by the large size of the sample (about 1700 children in over 70 classes in each of the two cohorts) and the consequent need for brevity, simplicity and uniformity since we rely on teachers to administer the tests.

We have evidence through case-studies that a single child’s test performance on a particular occasion is not particularly reliable; however our aim is not accurate assessment of individuals. First, we will make inferences about progression in learning of English children at a particular point in time. This will be based on changes in the proportion of the cohort over a particular time span who are able to obtain correct answer to a linked set of items. Thus most idiosyncratic variation in individual children will cancel out but sources of systematic bias will remain. We will however present as much data as possible for others to critique our conclusions.

For example, after a practice item where children discuss with their teacher a quick way of finding 30+21 if they know 30+20=50, they are given on their booklets that 86+57=146 and asked quickly to use this to work out answers to different questions. Different forms of this item were on the tests used from Year 2 to Year 6 (each year was tested in October and June), and the percentages successful were:

This information illustrates the second purpose of the testing which is to examine the effect of different factors which may influence numeracy attainment. We have related the average gains each class makes between October and June each year to a variety of other data on pupils, teachers, teaching, and schools. To remove the important prior attainment factor, the tests have been designed so that the average gains over this period are independent of the initial scores. Examples of the results on this analysis are given in the plenary paper (Brown, 2002).
Concerning curricular validity, there is little agreement internationally or indeed even in the UK (Brown et al., 1998) on the definition of numeracy. The tests have in fact been developed and researched over a long time-span. The original diagnostic interview was designed in the light of the research literature on development of knowledge and skills in number which seemed relevant to the 1980s curriculum in most English schools; this evolved and was evaluated in a PhD study (Denvir & Brown, 1986). This instrument has been updated as part of another study (Askew, Bibby & Brown, 2000) and is now published for teachers' use (Bibby & Denvir, 2002). A further study entailed the adaptation of the test for class use and validated it against the individual interview assessment (Denvir & Brown, 1987). Finally the test has been modified and trialled for use in three different age groups (Askew et al., 1997) before being adapted and trialled for 6 age groups in this study (Brown et al., 1996). In each of these adaptations a check was made that the content matched the primary number/numeracy curriculum at that time in England.

There are for practical reasons no long items of a problem-solving or investigative nature, but these are currently little used in teaching in England. An investigative item was abandoned when the analysis of the data revealed large inter-class differences in strategy which suggested that teacher influence was overwhelming. In addition to the much researched and refined nature of the tests we have other reasons for having confidence in the comparative validity and reliability of the tests:

- we have compared performances on specific items on seven successive occasions for our case-study sample of 30 children per cohort: this suggests that the results are generally consistent. The results are also generally consistent with our observations of these children's cognitive behaviour in their normal lessons:
  - the overall performance of a whole cohort on successive occasions is consistent;
  - the reliability measure on a single test occasion is high (Wiliam et al., 1998);
  - we have observed classes and interviewed all teachers each year; this enables us to investigate any results which seem to be inconsistent with classroom performances;
  - teachers have been very satisfied with the content of the tests, except that some are concerned that some questions are too difficult and go beyond what has been taught. (This is unfortunate and may affect results for some children, but it is a necessary part of the test design to measure progression for children across the whole range; teachers are asked to explain to children before they start that they are not expected to be able to do all the questions as some are designed for older children.)

4. Consultation, dissemination and application

Headteachers were asked to consult staff before agreeing to take part (and almost all did). Over five years of intense national change only 3 schools out of 40 have withdrawn, due to new headteachers. Permission was sought from all parents.
The study has involved 45-minute interviews with all teachers (about 600 over 5 years, with less than five refusals), annual interviews with headteachers and mathematics co-ordinators, and 45-minute interviews and many informal conversations with the case-study sample of about 60 pupils (Years 3 and 6). In all interviews participants have been asked about their views of the tests and other aspects of the study. There was limited scope for changing the tests for that year group as the model was already set, but tests for other year groups could be and were slightly affected, as they were developed and trialled one year at a time.

Payment for teacher cover during the interviews has been provided so that schools and teachers did not suffer. Annual feedback on test results is provided to local authorities, headteachers and teachers, but names of schools, classes and children are not given in accordance with promises of confidentiality. At the same time we have provided some summary of aspects of the interim project findings. The majority of schools and teachers have voluntarily expressed their regret that the project is now finishing, so presumably they have found participation useful; several have cited specific uses of the feedback e.g. in self-evaluation or inspection.

We have presented papers for discussion and critique at both national and international research meetings, at the stage of design (e.g. Brown et al., 1996) as well as at the results (Wiliam et al., 1998; Rhodes et al., 1998, Brown et al., 2000; Brown, 2000). However we have generally avoided wide scale national publication of, and publicity for, interim results beyond the research community, as we have preferred to wait until possible effects were confirmed or contradicted in the data for successive years. We are contracted to Kluwer to write a series of four books.

In terms of our aims, the main output is in knowledge and understanding about primary numeracy in order to improve attainment; hence the main beneficiaries should be future generations of pupils and teachers. Specifically from the longitudinal study this relates to progression in learning and factors which affect it. On the basis of reactions to presentations we have given and articles we have published in professional journals (e.g. Brown, 1999) we believe that the large-scale results, illustrated by specific examples, will be of use and interest to individual teachers as well as to researchers, developers and policymakers. Apart from our own uses, both to achieve our aims and to exercise our right of policy critique, we will of course have little control over how the data is eventually used once it is in the public domain. But that is a necessary part of an open society.

numeracy attainment and progress in a Year 4 cohort. Paper presented at the British Educational 
SYSTEMIC MOTIVATION

In the late 1980s, both levels of government in Australia collaborated in specifying the outcomes that could define learning (see Australian Education Council, 1991). While this type of curriculum specification and measurement was comprehensibly criticised (e.g., Ellerton & Clements, 1994) as constraining teaching and restricting achievement of students, it has also been argued that defining of curriculum goals in terms of standards and targets creates pressure on governments to provide resources for initiatives to ensure that the targets are met (e.g., Willis, 1995). It seems that both predictions have come true, although we focus on the latter here.

Governments have taken the standards seriously and initially invested heavily in literacy achievement for early years children with broad community support. Numeracy, which for all purposes at this level is used interchangeably with mathematics, received slightly lesser but still enthusiastic government and community support. Arising from this interest the relevant Victorian government department invited submissions for a large-scale research project, which was won by a team including these three authors. For this forum, there are two relevant motivations to consider: the motivation of the government department in soliciting the tenders and the motivation of the team who won the tender in pursuing their research goals.

For the government’s part, they were keen to gather data to allow them to argue in competition against other sections of government for funding support for on-going professional development, school-based grants for co-ordination and resources, curriculum initiatives, and other support for teachers. Recognising that essentially different arms of government both within and outside education compete with each other for initiatives and support, the gathering of data which could justify support in one area as against another is central to the working of the bureaucracy. The government department was also keen to identify the content of professional development and resources which could be produced to support teaching.

From the researchers’ perspectives, while the tender required us to serve the above goals, we had other aspirations. We sought insights that could describe student learning over time, perhaps identifying discontinuities that could be the focus of particular resource support, and articulating reasonable expectations for students in schools. We were also concerned about teachers and strategies for developing their confidence in teaching mathematics.
EARLY NUMERACY RESEARCH PROJECT

The Early Numeracy Research Project was initiated in Victoria following the success of the Early Literacy Research Project. The Early Literacy Research Project (Hill & Crévola, 1999) worked with 27 disadvantaged Victorian primary schools to bring about substantial improvements in early literacy outcomes. Part of this research involved the development of models and guidelines for teaching, assessment and additional support for young children learning to read. As a result of the research, Hill and Crévola offered a “general design for improving learning outcomes” (p. 122), which they believed had application in literacy, numeracy, and other curriculum areas.

The Early Numeracy Research Project (ENRP) was established in 1999 by the (then) Victorian Department of Education, with similar aims to those of the Early Literacy Research Project, but with a mathematics focus in the first three years of schooling.

The 35 trial schools were selected from approximately 400 schools who applied to participate. The trial schools were chosen to represent the range of Victorian schools, in terms of geographical location, socio-economic status, language background, school size and indigenous population. The 35 reference schools were matched from remaining Victorian primary schools, seeking the closest match taking into account the above variables.

The stated aims of the Early Numeracy Research Project were

- to assist schools to implement the key design elements as part of the school’s numeracy program;
- to challenge teachers to explore their beliefs and understandings about how children develop their understanding of numeracy, and how this can be supported through the teaching program; and
- to evaluate the effect of the key design elements and the professional development program on student numeracy outcomes.

The central part of the data collection was an individual interview addressing nine domains of mathematics. In each domain, previous research was surveyed to identify key issues associated with developmental learning within those domains. These “growth points” were the basis of the quantitative scale used (Horne & Rowley, 2001). While a requirement of the data collection process, these growth points served a function of describing student thinking. It was intention of the research team to focus on student mathematical thinking and strategies. The nature of mathematical understanding was clearly implicit in the nature and form of the growth points (for more detailed discussion see Clarke, 2001). Essentially we believed that teachers can focus on a small number of big ideas in each of the domains and this can guide teaching, learning and assessment in way that can facilitate student learning. Ultimately we hoped that the description of the student achievement at this level
would inform curriculum, both in scope and in sequence (see, for example, Sullivan, Clarke, Cheeseman, & Mulligan, 2001). The interview was used on 34,398 occasions with children during the ENRP, with 11,421 children being interviewed at least once. In addition, 1,152 and 868 interviews were conducted with Grade 3 and 4 children, giving a total of 36,426 interviews in the period 1999-2001.

The key recommendations from the student data overall were:

- The data considered individually and collectively highlighted the independence of the respective mathematics domains, and all domains should be part of the curriculum at each grade level in the early years of schooling.
- The growth points seem to provide clear indications of standards for learning and targets for teaching at these levels, and teachers could use these to inform planning, teaching, and assessment.
- By using the assessment interview, teachers can gain important insights into the learning of their individual children. The growth points then provide important information for teachers to allow them to adjust classroom experiences to address the particular learning needs of each student.
- In a number of the domains, barriers to student learning were identified. These were growth points that it seemed to take students significant time to achieve. Particular experiences should be planned by teachers to address the elements of the barrier explicitly.
- In each domain specific recommendations related to changes in the emphasis and specification of the Victorian framework were made. In some places serious deficiencies were identified.

The interview, of course, was only one part of a project. Indeed it could be argued that the most informative parts of the project are the intensive case studies conducted with both schools and individual teachers who appeared to have higher achievement of their students over the period of the research. Nevertheless, the data from the interviews revealed important information about the sequence and rate at which young children learn those elements of numeracy that were part of the framework, and the results can be used to inform curriculum and resource development, and pre- and in-service teacher education.

We also conducted extensive professional development and gained significant insights into the way that such professional development changes teachers’ beliefs and orientation to teaching, as discussed in the next section.

**The impact of measuring and describing learning on the participating teachers**

A range of data both qualitative and quantitative data was collected from the teachers. There were approximately 250 teachers involved in the professional development program throughout the three years of the project. Support provided to
the teachers within the project can be considered as three “opportunities”:
1. Opportunity to develop knowledge of children’s learning of mathematics through a framework of key growth points and a task-based interview that provides insights into the range of strategies children understand and use, as well as an understanding of more sophisticated strategies that the children can be encouraged to work towards.
2. Opportunity to develop knowledge of students through one-to-one, mathematically-focused interaction during the interview.
3. Opportunities to explore a range of classroom strategies, in an environment of collegiality, to build upon children’s mathematical understanding, through purposeful and informed teaching.

The ENRP growth points were designed to provide teachers with a framework to describe their children’s learning in mathematics and the interview measured this learning. The perspective of the research team was of the teachers as co-researchers and teachers as having responsibility for the making of curriculum (Clarke, Clarke, & Sullivan, 1996).

It seems that the growth points provided not only a way to discuss what the children already know but the direction to move. Teachers in the ENRP had a clearer picture of the typical trajectories of student learning (Carpenter & Lehrer, 1999), and can recognise landmarks of understanding in individuals. Such a picture guided the decisions they make, in planning and in classroom interactions, as their knowledge of the understanding of individuals informs their practice. This increased knowledge in turn seemed to build the confidence of the teachers:

I used to avoid maths when something had to be missed, now I can’t find the time to do enough! I’m more confident and I enjoy it more. I’m more flexible and more responsive to the children. I have a better understanding of how children think and reason, due to the assessment. This has impacted on what/how I teach.

The main thing that has changed is my confidence in my maths teaching, because I have more knowledge of how children learn maths, what they should know and some ideas of how to get them there. My lessons are more varied and fun now.

It has given me a greater understanding of why and how I teach maths, therefore increasing my confidence in my maths teaching.

While ultimately the recommendations of the project reflect the statement of the growth points which in turn informed the assessment items, the findings can inform curriculum development, teacher education, and further research. The data were collected from large numbers of students over three years with a carefully selected, stratified sample, to ensure all sections of the community were represented, and can be taken as an accurate representation of the potential of all students to answer the questions asked at these levels. The teachers have been empowered through increased knowledge and a belief in their own teaching and we would argue –the freedom to make their own professional decisions. The project sees the provision of...
similar professional development for other teachers as a key recommendation for government action.

International studies, such as TIMSS and PISA, consider how well different countries educate their students. These large-scale studies also highlight associations between student background characteristics and student performance. The important question of these studies is not the rating of the countries. The important questions had to do with attempting to discern what it is about the instructional practices, school policy, the curriculum, and the psycho-sociological environment in certain countries that result in higher levels of student achievement (Willms, 2001).

Along with international studies, many countries conduct also national surveys on students' mathematical achievements. The main purpose of these surveys is to provide insights into the factors that influence the development of mathematical knowledge, skills, and competencies, how these factors interact, and the implications of the findings for policy making. As part of this process, researchers seek to measure and describe the relationships between the "inputs" and the "outputs" as well as between the intended, implemented, and attained curriculum.

Who are the audience of large-scale studies? Whose interests they intend to serve, and how? Whose interests are indeed served, and how? By supporting a shift in policy focus from educational inputs to learning outcomes, large-scale studies aim to provide insights into the factors that contribute to the development of competencies and into how these factors operate. Undoubtedly, such studies seek to combine the P and the E in PME. By that, these studies intend to assist policy makers, as well as mathematics educators and the community in large.

Yet, the ambitious scope of these studies and their tremendous costs raise the issue of the extent to which large scale projects indeed play a part in the improvement of students' learning of mathematics. Repeatedly, PME researchers raise the question of the extent to which such projects can assist educational systems in developing students' mathematical competencies: How can the findings serve as a basis for changing classroom practice? How can they assist in developing mathematics curriculum? Or, how can they set up the infrastructure for effective professional development? The present study addresses some of these questions.

**Do large scale projects play a part in the improvement of students' learning of mathematics?**

Many think that research has no impact on policy: policy makers do not get assistance from researchers, and if they get it, it is often either too late, or too
"theoretical", or too vague. Researchers, on the other hand, have the feelings that policy is not based on empirical findings. The frustration is expressed by many researchers. Husen (1968), for example, claimed that "in retrospective, I am completely aware of the failure of research to influence reforms in schools. One may ask if the policy would be different if the research would not be conducted on the first place." Ten years later, Malmquist and Grundin (in Mevarech & Blass, 1999) argued that "those who are responsible of the educational policy do not expect research to give answers to the ongoing problems that the educational system faces ... policy makers tend to consider research as a marginal activity." Recently, Robitaille et al (2000) summarize the impact of TIMSS by saying: "the results (of TIMSS) seem, at least until now, to have made a greater impact on the general public and in political circles through the mass media than they have on educators."

The impact of national and international studies on the mathematics education research community is also far from being significant. So far, large-scale studies have contributed very little to the development of new theories or to clarifying the "how's" questions regarding teaching, learning, or curriculum development. Gravemeijer (in Arcavi, 2000) explained: "the question with which the researchers are struggling is... how to design instructional activities that (a) link up the informal situated knowledge of the students and (b) enable them to develop more sophisticated, abstract, formal knowledge, while (c) complying with the basic principle of intellectual autonomy" (pp. 278-279). Maybe, large-scale studies are not appropriate for addressing such questions. Probably, studies that are based on qualitative methods or small scales are better able to answer this kind of questions than large-scale studies such as TIMSS, PISA, or national surveys. Why such ambitious studies have (so far) only small impact on policy, even though such studies are frequently cited in the media and often funded by institutions that make the policy? To answer this question we have to consider another series of questions: Whose agenda is the project? Who benefits from the project, and how: students, parents, teachers, society, Government, the mathematics education community? Are there any losers? Unfortunately, in many countries, Israel included, TIMSS findings are not on the agenda of the educational system. Even though the Ministry of Education funded the project, the educational system does not consider itself obliged to the findings. Several reasons may explain it. First, those who made the decisions felt threaten by the findings and thus defend themselves by ignoring it. Second, the immediate implications of the findings are not very clear – the studies did not identify the reasons for the low achievements, nor did they describe the factors that contribute to the good performance in high achieving countries. Third, ironic as it sounds, researchers may also be blamed (explicitly or implicitly) for the outcomes particularly in those countries where researchers are involved in curriculum development. Finally, given the assumption that there is a relationship between the intended, implemented, and attained curriculum, even teachers and principals may be criticized (implicitly or explicitly) for not being effective. Thus, even though
students, parent, teachers, and the society in large can benefit from the study, the list of losers is not shorter.

There is, however, another option. The usefulness of large scale studies lies in identifying the factors that contribute to mathematics education. As indicated by Robittaille (2000): "educational systems can learn from one another. They can learn that different approaches to common concerns -- such as the streaming of students by some measure of ability are taken in different countries. They can study the relative success and efficacy of those different approaches and then make decisions about what might work in their setting." (p. 169). The following is an example that shows the usefulness of international studies beyond what can be achieved by any other kind of research.

Mathematics Education, Resource Allocation, and Equity Policy

Educational inequality remains a major challenge to policy makers as well as to researchers. There is a long debate in the educational community regarding the duality between excellency and equality in education. Whereas many believe that the role of society is to reduce inequality even if it may come on the expanse of excellency, others argue that the role of schools is to enable each student to fulfil his/her potential and attain high levels of achievements. To address the issue of the duality between excellency and equality, we investigated the relationship between mean achievement in mathematics and measures of inequality in mathematics performance across countries by using TIMSS-1999 data. Inequality in mathematics performance was defined as the gap in achievement between the 5th and 95th percentiles within each country. The analysis indicated that the correlation between mean achievement and inequality is -.75. In other words, countries in which mean performance is high the level of inequality is low and vice versa. Further analyses showed that countries that improved performance between 1995 and 1999 reduced inequality. It is interesting to note that analyses of economical data from 67 countries reveal similar findings regarding the strong negative relationships between growth and inequality. Additional analyses indicate that the strong negative correlation between achievement and inequality is not a function of investment. These findings led us to examine the contributions of social capital or human capital to excellency and inequality. (More information will be reported at the conference.)

This finding along with additional analyses explaining the factors that contribute to the high correlation reported above has clear indications for policy makers and for mathematics education community: schools can make a difference, curriculum can make a difference, and resource allocation can make a difference. This finding calls researchers in mathematics education to provide policy makers models that enhance mathematical performance along with reducing inequality. Examples of such models are those which utilize metacognitive instruction in mathematics education (e.g., Mevarech & Kramarski, 1997). To my knowledge, several countries have started to work in this direction.
Large-Scale Projects Looking for Identity

Arcavi (2000) distinguishes between two kinds of research in mathematics education: theory-driven and problem-driven. Within problem-driven research, he identifies three kinds of research: interesting/puzzling behaviors, a curriculum or a practice, and didactic opportunities. Large-scale projects do not fit any of these categories. It seems that a new category is suitable for large-scale studies. I suggest "checkup-driven research". (I prefer the term knowledge-driven research, but tend to believe that all research is knowledge driven.) By checkup-driven research I refer to a systematic inquiry into a subject, in our case -- mathematics education, designed to uncover pertinent information about mathematics education and the educational system in large. Checkup-driven research is more than comparing countries' curricula, or analyzing cost-effectiveness between and within countries. It is also more than explaining students' puzzling behaviors, didactic opportunities, or practices. Checkup-driven research has to provide analytical descriptions of the system, usually with respect to certain possible causal connections. [So far, TIMSS, PISA and national surveys provide reliable descriptive information, but their causality part is weak.] Conceiving large-scale studies as a checkup-driven research enables us to develop appropriate expectations of such studies: their main purpose is to provide ongoing evidence on the development of mathematics competencies, and to suggest follow-up research whenever a problem is discovered.

Like medical check-ups, also educational checkups have unique characteristics and methodologies that distinguish them from theory-driven or problem-driven research. Of these characteristics, perhaps the most important ones are those in which evaluation is viewed as a process of identifying and collecting information to assist decision-makers in planning knowledge-based policy, and researchers in understanding the macro picture of mathematics education. Since large-scale research is a relatively new kind of research, its main concern is now setting up an original framework, and developing its own concepts and methods that would satisfy three criteria: relevance to the observable phenomena, exhaustivity with our understanding of mathematical thinking, learning, and teaching, and consistency of the concepts and methodology within the theoretical framework. Large-scale research should include, therefore, the methodological requirements of sharing knowledge, reflections, and curriculum design. These comprise methodological and ethical questions and call for larger involvement of the mathematics education research community, and other academic communities at all stages of the research. Prior arrangements such as these may eventually lead to knowledge-based policy making and may serve as a springboard for changing curriculum, classroom practice, and even national policy in attempts to enhance mathematical education. These issues will be further elaborated in the forum.
References

This paper is dedicated to the Dutch TAL project. In this project learning-teaching trajectories for primary school mathematics are being developed. Regarding the title of this Research Forum, the focus of this paper is rather on "describing goals" than on "measuring learning". Different from an approach in which large-scale assessment projects are carried out to provide evidence for policy on developing mathematical competence, the TAL project can be characterized as a didactical-phenomenological approach in which the nature of mathematical learning content, its sequencing over the grades and the way it is taught in primary school, are reviewed and overhauled.

INTRODUCTION

The nineties can be seen as the decade of standards. In many countries, at governmental level, decisions are made about what schools should teach their students. Examples of these standards are the NCTM Standards in the United States, the National Curriculum and Numeracy Project in the United Kingdom, and the Learning Framework in Number in Australia. This paper deals with the Dutch chapter of this trend.

Compared to many other countries, the Netherlands do not have centralized decision making for the primary school mathematics curriculum (see Mullis et al., 1997). Nevertheless — or probably one should say thanks to this — the mathematical content taught in primary schools does not differ much between schools. In general, all teachers follow roughly the same curriculum. A very important reason for this is the existence of a qualitatively high-standing base of commercially published mathematics teaching methods. Even the implementation of the Dutch reform of mathematics education has in fact been achieved voluntarily through these methods. This rather informal implementation mechanism is more or less the result of the existence a strong community of researchers and developers of mathematics education in the Netherlands. This provides a strong driving and regulating force for reform.

THE CORE GOALS FOR PRIMARY-SCHOOL MATHEMATICS CURRICULUM

Until recently, there was no real interference from the Dutch government regarding the content of educational programs. There only was a general law containing a list of subjects to be taught. In 1993, however, government policy changed and the
Ministry of Education came up with a list of 23 attainment targets for the end of primary school, called “core goals”. The goals are split into six domains, including general abilities, written algorithms, ratio and percentage, fractions, measurement, and geometry. Table 1 shows the goals for the first two domains.

Table 1: Part of the core goals for Dutch primary school students in mathematics

<table>
<thead>
<tr>
<th>General abilities</th>
<th>Written algorithms</th>
</tr>
</thead>
<tbody>
<tr>
<td>1 Can count forward and backward with changing units</td>
<td>8 Can apply the standard algorithms, or variations of these, to the basic operations, of addition, subtraction, multiplication and division in simple context situations</td>
</tr>
<tr>
<td>2 Can do addition tables and multiplication tables up to ten</td>
<td></td>
</tr>
<tr>
<td>3 Can do easy mental-arithmetic problems in a quick way with insight in the operations</td>
<td></td>
</tr>
<tr>
<td>4 Can estimate by determining the answer globally, also with fractions and decimals</td>
<td></td>
</tr>
<tr>
<td>5 Have insight into the structure of whole numbers and the place-value system of decimals</td>
<td></td>
</tr>
<tr>
<td>6 Can use the calculator with insight</td>
<td></td>
</tr>
<tr>
<td>7 Can convert simple problems which are not presented in a mathematical way into a mathematical problem</td>
<td></td>
</tr>
</tbody>
</table>

Compared to goal descriptions and programs from other countries this list is a very simple one. It means that there is a lot of freedom in interpreting the goals. At the same time, however, such a list does not give much support for educational decision making.

In the years since 1993, there have been discussions about these core goals (see De Wit, 1997). Almost everybody agreed that they can never be sufficient to support improvements in classroom practice or to control the outcome of education.

LEARNING-TEACHING TRAJECTORIES — A NEW FACTOR FOR MACRO-DIDACTIC TRACKING

For several years it was unclear which direction would be chosen for improving the core goals: either providing a more detailed list of goals for each grade, expressed in operationalized terms, or a description which supports teaching rather than pure testing. In 1997, the Dutch Ministry of Education tentatively opted for the latter and asked the Freudenthal Institute to work out the description for mathematics. In September 1997, this decision resulted in the start of the TAL Project.

Aim of the TAL Project

The aim of the TAL Project is to develop learning-teaching trajectories for all domains of the primary-school mathematics curriculum. In total three learning-teaching trajectories will be developed: a trajectory for whole number calculation, one for measurement and geometry, and one for fractions, decimals and percentages.

The project started with the development of a learning-teaching trajectory for whole-number calculation. This first trajectory description for the lower grades (including K1, K2, and grades 1 and 2) was published in November 1998. The definitive
version was released a year later. The following year the whole-number trajectory for the higher grades of primary school (including grades 3 through 6) was published. In 2001, both learning-teaching trajectories were translated in English and published together in one book (Van den Heuvel-Panhuizen, 2001).

In 1999, a start was made on the development of a learning-teaching trajectory for measurement and geometry. This will be finished in the end of 2002.

What is meant by a learning-teaching trajectory?

Giving the teachers a pointed overview of how children’s mathematical understanding can develop from K1 through grade 6 and of how education can contribute to this development is the main purpose of this alternative to the traditional focus on strictly operationalized goals as the most powerful engine for enhancing classroom practice. In no way, however, is the trajectory meant as a recipe book. It is, rather, intended to provide teachers with a “mental educational map” which can help them, if necessary, to make adjustments to the textbook.

Although a learning-teaching trajectory puts the learning process in line, it should not be seen as a linear and singular step-by-step regime in which each step is necessarily and inexorably followed by the next one. A learning-teaching trajectory should be seen as being broader than a single track and should have a particular bandwidth. It should do justice to differences in learning processes between individual students and to the different levels at which children master particular skills and concepts.

A new educational phenomenon

Compared to the goal descriptions that were traditionally supposed to guide education and support educational decision making, the learning-teaching trajectory as it is worked out in the TAL Project has some new elements that makes it a new educational phenomenon.

First of all, the trajectory is more than an assembled collection of the attainment targets of all the different grades. Instead of a checklist of isolated abilities, the trajectory makes clear how the abilities are built up in connection with each other. It shows what is coming earlier and what is coming later. In other words, the most important characteristic of the learning-teaching trajectory is its longitudinal perspective which has a long history in the Dutch didactical (subject-matter connected) approach to mathematics education.

A second characteristic is its double perspective of attainment targets and teaching methods. The learning-teaching trajectory does not only describe the landmarks in student learning that can be recognized en route, but it also portrays the key activities in teaching that lead to these landmarks.

The third feature is its inherent coherence, based on the distinction of levels. The description makes it clear that what is learned in one stage, is understood and
performed on a higher level in a following stage. A recurring pattern of interlocking transitions to a higher level forms the connecting element in the trajectory. It is this level characteristic of learning processes, which is also a constitutive element of the Dutch approach to mathematics education, that brings longitudinal coherence into the learning-teaching trajectory. Another crucial implication of this level characteristic is that students can understand something on different levels. In other words, they can work on the same problems without being on the same level of understanding. The distinction of levels in understanding, which can have different appearances for different sub-domains within the whole number strand, is very fruitful for working on the progress of children’s understanding. It offers footholds for stimulating this progress.

The fourth attribute of the TAL learning-teaching trajectory is the new description format that has been chosen for it. The description is not a simple list of skills and insights to be achieved, nor a strict formulation of behavioral parameters that can be tested directly. Instead, a sketchy and narrative description, completed with many examples, of the continued development that takes place in the teaching-learning process is given.

Development of the TAL learning-teaching trajectories

In the development of the TAL learning-teaching trajectories “didactical phenomenological analyses” – as Freudenthal (1983) called them – play a crucial role. These analyses reveal what kind of mathematics is worthwhile to learn and which actual phenomena can offer possibilities to develop the intended mathematical knowledge and understanding. Important is that one tries to discover how students can come into contact with these phenomena, and how they appear to the students. This means that problems and problem situations that give students opportunities to develop insight in mathematical concepts and strategies must be identified. Therefore a team, containing all kinds of specialisms in primary school mathematics, has been formed. The group contains experience in research and development of mathematics education, assessment, teacher educating, teacher advice, and teaching mathematics in primary school. The core of the work is formed by the (almost) weekly discussions in the project team, for which input comes from a variety of sources: analyses of textbook series, analyses of research literature, investigations in classrooms, and extensive consultations of experts in mathematics education. An earlier example of such an approach, but aimed at finding the long term learning process for the domain of ratio, can be found in Streefland (1984/1985).

THE TAL TRAJECTORY FOR WHOLE NUMBER CALCULATION

In the TAL trajectory for calculation with whole numbers (see Figure 1), calculation is interpreted in a broad sense, including number knowledge, number sense, mental arithmetic, estimation and algorithms. The trajectory description gives an overview of how all these number elements are related to each other.
The scheme reflects that the students gradually come from a non-differentiated way of counting-and-calculating to calculations in more specialized formats that fit particular kinds of problems in a particular number domain. Mental arithmetic is considered to play a central role in whole number calculation. It is seen as an elaboration of the arithmetic work that is rooted in the lower grades and forms the backbone in the upper grades.

ESTIMATION AS AN EXAMPLE

New in this trajectory is also the proposed didactics for estimation. Although estimation is now widely acknowledged as an important goal of mathematics education, in most textbooks a framework for how to learn to estimate is lacking. The textbooks at most only contain some problems on estimation, but doing some estimation problems from time to time is not enough to develop real understanding in how an estimation works, and it is not sufficient to comprehend what is ‘allowed’ and what is not when estimating.

At the Research Forum an overview will be presented of the TAL trajectory that has been developed for the domain of estimation. The proposed sequenced teaching structure with the intermediate attainment targets will be compared with the findings of the PPON, a large-scale Dutch assessment of students’ performance in school subjects (Janssen et al., 1999).

Mathematics education researchers should play a part in the improvement of students’ learning of mathematics. The question however is how? Providing empirical evidence about student performance is certainly important input, but will
students’ scores be sufficient to answer the core question about the goals to be achieved?

Notes

1. In the Netherlands, primary school is meant for students of ages 4 to 12 and includes eight grade classes. The first two are kindergarten classes.

2. The TAL Project is carried out by the Freudenthal Institute and the SLO (the Dutch Institute for Curriculum Development), in collaboration with CED (school advisory center for the city of Rotterdam). TAL is a Dutch abbreviation and stands for Intermediate Goals Annex Learning-Teaching Trajectories. Since the beginning of the project the following people have contributed to the development of the learning-teaching trajectory: Joop Bokhove (FI), Jan van den Brink (FI), Arlette Buter (FI/CED), Kees Buys (SLO), Nico Eigenhuis (CED), Erica de Goeij (FI), Marja van den Heuvel-Panhuizen (co-ordinator) (FI), Jan Hochstenbach (FI), Christien Janssen (FI), Julie Menne (FI), Ed de Moor (FI), Jo Nelissen (FI), Anneke Noteboom (FI), Markus Nijmeijer (FI), Adrie Treffers (FI), Ans Veltman (FI), Jantina Verwaal (FI). In total the size of the TAL Team was equivalent to three fully employed persons.

References

The large school system referred to in this paper is the government school system in the state of New South Wales (NSW), Australia. The school system serves a population of approximately seven million people. In administrative terms, the school system is organised into 40 districts of roughly equal student populations. Approximately half of these districts serve part of the metropolitan area of Sydney and the other half serve regional and rural areas of the state. Almost all aspects of school administration and governance occur at the state rather than the district level.

The school system has approximately 1,700 schools with classes in the K-6 range. The age range of K-6 students is about 4 years 9 months to 12 years plus. In 1989, the government introduced a basic skills testing program (BSTP) in literacy and numeracy. All students in government primary schools in NSW in Years 3 and 5 are required to take these tests. As well, the tests are used by many of the non-government schools in NSW. The stated purpose of these tests is diagnostic. The tests are intended to provide information to teachers and schools about weaknesses in knowledge at individual, class or school levels. These tests are developed using Item Response Theory (IRT), have a predominantly multiple choice format and are computer-scored.

Assessment can have many different purposes and a range of audiences. The audience for the BSTP is parents, who receive individual reports of their child’s performance, and teachers, who have access to the diagnostic information from the test — a pencil and paper, single-occasion assessment. The mandatory testing system just described is not the main focus of this paper. The description of the testing system is given to provide contextual background to the main focus of the paper, that is, a novel approach to student assessment that has been adopted by the school system. This approach involves interview-based assessments undertaken by class teachers, for the purpose of documenting students’ knowledge and learning.

THE NEED FOR A SYSTEMIC INITIATIVE IN EARLY NUMBER

In 1995, the NSW school system recognised a need to undertake a systemic initiative in mathematics in the early years (Years K, 1 & 2). This initiative was intended to address several issues: (a) There were vast differences in the levels of mathematical knowledge of students at the Year 3 level, as indicated by the state-wide basic skills testing program. (b) Approaches to assessing students’ mathematical knowledge in the K-2 range were problematic. (c) Some students (K-2) were not being sufficiently challenged in mathematics. (d) Teaching programs were not catering sufficiently for the range of student knowledge in mathematics. (e) By and large, teaching programs
did not reflect particularly strong or useful theories of young children’s mathematics learning or teaching. In the early 1990s, school systems in NSW and other states had undertaken significant initiatives in early literacy learning. These initiatives seemed to address issues in literacy, many of which are similar to those listed above for early mathematics. Thus at this time, the NSW school system was ready to focus attention on reviewing and overhauling the teaching of mathematics in the early years.

BACKGROUND AND OVERVIEW OF CMIT

Development of the CMIT initiative involved from the outset, collaboration between system leaders in mathematics on one hand, and university-based researchers in mathematics education on the other hand. An interview-based assessment had already been developed by researchers and had been used for example, to document the mathematical knowledge of school entrants (Wright, 1991) and the development of mathematical knowledge during the first two years of school (Wright, 1994a). As well, during 1992-5, this approach to assessment had been the basis of a major research program, the focus of which was teacher development in assessing and teaching mathematics in the early years of school (Wright, 1994b; 2000; Wright et al., 1996). Thus the initial development of CMIT involved adapting several key aspects of the earlier research program. This included (a) the assessment tasks; (b) the approach to assessment; (c) the theoretical orientation to learning; (d) explanatory models of student learning; and (e) approaches to teachers’ learning (Wright et al., 2000; 2002).

The goal of the CMIT initiative is to develop teachers’ professional knowledge of teaching and learning mathematics in the early years, and through this to increase their students’ learning of mathematics (NSW Department of Education and Training, 2000). Within CMIT assessment provides the central impetus for teacher change. It is for this reason that the main audience for the assessment data is the classroom teacher. The assessment plays a pivotal role in providing information on what each student can do. Assessment in CMIT is viewed as the process of gathering information to provide direction for teaching. That is, assessment is not an endpoint but a starting point to step into the cycle of teaching and monitoring. If the purpose of the assessment is to provide a lens for teachers’ practice then the teacher must trust and own the data. The one-to-one assessment interview is used not only to obtain information as to what students can do. Rather, the teacher carries out assessment in order to learn more about their students’ thinking. In this way teachers develop a very strong sense of ownership of the assessment data.

The approach to teachers’ learning is school-based, problem-based and team-based. In each of the 40 districts a position of K-8 numeracy coordinator was created. One of the key responsibilities of the numeracy coordinator is the support of CMIT in the schools of their district. Typically this involves supporting an implementation of CMIT in 8-10 of the districts schools, each year. The introduction of CMIT was both
an outside-in and inside-out process. As Fullan (1999, p.62) notes, ‘Two-way inside-outside reciprocity is the elusive key to large-scale reform’. The numeracy coordinator provides ‘at the elbow’ consultancy support in classrooms working as a learning partner to teachers in the school teams. The classroom becomes the place of learning for both students and teachers. Teachers learn more about how students think and use that information to adjust the planned instruction for students. Often, the desire to participate in the program originates in the school. Over a period of 6-8 years, almost all schools will implement the initiative.

The resource materials for CMIT took the form of a professional development package which provides a basis for the teachers’ learning. Key elements of the professional development package are the Learning Framework in Number (LFIN) and the Schedule for Early Number Assessment (SENA). These are described in the next two sections. Development of these resources drew on current research and in particular the constructivist teaching experiment methodology and results of Steffe and colleagues (Steffe & Cobb, 1988) and investigations by Wright (1994a, 2000).

THE LEARNING FRAMEWORK IN NUMBER (LFIN)

The LFIN (Wright, 1998; Wright et al., 2000) provides several key ingredients for the CMIT initiative. First, it provides a general orientation to young children’s learning of number. This includes highlighting the significant mathematics content to be learned, describing instructional contexts and tasks for assessment and teaching, and detailing the strategies students use to solve tasks which are problematic for them. The LFIN describes a range of significant aspects of students’ learning of early number. These include strategies students use in counting, additive and subtractive situations, students’ facility with number words and numerals, students’ knowledge of simple addition and subtraction combinations (number facts, number bonds), early multiplication and division strategies (Mulligan & Wright, 2000), ability to think about multi-digit numbers in terms of tens and ones, and use of finger patterns and spatial patterns in numerical contexts. As well, the LFIN provides an indication of directionality in student learning. The teacher using the LFIN should be able to determine the extent of the students’ learning in various aspects of LFIN, likely progressions in the students’ learning, and instructional situations based on the framework which are likely to lead to those progressions. LFIN can be regarded as a rich description of children’s early number knowledge. The term ‘knowledge’ is used here in an all-encompassing sense — everything the child knows about early number, and includes but is not limited to the child’s arithmetical strategies.

Another key feature of the LFIN is that it enables profiling of students’ knowledge across various aspects of early number learning. This feature involves writing summary descriptions of aspects of early number learning in tabular forms. Aspects of early number learning for which tabular forms are used include early arithmetical strategies, that is strategies for counting, adding and subtracting, early multiplication
and division strategies, knowledge of forward and backward number word sequences, numeral identification, and knowledge of tens and ones. These so-called models of aspects of early number learning can be used to document in summary form, students’ current knowledge and progressions of knowledge over time of large numbers of students (Wright et al., 2000; 2002).

THE APPROACH TO ASSESSMENT

In CMIT, individualised student assessment is regarded as a key initial part of teachers’ learning (Bobis & Gould, 1998). Teachers learn to administer a schedule of assessment tasks, that is the Schedule of Early Number Assessment (SENA). This involves a one-to-one interview during which the teachers’ goal is to elicit as much information as possible about the students’ arithmetical knowledge and strategies. Reviewing of the interviews involves using a standard procedure to complete an assessment record sheet, which details the child’s responses and strategies, and leads to determination of the student’s levels. The assessment process results in three levels of assessment information relating to the students’ early number knowledge. First, and most detailed is the videotape record of the assessment interview; second is the completed assessment record sheet which contains extensive written information about the child’s responses and strategies. Third, is a table showing the levels of the student’s knowledge in terms of four or five of the key aspects of LFIN. The latter constitutes a summarising profile of the students’ knowledge and is particularly useful when documenting the knowledge of large numbers of students and making comparisons in students’ knowledge over time (Bobis & Gould, 1999).

The CMIT assessment procedure recognises that children frequently use strategies that are less sophisticated than those of which they are capable. This may happen for one or more of several reasons, eg (a) it may be easier and although it may take more time, this may not be of concern to the child; or (b) some feature of the child's thinking immediately prior to solving the current task may focus the child's attention on a less sophisticated strategy. Thus an important challenge for the teacher as observer and diagnostician is to attempt to elicit the child's most sophisticated strategy. This is crucial to gaining a powerful understanding of the leading edge of the child's current knowledge. Viewing assessment and teaching through the lens of the learning framework helps to mediate its adoption by classroom teachers. ‘Learning about the Learning framework: I can see...understand where individuals fit in, and therefore what I need to teach them in more detail and more specifically than I’ve learnt from using the curriculum’ (Kindergarten teacher, 16-20 years experience).

DISCUSSION

The approach to documenting student learning that is described above can and should be considered in its broader context. CMIT is a program of teacher development and systemic change that seems to be effective. The program is well-
regarded by participating teachers and schools, and also by external observers (Bobis 
& Gould, 1998; 1999). As well, there are good indications that the program has 
positively influenced the number learning of vast numbers of students (White 
& Mitchelmore, 2002).

The novel approach to assessment described above is one of the key elements of the 
initiative. Assessment in CMIT focuses on more than simply ‘right or wrong’. The 
psychological models that are integral to the learning framework determine the 
nature of the assessment. The methods of solution children use are important to 
determine the child’s location within the models. The nature of the models also 
provides a sense of direction for instruction. We agree with Simon (1995) in that our 
conceptual framework with respect to mathematics teaching includes an emphasis on 
teachers’ inquiry into the nature of students’ understandings so they can pose tasks in 
which those understandings might be challenged and extended.

CMIT does not involve prescribing teaching programs and lessons for teachers. 
Rather, it provides a school-based context for teachers to review their professional 
practice. When a team of teachers in a given school participate in the processes 
associated with CMIT, in a very significant way, they invent or construct the 
program. CMIT recognises that there is not a single mathematics curriculum 
designed, delivered, attained, assessed). Rather, the program works on aligning the 
assessed curriculum, the implemented curriculum, and the attained curriculum. In 
overall terms, CMIT is a learning community that: (a) includes students, teachers, 
numeracy coordinators, system leaders and researchers; and (b) incorporates Senge’s 
(1990) five basic learning disciplines — systems thinking, personal mastery, mental 
models, building a shared vision and team learning.

RESEARCH FORUM 4

Theme
From number patterns to number theory: issues in research and pedagogy

Coordinators
Rina Zazkis and Stephen Campbell

Contributors
Rina Zazkis and Peter Liljedahl, Nathalie Sinclair, John Mason, Tim Rowland
RESEARCH FORUM 4

Theme
From Number Patterns to Number Theory:
Issues in Research and Pedagogy

Coordinators
Rina Zazkis and Stephen Campbell

Session 1
- Introductions and opening remarks
- Short presentations (all interspersed with questions/answers, problems & discussion)
  "Making a case for number theory" by Rina Zazkis and Stephen Campbell
  "What is number theory? (Part 1)" by Stephen Campbell
  "Repeating patterns as a gateway?" by Rina Zazkis and Peter Liljedahl
  "For the beauty of number theory" by Nathalie Sinclair
- Plenary discussion
- Homework assignment (optional)

Session 2
- Short presentations (all interspersed with questions/answers, problems & discussion)
  "What makes an example exemplary? Pedagogical & research issues in transitions from numbers to number theory" by John Mason
  "Proofs in number theory: History and heresy" by Tim Rowland
  "What is number theory? (Part 2)" by Stephen Campbell
- Checking the homework
- Plenary discussion
- Concluding remarks
This research forum reflects on what number theory is, why it is relevant and important, how it connects with and builds upon number patterns, and with other research pertinent to this area (e.g., Campbell & Zazkis, 2002). Number theory is usually considered as a generalisation of whole number arithmetic or as a whole number specialised adjunct of algebra (Campbell, 2001). As such, it is not considered as a topic of study in K-12 mathematics education, in and of itself. In North America, for instance, the limited profile that number theory enjoyed in the NCTM Standards (1989) has been diminished in the NCTM Principles and Standards (2000). Nevertheless, introductory problems from elementary number theory typically abide and can be found sprinkled about various K-12 curricula around the world. On the bright side, there has been an increasing emphasis on using problems from number theory with respect to mathematical reasoning and proof in the middle grades, despite usually being presented under the guise of arithmetic or algebra.

The development and continual refinement of the number system is one of the great, and arguably the most important accomplishment in the history of mathematics. Yet, considering the whole numbers as a proper subset of the real numbers is a relatively recent innovation, and one that has evidently become widely incorporated in mathematics education around the world. There can be no denying the importance of rational and real numbers, practically and theoretically, in teaching and understanding arithmetic, algebra, and especially the calculus. Making a sound case for number theory, however, presupposes that one carefully discerns the integers and whole numbers from rational and real numbers, along with their respective properties, relations, and operations. Only in this way can number theory be properly and justifiably distinguished from and related to other topics in the mathematics curriculum.

A case for number theory can be built, and critiqued, from several different perspectives: its formal mathematical nature, particularly with respect to the additive and multiplicative structure of the integers and whole numbers, its profound beauty and mystique, its utility (or perceived lack thereof) and accessibility, not to mention its contribution to the history and philosophy of mathematics. We hope to touch on all these perspectives, and perhaps others, through the course of this forum. After a brief welcome and introduction to the goals and participants, we first consider the question of what number theory actually is. Campbell treats this issue by identifying some of the main concepts involved, illustrated through a classification schema for problems that comprise number theory in the K-16+ curriculum.

A natural access to number theory is provided through the exploration of patterns. Such exploration, which is typically practiced in elementary years, should not stop there. Zazkis and Liljedahl suggest that a more systematic approach to number patterns
may serve as a gateway for introducing concepts and relations pertaining to number theory. They discuss trends and difficulties that surfaced in preservice elementary teachers’ work with repeating patterns, connecting them with themes identified as troublesome in previous research. In rounding out the first session of this research forum, Sinclair makes a case for beauty, or aesthetic experience in mathematics education. She presents a model for describing the evaluative, generative, and motivational character of aesthetic activity, and illustrates various ways in which it applies to number theory.

It has become customary in mathematics education to argue for teaching the practical utility of mathematics through “real life” applications. We recognise the “practicality” of number theory in more advanced areas of application, such as cryptology, and that elementary number theory does not readily fit in the realm of applicability of “daily life.” Knowledge of number theory will not help in calculating taxes or balancing checkbooks. We consider the utility of number theory from a different perspective -- its utility for teaching and learning mathematics.

Topics from number theory, such as factors and multiples, provide natural avenues for developing mathematical thinking, for developing enriched appreciation and understanding of numerical structure, especially with respect to identifying and formulating conjectures, and establishing their truth. Applying his method of noticing to the question as to how certain task-exercises can lead to theoretical insight, Mason opens the second session by exploring how learners can make transitions from numbers to number theory. Continuing on this theme into more advanced levels, drawing on famous examples such as Gauss’s method and Wilson’s theorem, Rowland illustrates ways in which generic examples in number theory provide exemplary means for teaching and learning proof. Campbell brings the forum full circle by revisiting the question as to what number theory is by analysing why it is distinct from arithmetic and algebra, and how it can readily be treated as such in the early and middle grades.

References

In making a case for number theory, it is helpful to consider various ways in which number theory can be defined and, what is related but not necessarily the same thing, to various ways in which it can be understood. In this paper both are taken to be involved in addressing the question as to what number theory is. One way to begin is to consider the kinds of problems involved. A problem classification scheme is introduced to provide further granularity in this regard. Number theory is then considered with respect to the field axioms implicitly underlying the K-12 curriculum in arithmetic and algebra. Whole number division with remainder, as a result of this analysis, is identified as the key factor in understanding number theory. This result supports evidence suggesting that understanding number theory is enhanced by quotitive dispositions toward division with remainder, and otherwise diminished by partitive dispositions (Campbell, 2002).

Defining Number Theory: Problem Classification

Number theory in K-12 and teacher education programs is typically restricted to introductory topics from elementary number theory. Such topics include the study of multiples, factors, and divisors, divisibility, divisibility rules, least common multiples (lcm), greatest common divisors (gcd), prime factorisation, prime and composite numbers, prime powers, relatively prime numbers, linear sequences, and so on. More substantive topics such as congruence relations, continued fractions, quadratic residues, Diophantine equations, and so on, are typically found in undergraduate number theory courses offered by departments of mathematics.

Most of these topics, along with the many problems in number theory that they readily give rise to, can roughly be grouped into four main problem classes: multiplicative, additive, linear, and non-linear. Although many problems fall clearly into one class or another, these classes are not disjoint. No claim is made or presumed regarding the comprehensiveness, uniqueness, or finality of this classification.

Multiplicative problems typically derive from the fundamental theorem of arithmetic, which asserts that every integer greater than one can be uniquely expressed, independently of order, as a product of prime numbers. Multiplicative problems presuppose divisibility properties of integers, and are often posed in those terms. Problems that require the use, identification, or derivation of various factors, multiples, and divisors are multiplicative. The following are examples of introductory multiplicative problems from elementary number theory:

Consider \( M = 3^3 \times 5^2 \times 7 \). Is \( M \) divisible by 2? 3? 5? 63? (Zazkis & Campbell, 1996a)

Find a number with exactly 13 factors (Mason, this volume).
Determining the number of factors (or divisors) of the integers provides a paradigm case for multiplicative problems in elementary number theory. For an illustration of how this problem can be implemented in the classroom, see Teppo (2002).

**Additive problems** are typically concerned with determining sums and/or sequences of summands of integers. A classic example here is Goldbach’s conjecture that all even numbers greater than four can be expressed as the sum of two primes. Mason (this volume), for instance, invites us to attend to the patterns in the following series of equations involving sequential sums:

\[
1 + 2 = 3 \\
4 + 5 + 6 = 7 + 8 \\
9 + 10 + 11 + 12 = 13 + 14 + 15
\]

Other well known additive problems in elementary number theory include determining which numbers can be represented as sums of consecutive numbers, or consecutive odd numbers, or sums of squares, and so forth.

**Linear problems** are exemplified by the “Division Algorithm” and the “Euclidean Algorithm.” These two algorithms are not just methods for dividing integers and determining greatest common divisors respectively, they are two of the most fundamental theorems of number theory. Both of these theorems are characterised by a linear structure combining multiplication and addition. Linear sequences of integers also fall under this category. Zazkis and Liljedahl (this volume) focus on repeating number patterns and their classic relation to linear sequences.

**Non-linear problems** typically involve non-linear equations in one or more variables such as the classic problem of determining Pythagorean triples, namely, integer solutions to the non-linear equation: \(x^2 + y^2 = z^2\). The generalisation of this problem, and the Pell equation, \(x^2 - dy^2 = 1\), provide other good examples of classic non-linear problems of elementary number theory, even though in many cases more advanced non-integral methods are required to solve them. Determining integral solutions to non-linear equations are usually referred to as Diophantine problems, in honour of the Hellenic mathematician, Diophantos of Alexandria (fl. ~250 AD).

Although there are many important problems in elementary number theory that can readily be identified with one or another of these four classes, there are also problems that blur the boundaries. Consider Gauss’s method for determining the sum of the first 100 non-zero integers (Rowland, this volume). The formulation of this problem is ostensibly additive, but the solution is a non-linear integer function (i.e., \([N(N+1)]/2\)).

Aside from linear and non-linear problems, there are many others with combined emphases placed on addition and multiplication. Determining perfect numbers, in which divisors must be determined and also summed, provides a case in point. Other problems involving base representation, divisibility rules, distributivity, and congruence also place combined and deeply interrelated emphases on these two operations.
Defining Number Theory: Fields and Rings

With a sense of the kinds of problems to be found in number theory, let us turn now to some axiomatic considerations that distinguish number theory from the underlying assumptions upon which K-12 arithmetic and algebra are based. The set of integers constitute an algebraic structure called a ring, whereas sets such as the rational and real numbers constitute algebraic structures called a field. It is helpful in defining and understanding number theory to consider differences between these formal structures.

A field is a (not necessarily numerical) set \( F \) with two operations, called addition and multiplication, which satisfy a collection of axioms, known as field axioms. Field axioms can be separated into axioms for addition, axioms for multiplication, and the distributive axiom (i.e., distributive law) relating these two operations (Rudin, 1976).

The field axioms for addition and multiplication define the properties of closure, commutativity, and associativity for these operations. They also include axioms establishing the existence of operational identities and inverses. Uniqueness properties of operational identities (i.e., 0 and 1) and inverses (i.e., \(-x\) and \(1/x\), such that \(x + (-x) = 0\), and \(x(1/x) = 1\)) can readily be deduced from these field axioms. The existence of unique operational inverses for all elements in the field (with, of course, the notorious exception of zero for multiplication) provides the logical basis for defining the operations of subtraction and division in terms of addition and multiplication respectively (i.e., \(y - x = y + (-x)\), and \(y + x = y(1/x)\)).

A (commutative) ring is a (not necessarily numerical) set \( R \) that conforms to all of the field axioms with the crucial exception of the axiom establishing the existence of operational inverses for multiplication. In a ring such as the integers, without multiplicative inverses, division simply cannot be defined or understood in the same sense as that operation is in a field.

This may not come as a surprise as there is another, more familiar way of reaching basically the same conclusion. It is well known that division as defined by the multiplicative field axioms suffers a lack of operational closure over the integers, when integers are considered independently as a subset of the rational or real numbers (e.g., there is no integral solution for \(7 \div 5\)). What may be surprising is that the lack of closure here is not due to the fact that some integers do not have multiplicative inverses. Rather, it is because no multiplicative inverses exist in the integers whatsoever. The apparent "exceptions" are a result of the divisibility property of the integers (e.g., \(8 \div 4 = 2\) because \(8 = 2(4)\)), they are not (partitive intuitions aside) due to multiplication by a multiplicative inverse (e.g., \(8(1/4) = 2\)).

The above considerations have not been raised in some covert "neo-new math" attempt to resurrect formalisms back into the K-12 curriculum. Rather they have been raised to emphasise, contrary to popular opinion, that division with integers and whole numbers is fundamentally different than rational number or real number division. There is evidence to suggest that when the two are conflated, trouble follows (Campbell, 2002; 2001).
Understanding Number Theory

This brief reflection on axioms defining rings and fields clearly and strongly indicates that understanding number theory in relation to and in contrast with arithmetic and algebra primarily involves questions pertaining to division. More specifically, this means, in teaching and learning number theory, that close consideration be given to understanding terms, procedures, and concepts pertaining to division with remainder (Campbell, 2002; Zazkis, 1998), divisibility (Brown, Thomas, & Tolias, 2002; Zazkis & Campbell, 1996a), and prime decomposition (Zazkis & Campbell, 1996b).

There are both reasons and evidence to suggest that when students have trouble understanding number theory, it is often because they are thinking of division with remainder (i.e., integer and whole number division) in terms of rational or real number division. Campbell (2002) noted that whereas 10 out of 10 students with a partitive disposition toward division were unsuccessful in conducting division with remainder using a calculator, 7 out of 8 students with a quotitive disposition toward division were successful. Campbell suggested those observations could be accounted for by structural similarities between the division algorithm (i.e., $A = QD + R$, where $0 \leq R < D$), which serves to define whole number and integer division, and the quotitive model of division.

These structural similarities alone indicate the quotitive model would be a much more appropriate model for teaching and learning division with remainder than the partitive model. These considerations, of course, take nothing away from, and can only complement the effectiveness of using the quotitive model for teaching and learning division with fractions. Partitive dispositions towards division, on the other hand, insofar as they allow for the possibility of non-integral quotients, seem at the very least to interfere with, if not completely undermine, students’ understanding of number theory.

Even in the limited case of divisibility, where one might be tempted to think that it applies, the partitive model seems quite at odds with the multiplicative structures upon which the concept of divisibility is based (i.e., for any non-zero integer D, D divides A if and only if there exists an integer Q such that $A = QD$). Partitive dispositions, at least insofar as they entail a whole number divisor, are more appropriately applied to and should be reserved for teaching and learning rational and real number division, not number theory.

Concluding remarks

Number theory (qua arithmos) dates back to the emergence of mathematics as a formal conceptual discipline (Campbell, 1999), and there are grounds to suggest that history can inform the psychology of mathematics education (Campbell, 2001). Logical and empirical grounds provided here further suggest that number theory can, and should be treated as a distinct conceptual field in the teaching and learning of mathematics. There are important ways in which number theory is formally and conceptually distinct from arithmetic and algebra, especially with respect to division.
References

Mason, J. (this volume). What makes an example exemplary?: Pedagogical and research issues in transitions from numbers to number theory.

Zazkis, R., & Liljedahl, P. (this volume). Repeating patterns as a gateway.
Consider the following problem:

*Imagine a toy train, in which the first car is red, the second is blue, the third is yellow, the forth is red, the fifth is blue, the sixth is yellow and the same pattern repeats for all the cars. What is the color of the 100th car? If the train has 200 cars, what is the number of the last yellow car?*

Even very young children can engage in activity of continuing with this pattern. They can make a kids-train and declare or pick a label identifying the color. At an early age child's ability to continue the sequence can rely on recursive observations, that is an ability to relate items to adjacent items (such as blue after red, red after yellow, etc.), as well as on a "rhythmic" approach in memorizing the unit of repeat.

Work with patterns is justified in helping acquire mathematical reasoning that is important to learning – as a context for generalization, as a conceptual stepping stone to algebra, as a context for recognition, conjecturing and communication of rules (Threlfall, 1999). However, in order to achieve this relevance it is essential to develop a perception of the unit of repeat in a repeating pattern. Only then can one attend to the question *"What is the color of the 100th car"*. We further suggest that repeating patterns provide a vehicle for directing student's attention to the multiplicative structure of natural numbers, and in such provide a gateway to introducing the concepts of number theory.

So, what is the color of the 100th car? This may be too challenging for a very young child. Let's think, in Polya's tradition, of a similar but simpler problem. What is the color of the 15th car? While young children will play out the sequence explicitly, older ones may start paying attention to the "unit of repeat". Another way to simplify the problem is to consider a two colour train. This may present a wonderful, and for some learners the first, opportunity to consider even and odd numbers. Extending the unit of repeat, that is, the number of colours in a repeating pattern, could introduce or foster a concept of a multiple in elementary school years.

Now let's imagine a 1000 cars toy train in a 7-colours repeating pattern (red, orange, yellow, green, blue, purple, white) and consider the color of the 800th car. A number theoretical analysis of the problem provides a systematic means for predicting the color of any car in the sequence. Strategies for determining such number patterns rely on introductory concepts of number theory, such as factors, multiples, and divisibility. A systematic solution may rely on division with remainder: 800 leaves a remainder of 2 in division by 7, therefore the 800th car is orange. An alternative strategy is to "count up from a multiple": every 7th car is white, therefore the 798th car is white, the 799th is
red and subsequently the 800th car is orange. In what follows we describe the themes that emerged in analyzing the solutions to this problem in a group of preservice elementary school teachers and connect them to the findings of prior research on the understanding of concepts and relations underlying elementary number theory.

**Multiplication and division, multiplication and addition**

The strategy of "counting up from a multiple" was preferred. Even students who recognize and confidently implement both strategies are often unable to describe the connection, that is, to consider "remainder" as a distance from a multiple. Remainder is perceived as one of the numbers you get in performing division with remainder (Liljedahl & Zazkis, 2001). Participants' lack of connection between remainder and "distance from a multiple" is a particular explication of a lack of a more general connection—connection between division with remainder and multiplication. This issue is discussed in detail by Campbell (2002). A very illustrative example is presented in a request to determine quotient and reminder in division by 6 of the number A, where A=147x6+1. Fifteen out of 21 participants in Campbell's study calculated the dividend A and used a long division algorithm in order to answer this question. Generalizing further, a fragile connection between multiplication and division with remainder could be seen as a manifestation of a "weak link" between multiplication and division in general. Consider for example the question of divisibility of M by 7, where M=3^3x5^2x7. As reported by Zazkis and Campbell (1996), it was not uncommon to calculate the value of M and then divide it by 7 in order to conclude divisibility.

In applying "counting up from a multiple" strategy, it was common not to focus on the closest multiple, but rather on a "convenient" multiple. For example, a student could start "counting up" from 700. However, rather than attending to 770, for example, as the next possible benchmark for a "easy" multiple, a students would engage in a "long" sequence of 707, 714, 721... until 798 was eventually reached. We see in this strategy a strong preference towards addition, rather than multiplication. This can also be explained as incomplete understanding of the fact that repeated adding of 7 is equivalent to adding a multiple of 7. The theme of additive dispositions has repeatedly appeared in prior research (e.g. Brown, Thomas and Tolias, 2001).

**Divisibility and division with remainder**

The remainder strategy may appear as advantageous for a "mature" mathematical thinker. However, we observed instances of correct algorithmic applications of the strategy, without an understanding of "why it works". "Counting up from a multiple" strategy, though it may appear as less sophisticated, entails in it an important underlying idea of the number structure: the idea that "every seventh number is divisible by 7", or, in general, that "every nth number is divisible by n". Prior research shows that this property is not among the properties that students take for granted. For example, participants in a study of Zazkis and Campbell (1996) had difficulty in deciding whether there is a number divisible by 7 in a given interval of ten (they were asked to consider numbers between 12358 and 12368) without explicitly finding such a number in this
interval. Furthermore, after correct calculation of remainder in division of 12358 by 7, not everyone could determine, without calculation, what would be the remainder in division by 7 of 12359.

In mathematics the idea of "every nth number is divisible by n" is naturally extended to the partition of natural numbers into disjoint sets by the relation of congruency modulo n. (That is, elements in each set of such partition are congruent to each other modulo n). This idea is expressed in terms of our pattern as "every seventh car is white". However, depending on where the count begins, it is equally true that every seventh car is blue and every seventh car is orange. While this may appear as "trivial" when considering cars, the mathematical manifestation of this property – that, for example, numbers leaving a reminder of 5 in division by 7 are "7 apart" on the number line – was not applied naturally by some participants. For example, having identified the color of a specific car as red, a participant had to count up in order to decide what would be the number of the next red car.

The ideas of partitioning of natural numbers have been explored further in the study that focused on arithmetic sequences (Zazkis & Liljedahl, 2002). In one of the interview questions students were asked to consider whether a given (large) number was an element of a given arithmetic sequence. Our analysis made a distinction between sequences of multiples (e.g. 3,6,9,12, ...) and sequences of so-called "non-multiples" (e.g. 2,5,8,11, ...). While the divisibility of a number by d (d is the common difference) gave a clear indication of belonging to a sequence of multiples, the lack of divisibility by d left students uncertain about its membership in a sequence of "non-multiples". This is another indication that extending the property of "every nth" from division to division with remainder should not be taken for granted.

**Notable misgeneralizations**

In previous sections we described students' approaches that may be seen as inelegant or mathematically unsophisticated, but at least they weren't wrong. In this section we describe several recurring mistakes related to recognition of numerical patterns.

- A notable misapplication of the above mentioned property "every 7th number is divisible by 7" appeared when students assigned to a car, which number was divisible by 7, the color "red", the color of the first car, rather than "white" - the color of the seventh car. These students noted the property of "every seventh", but applied it starting with the first, rather than the seventh, element (Liljedahl & Zazkis, 2001).
- Another improper generalization repeatedly appeared when participants generated the property of the kth attribute (blue) to "every kth" car, without attention to the unit of repeat. A claim such as "Since the blue car is in the 5th position, all the multiples of 5 will be blue" illustrates this approach.
- For a number of students that clearly and correctly identified that multiples of 7 are the key to solving the pattern, the ways to determine such multiples were improperly generalized. We witnessed claims that "the 137th car is white
because 137 is divisible by 7 as it ends in 7" and also "151 is divisible by 7 because of the sum of the digits" - which are based on overgeneralization of familiar divisibility rules for 5 and 3. Though these claims were infrequent, they confirmed appearance of similar improper generalization reported in prior research (Zazkis & Campbell, 1996).

- Consideration of a multiples of \( d \) (\( d \) is the common difference) is the key in situations of determining membership and generating elements in arithmetic sequences of multiples (described above). However, this strategy has been improperly extended in consideration of sequences of non-multiples as well. A claim such as "700 is an element in the sequence 8,15, 22, ... because 7 is a factor of 700" illustrates this extension. Similar phenomenon, referred to as "difference product" or "direct proportion", was observed by researchers investigating middle school students generalization of repeating patterns (Orton and Orton, 1999, Stacey, 1989).

Conclusion

There is a recent trend in mathematics education to make mathematics "relevant" to the students by presenting it in "context". "Relevance" and "context" are often interpreted as activities related to "everyday" or "real" life. In contrast, it is argued that numbers themselves offer a "context" for investigation and for rich background of ideas and experiences. We agree with Nemirovsky (1996) that "real contexts are to be found in the experience of the problem solvers" (p. 313), rather than in formulation of the problem.

Focusing on patterns is advocated in the research literature as a stepping-stone in the generalization approach to algebra (Lee, 1996). In particular, Threlfall (1999) argues that linear, or one-dimensional, repeating patterns represent the first step towards number patterns in algebra. Extending these claims, we suggest that attending to number patterns is also a stepping-stone to number theory. We believe that consideration of repeating patterns can either introduce or enhance concepts and relationships underlying elementary number theory, and especially the multiplicative structure of natural numbers.

References

Imagine if—instead of following the established formal mathematical structures that dictate the basic guidelines of curriculum—we based our choices on more aesthetic aspects: which mathematics will students find appealing, wonderful, surprising and intrinsically satisfying? Why might we do this? Which topics would we choose? In this short article I will outline some of the potential aesthetic aspects of elementary number theory and thus provide additional support to several researchers’ recommendations for its increased curricular emphasis (Campbell and Zazkis, 2002).

Introduction

There are no shortage of quotes, such as Bertrand Russell’s assertion that mathematics possesses a “supreme beauty... capable of a stern perfection such as only the greatest art can show” (1917, p. 57), in which mathematicians profess the beauty and elegance of their discipline. Many mathematicians have also claimed that the aesthetic plays an important if not necessary role in mathematical activity, a claim that has had curiously little impact on mathematics education research—partly, perhaps, because we know so little about the roles of the aesthetic in the production and appreciation of mathematical knowledge.

Given its low profile—and even, at times, its outright dismissal—in the mathematics education research community (as opposed to the professional mathematics community), why should the aesthetic play any part in determining curricular and educational goals? There are three different though related reasons that I have formulated: a) the aesthetic should play a major role in mathematics education because it plays a fundamental role in research mathematics; b) the aesthetic should play a major role in mathematics education because aesthetic ways of thinking and knowing are central to learning and meaning-making; and c) the aesthetic should play a major role in mathematics education because providing students with access to aesthetic experiences—that is, intrinsically satisfying experiences of mathematics inquiry—is a basic goal of education.\(^1\)

Since I adopt a broad interpretation of the aesthetic that extends beyond restrictions to responses to objects of ‘art,’ and that encompasses other domains of inquiry through which humans attempt to make their experiences meaningful and ‘fitting,’ I begin by elaborating a model of the roles of the aesthetic in mathematical activity.

---

\(^1\) In the following section, I provide warrants for the first reason. I have provided arguments for the second reason in Sinclair (2002b). The third argument rests on particular goals for education that some may disagree with; it loosely corresponds to the Deweyian (1938) goal of “assisting the personal growth and development of individuals.”
Model of the roles of the aesthetic in mathematical activity

Through an empirical/analytical interdependency methodology (Toulmin, 1971) I have shown that the aesthetic dimension of mathematical activity is not merely a fanciful, romanticised, after-the-fact judgement of mathematical beauty; but rather, it permeates mathematical activity and purposively animates mathematical knowledge (Sinclair, 2002b). I have identified three distinguishable aesthetic characteristics that play varying roles in mathematical activity: the evaluative, generative and motivational.

The evaluative characteristic concerns the aesthetic nature of mathematical products and the role of the aesthetic in making value judgements on these products (including theorems, proofs, definitions, diagrams, questions and theories). The evaluative characteristic of aesthetics is not just about objectively deciding whether a proof is elegant. Rather, it is involved in a mathematician’s decision-making about truth, understanding and value. Without aesthetic judgement, it would be very difficult to distinguish the select results—of the thousands and thousands produced each year—that are worthy of further attention, of recognition, of passage into the ‘canon’ of textbooks, and of funding.

The generative characteristic focuses on the role of the aesthetic in inventing or discovering mathematics; it may be the most difficult of the three characteristics to discuss explicitly, operating as it most often does—for mathematicians at least—at a subconscious or tacit level (Hadamard, 1945; Poincaré, 1908). The aesthetic choices guiding mathematicians’ processes of inquiry manifest a form of understanding that is qualitative, that is, neither formal nor propositional. These choices are made based on sensitivities to aesthetic qualities such as symmetry, analogy, simplicity and order. Mathematicians as well as philosophers (Dewey, 1938; Polanyi, 1962) have argued that the process of (mathematical) inquiry relies on the extra-logical form of thinking of the generative characteristic of aesthetics as much as on the more frequently cited logical and sequential forms of thinking.

The motivational characteristic relates to the role of the aesthetic in prompting or inspiring mathematical activity. This character is necessary to the process of selection and initiation in the mathematician’s work. But more importantly it is directly involved in motivating inquiry as it directs the attention of the mathematician—what will be noticed—and frames the types of questions a mathematician will ask about a certain situation. Thus the motivational characteristic not only determines the field(s) and problems on which a mathematician works, but actually shapes the mathematician’s inquiry (Dewey, 1938).

My model of the roles of the aesthetic in mathematical activity also accounts for a more encompassing theme in mathematical inquiry not explicitly mentioned in the literature: the aesthetic qualities of experiences which mathematicians describe having that unify and make memorable some of their encounters with problematic situations. This experiential dimension—pervading feelings and responses that arise out of mathematicians’ experiences—contrasts with the more distinctive, cognitive roles of
aesthetics identified above (see Sinclair (2002a) for an analysis of the aesthetic as a theme in mathematical experience).

The aesthetic in number theory

The following 1989 NCTM Standards quote nicely draws attention to the aesthetic potential of elementary number theory: “Number theory offers many rich opportunities for explorations that are interesting, enjoyable and useful. These explorations have payoffs in problem solving, in understanding a developing mathematical concepts, in illustrating the beauty of mathematics, and in understanding the human aspects of the historical development of number” (p. 91). What is meant mean by “interesting” and “enjoyable”? What is meant by the phrase “illustrating the beauty of mathematics”? Are these aesthetic opportunities actually valued as fundamental to mathematics learning by the education community or are they seen as epiphenomenal? By analysing five different dimensions of elementary number theory in light of my aesthetic model, I would like to inquire further into these aesthetic qualities of mathematics, as well as better articulate why they should be valued.

Children have number

Non-negative integers—the primary objects of elementary number theory—are pervasive in children’s lives, as are the operations of multiplication and division. These are objects and operations that children see, know and use “... students from middle school through college feel comfortable dealing with whole numbers” (Selden and Selden, 2002, p. 214). This level of comfort and acquaintance can help in conjecturing and problem solving, and I claim it can also stimulate both the generative and motivational characteristics of aesthetics. In terms of the generative, students working with number theory situations or activities have the cognitive liberty of concentrating on exploring, guessing, and ‘playing with’ without being distracted by having to simultaneously extend their conceptions of mathematical operations and objects. Silver and Metzger (1989) have shown how this cognitive liberty is crucial to enabling aesthetic thinking—even in ‘expert’ mathematical activity.

A higher level of comfort and acquaintance can also stimulate the motivational characteristic of aesthetics, particularly with respect to the potential for surprise and paradox: the more you know about something, the more you will expect certain regularities based on your experiences, and the more likely you will be surprised by contradictions or interruptions. Zazkis (1999) illustrates a simple example of potential surprise with respect to the number for factors of an integer \( F(n) \): students expect that the greater \( A \) is, the greater \( F(A) \) should be (or if \( A_1 > A_2 \) then \( F(A_1) > F(A_2) \)), using the reasoning that works well in everyday contexts that ‘the more of A, the more of B.’ Students are surprised by mathematics when their expectations, even those based on their intuitions, are contradicted. For instance, students can be surprised that a small change can make a big difference, that a random collection of objects can share a common property, or that analogies can prove to be non-analogous. Moreover, as Movshovits-Hadar (1988) argues, surprise can not only provide exciting experiences
for students in the mathematics classroom, it is also deeply connected to learning. The feeling of surprise stimulates students’ curiosity which can, in small steps, lead towards intelligibility; it makes the students struggle with their expectations—and with the limitations of their knowledge—and thus their intuitive, informal, and formal understandings; and lastly, it provokes students to develop an appreciation of the significance of the concept in question.

Humans have had number for a long, long time

Mathematicians are often aesthetically motivated by a feeling that mathematics is somehow transcendental—providing them with a sense of order and certainty in our otherwise chaotic world. Similarly, there is an appeal to the seemingly transcendental types of problems and concepts that have been with us—or could have been with us—since the time of the Ancient Greeks: mathematicians continue in the tradition of Pythagoras to look for proofs of the irrationality of 2; many questions about prime numbers, factoring, and partitioning are as vibrant today as they were 2000 years ago. The realisation that she is posing a problem, or working on one, that Zeno or Euler could have posed might stimulate in a student an aesthetic motivation—one that is much more profound than the purported motivation factor associated with the ‘real-life’ problems pervading so many textbooks and curricula.

More than meets the eye!

As Selden and Selden (2002) write, “it is a well-known ‘folk theorem’ among mathematicians that number theory questions and conjectures can be easy to state but phenomenally hard to prove” (p. 214). For mathematicians this is a frequent source of aesthetic motivation: questions that are easy to state can elicit in them not only with the same sense of wonder that Aristotle claimed grips philosophers, but can provide them with a way of connecting with non-mathematicians and mathematicians alike—everyone can understand Goldbach’s conjecture! In a related way, elementary number theory features many of the aesthetic wonders of mathematics—ideas such as infinity and scale, which Egan (1990) has shown have intrinsic appeal to students. Such ideas can thus initiate Whitehead’s (1929) romantic stage of mathematics learning during which the “subject-matter has the vividness of novelty; it holds within itself unexplored connexions with possibilities half-disclosed by glimpses and half-concealed by the wealth of material” (p. 29). Whitehead argued that this stage was crucial and necessarily antecedent to the stages of precision and generality which students are often pre-maturely pushed into.

A study of patterns

The types of problems that crop up in elementary number theory are, as Ferrari (2002) notes, particularly well-suited to those actions of pattern-discernment and exploration which are eminently available to students. This can stimulate the motivational, generative, and evaluative characteristics of aesthetics. Humans are good at patterning—it is how they learn about and appreciate their world. When students recognise that they can activate a behaviour they know they are good at, they can
derive the same kind of aesthetic appeal that motivates mathematicians to seek out and take on the types of problems that activate the ways of thinking with which they have had success—whether its symbolic juggling or visual representation. Also, many of the problems and objects of number theory can be patterned in concrete, accessible forms (for example: actual numbers as opposed to, say, abstract algebra objects; the patterned numbers in the colour calculator (Sinclair, 2001); figurate numbers; Pascal's triangle\(^2\)) on which the qualitative, aesthetic ways of reasoning can more easily operate. Finally, with such pattern-rich, accessible situations, students can undertake that most crucial of mathematical activities: problem posing (Brown and Walter, 1983). It is with the act of posing problems—deciding whether they are worth pursuing and convincing others that they are—that the evaluative characteristic of aesthetics is first operative for mathematicians, and can be first stimulated in students.

A mathematical showpiece

Of course, the evaluative characteristic is also operative in the judgements that mathematicians make about their results, be they theorems, definitions or proofs. It is this aspect of the aesthetic on which mathematics educators have traditionally focused—concluding that although it is important in mathematics, it cannot be introduced to, or appreciated by students until the 'basics' have been learned (e.g. Dreyfus and Eisenberg, 1986). Their conclusion is based on the fact that students do not have the same aesthetic responses as mathematicians. However, Brown (1973) has shown that students do have aesthetic responses—based on different criteria perhaps than those of mathematicians—which contribute to their sense of the value of mathematics and thus serve a similar animating purpose. While Brown's students responded to the degree with which a solution to a number theory problem revealed their own path through the problem, students can also appreciate, for instance, the efficiency of a solution (as evidenced in their responses to Gauss' purported method for summing the integers from 1 to 100), the cleverness of a proof, and the perspicuity of a diagram; these are all criteria that mathematicians such as Hardy (1940) have proposed for judging the worth of mathematical entities. Geometry has traditionally been the topic area through which students are exposed to that ultimate mathematical entity of proof (and its related arts of conjecturing and verifying), but apart from an exposure to the various proofs of the Pythagorean theorem—maybe—they have little opportunities to respond to the various elegant, brutish, insightful, practical ways that mathematicians have of explaining and convincing. However, through elementary number theory, even students with little mathematical background can encounter many of these methods such as proofs by contradiction, induction, generic examples (see Rowland, 2002), visual proofs and counterexamples.

\(^2\) In fact, Hawkins (2000) argues that by working with a combination of number and form—of the spatial and pictorial with the analytic means of understanding—that students' aesthetic engagement can best be stimulated and supported.
Concluding remarks

This article is but an initial, and very general, attempt at analysing the aesthetic potential of elementary number theory in mathematics education. Although my model of the roles of the aesthetic in mathematical activity is both theoretically and empirically grounded, more inquiry into the particular responses of students would greatly help in designing activities that can best capitalise on this aesthetic potential.

What makes an example exemplary?:
Pedagogical & research issues
In transitions from numbers to number theory

John Mason
Open University, UK

Worked examples have been used in teaching mathematics since the earliest of historical records, at least. In order for such examples to be useful, learners must see them as exemplifying something. If that 'something' is, for example (sic) 'the mystery of mathematics', 'the impossibility of doing something similar myself?', or 'the ridiculousness of all this stuff', then learners are unlikely to make mathematical progress. If on the other hand the 'something' is a class of problems and a collection of techniques and ways of thinking, then the worked examples have served at least some of their purpose. Looking through a particular and seeing generality is a form of, and a building block for, generating a theory. When a learner has constructed their own 'theory', their own seeing of how to do a whole class of problems, then real learning is taking place. In the language of Sinclair (this volume), learners participate in an aesthetic of efficiency and compactness afforded by their awareness of generality, or what the examples are exemplifying. Rowland (this volume) provides further examples of techniques for supporting learners in seeing the general through the generic particular (see also, Mason & Pimm, 1984).

The fact that text authors have, throughout the ages, inserted worked examples and only in some periods tried to start with general rules before illustrating their use in particular, suggests that in most generations teachers have been aware of the difficulty of proceeding from the general to the particular (at least unless very carefully guided: see Davydov 1990).

Method of working

My method of enquiry is to identify phenomena I wish to study, and to seek examples within my own experience. I then construct task-exercises to offer to others to see if they recognise, or can be directed to recognise, what I find myself noticing. Through refinement and adjustment of task-exercises in the light of experience and of reading relevant literature, I both extend my own awarenesses, and offer others experiences which may highlight or even awaken sensitivities and awarenesses for them. These sensitivities and awarenesses may inform their future practice. As task-exercises are developed and shared, actions which exploit what is noticed for the benefit of learners are incorporated. My method does not attempt to capture or cover the experience of readers. Rather it aims to make contact with that experience, perhaps challenging interpretations, perhaps pointing to other features not previously noticed. The data of this method are the experiences generated, the sensitivities to notice which are enhanced. If you recognise at least something of what I am talking about as a result of having worked on the task-exercises, then you may be stimulated to look out for similar experiences in the future, and over time, begin to act upon what you notice. Validity in this method lies in you finding your actions being informed in the future, not in what I say (Mason, 2002).
Examples

Consider the following task:

*Find the greatest common divisor (gcd) of 84 and 90. Find their least common multiple (lcm) as well.*

You can imagine a whole page of these sorts of questions, and if you do, then you have a sense of a class of tasks (for more on classifying problems in number theory, see Campbell, this volume). But do learners also have a sense of this class, even when they have worked through the page? Could they make up for themselves versions which ‘showed possible difficulties that can arise in some cases’ or which ‘illustrate what things can happen’? Are they aware of two approaches (factoring and the Euclidean algorithm), and do they have criteria for choosing one over another? If such tasks are augmented a little:

*Multiply your two answers together and compare the product with $84 \times 90$*

something more is suggested, which can be pushed further into the realm of generality with something like

*Might this always happen? or Will this always happen? or even, Can you find two numbers for which this does not happen?*

The indefinite pronoun ‘this’ may invite learners to clarify what the ‘this’ is, or may leave them helpless, depending on their past experiences with these kinds of question. To prompt learners to think of factoring, the task

*Find a number with exactly 13 factors*

makes use of a largish number (13) which invites simplification (try 3 factors, try 1 factor!) and then re-generalisation beyond the 13, with extensions concerning characterising or describing the class of all numbers with a given odd number of factors, and finding the smallest such number. There are also extensions to even numbers for the bold. This is typical of the approach developed in the 60s and 70s in the U.K. (Banwell et al., 1972) in that learners are invited to undertake a task in which they make choices in order to simplify on the way to re-complexifying for themselves.

Finding a number with exactly 13 factors is not a single task but an entry point into a whole domain of tasks which include finding numbers with a given number of factors, how many smaller numbers less than itself are relatively prime, among others (see Banwell et al., 1972 p. 37, pp. 102-3). Such a task domain includes various variants in presentation as well as in content. It is of pedagogic use only if it becomes a vehicle for learners to use their natural powers to imagine and to express, to generalise and to particularise, to conjecture and to convince, and if their attention is drawn to the fact of these powers and to ways of refining and honing them. For example, although an observer might say that they detected the emergence of a theory about the structure of numbers as products of primes, and about the parity of the number of divisors, participants might be wholly unaware that that is what they were doing. Their attention is likely to be confined to trying to sort out their ideas and to justify their conjectures. Yet what they are doing is what mathematicians do. Becoming
aware of the emergence and articulation of a ‘theory’ can both inspire and support the
development of a learner’s mathematical self esteem.

Another collection of tasks which promote number factoring are obtained by ‘undoing’ the
first task:

Find a pair of numbers whose gcd is 6; find another pair; and another ... leading to the
learner deciding spontaneously to classify or characterise all such pairs. Similarly, find
a pair of numbers whose lcm is 1260, leading to, how many different pairs can have a
specified lcm?

Participants are not only developing a theory about the structure of pairs of numbers with a
given lcm. They are also experiencing the use of their power to organise and characterise in
a mathematical context, much as mathematician are wont to do. In other words, by being
immersed in such tasks learners are likely to develop a ‘theory’ of what doing mathematics
is like, a theory which would be very different from a theory developed as a result of only
attending lectures and doing routine exercises (Watson & Mason, 1998).

A further advantage of refining and honing their powers to think mathematically is that
learners are less likely to be caught by, or to persist in, spontaneous theories such as that
‘all functions are monotonic’: if \( x > y \) then it is likely that \( f(x) > f(y) \) (Zazkis, 1999), or that
all functions are linear: e.g., \( \sin(A + B) = \sin(A) + \sin(B) \) and \( \ln(A + B) = \ln A + \ln B \). These
are all too common manifestaitons, even by learners who when questioned directly know
that they are false generalisations. The problem is perhaps that learners are entirely
unaware that they have these theories, and they are not in the habit of testing theories and
looking for counter-examples. In the midst of a complex problem, they simply do not have
sufficient free attention to monitor what they are doing.

The temptation of authors and teachers is to lay out examples, perhaps as tasks, and to
expect learners to build on the experience of a succession of tasks in order to become aware
of, or to experience that succession. But as Kant has quite rightly pointed out in his
Critique of Pure Reason: a succession of experiences does not add up to an experience of
that succession.

Evidence of this phenomenon can be found in many different contexts. For example, in a
professional development session I offered the following sequence of statements, with lots
of pausing so that participants would see that they were supposed to check each equation in
turn, and to attend to the patterns between equations:

\[
1 + 2 = 3 \quad 4 + 5 + 6 = 7 + 8 \quad 9 + 10 + 11 + 12 = 13 + 14 + 15
\]

‘We’ (meaning I wrote what some of the participants said) had written down two more
rows. I asked for an expression of generality. One person suggested

\[ n + (n + 1) = \ldots \] but was then a bit stuck.

It transpired that his attention was entirely on the first equation. The others were not seen as
part of ‘the experience to be generalised’. Rowland (2000) met the same thing with pre-
service primary teachers. Asked to check that:
and then to write down a statement in words generalising these three examples, many wrote nothing or nothing that could be construed, and some wrote a false generalisation such as:

*three consecutive numbers added together equals the product of the first two*

achieved by attending solely to the first 'example'.

It is quite likely that unfamiliarity with being asked to express a generality produced a tunnel vision effect, so that attention became focused on but one instance. The fact that the two threes play different roles could be overlooked, which would make the conjectured generality at least understandable. In the case of the sequence above, progress was made by asking people to chant the equations out loud but with emphasis first on the first number, then in a second pass, on the last.

Watson (2000) has pointed to the phenomenon of ‘reading with the grain’ and the necessity of ‘reading across the grain’ in order to experience structure. Thus in the Tunja sequences (Mason, 1999; 2001), which I developed in order to promote simultaneous work on factoring quadratics and on multiplication of negative numbers, I have found as expected, that non-mathematical audiences are perfectly capable of working with the grain—that is of following a pattern which is closely related to counting numbers and perhaps square numbers. For example:

\[ 3 \times 5 = 4^2 - 1 \quad 4 \times 6 = 5^2 - 1 \quad 5 \times 7 = 6^2 - 1 \]

can be extended ‘downwards’ to more equations by observing the counting-numbers in sequence. Being directed to read across the grain—that is to relate both sides of each ‘equation’—leads to the realisation that the symbolic expressions must be the same, somehow. This is one of the necessary awarenesses that make algebraic manipulations meaningful. Different looking expressions can nevertheless express the same thing, so there ought to be a way to get from one expression to the other simply by manipulating symbols. The sequence can also be pushed backwards, against the grain; to reveal necessary facts about multiplication of and by negatives, given that we want the ‘pattern’ to continue.

As is well known, specific kinds of questions can lead learners to unexpected metageneralisations. For example, being asked to express a pattern as a general formula can lead them to a pattern of behaviour which avoids the intended inner-task (Tahta, 1980) and exercises only the outer-task, namely, to find a formula which fits. As mathematicians well know, though intelligence testers seem yet to discover, no sequence, even the Tunja or the 'Consecutive Sums', uniquely defines its next term. There must be some source for a pattern which is agreed. Thus the sequence:

\[ 1, 2, 4, 8, \ldots \]

can have many different fifth terms (indeed, any fifth term, but see Sloane (1973) for examples of sequences which count things, and which begin this way). If the sequence is counting some aspect of a sequence of pictures, such as the number of regions of a circle formed by 0, 1, 2, 3, \ldots chords, or the number of regions of space formed by 0, 1, 2, 3, \ldots
planes in general position (Polya, 1965), then it is essential to have a statement of that
generality before embarking on trying to find a general formula.

But even where learners are frequently engaged in formula-finding, the whole exercise can
turn into ‘train-spotting’ (Hewitt, 1992) rather than productive mathematical thinking
which exercises and refines the power to generalise.

Consider then some further options for extension.

The act of finding the gcd and lcm of two numbers can be seen as functions, but this
requires the learner to step out of immediate action-experience, and to contemplate the
whole. Having achieved some measure of competence with these calculations, the
calculations themselves can be seen as objects. This is the domain of reification, when a
process is also experienced as an object. In Mason et al. (1985) this was used to
characterise one of the major steps in appreciating algebra, when expressions like 3x + 4
come to be seen both as a specification of a calculation process, and as the object resulting
from that process, and this dual nature then becomes the essence of algebraic expressions
which replace numbers as the objects to be manipulated. Sfard (1991; 1992; 1994)
developed the notion of reification while (Gray & Tall, 1994) used the term procept to
indicate the evolution of a concept from carrying out a process as a theorem-in-action
(Vergnaud, 1981) to seeing the process as an object in itself. Notation for the process helps
enormously, for once something is named, it comes into psychological existence.

One way to stimulate learners to experience calculations as processes is some variant of:

Tell an absent friend how to calculate the gcd and lcm of a pair of numbers.

Program a machine to find the gcd and lcm of a pair of numbers.

I am going to be given a pair of numbers, but I can't tell you what they are at the
moment (or I have a friend who has a pair ...). Please tell me how to calculate their gcd
and lcm.

Suddenly what seemed almost frighteningly open becomes bounded. A theory might just be
possible. Notice that I do not provide my ‘answers’ nor even my theories in the sense of
ways of seeing. For once theories are published, pedagogic value leaks away.

Final comments

Terms such as investigative teaching (and its variants such as discovery learning) provoke
extreme reactions in many audiences, while lecturing and starting from the abstract
provoke similar reactions in different audiences. Neither reactions are helpful as they are
based on emotive associations with general labels, rather than precise details of pedagogic
strategies. When teaching that is even marginally effective is examined closely, aspects of
both pedagogic stances, of starting from the particular and the concrete and starting from
the general and the complex will be found to have value. Strict adherence to one format is
likely to foster the pedagogic theory that ‘this is always how things are done’, whereas
variation in approach is more likely to broaden learners’ views of what mathematics is
about, what questions it addresses, and what methods it employs (Watson & Mason, 1998).
Above all, the most important theory we want learners to construct is that they do actually
possess the requisite powers to do mathematics and to think mathematically. Then they can make an informed choice as to whether to develop and make use of those powers within mathematics in the future.

**Bibliography**

My purpose in writing this paper is to advocate the use of particular-but-generic proof strategies in undergraduate classrooms and in textbooks, in order to convince students of the truth of number-theoretic theorems and student-generated conjectures. The domain of number theory lends itself particularly well to generic argument, presented with the intention of conveying the force and the structure of a conventional generalised argument through the medium of a particular case. The potential of the generic example as a didactic tool is virtually unrecognised. Although the use of such examples has good historical provenance, the suggestion that they might be an alternative to formal proof tends to be viewed as a kind of heresy from the perspective of modern proof practice.

Procedures and proofs

The use of examples to point to abstract concepts and to general procedures is commonplace pedagogical practice (see e.g. Mason’s paper for this research forum). In the field of number theory, a case in point might be explication of the Euclidean algorithm for the greatest common divisor of two natural numbers. Beginning with, say, 194 and 40 the demonstration proceeds:

\[
\begin{align*}
194 &= 4 \times 40 + 34 \\
40 &= 1 \times 34 + 6 \\
34 &= 5 \times 6 + 4 \\
6 &= 1 \times 4 + 2 \\
4 &= 2 \times 2 + 0
\end{align*}
\]

In order to apply the procedure to another pair of natural numbers, the student needs to become aware of the status of each number in each row of the procedure, and how each row relates to the next. That is, not only to agree that each line is a true statement, but to appreciate how it has been initiated and structured. As teacher, I might assist this by (say) underlining the quotients 4, 1, 5, 1, 2 in red. I might draw diagonal lines joining the divisor and remainder in each line to the dividend and divisor, respectively, in the next e.g. joining the two 40s, the two 34s, and so on. (It is relevant to pause to reflect on how you made sense of the previous sentence: perhaps the example was more illuminating than the somewhat archaic expression of the general procedure that preceded it.) The choice of example (194, 40) was made in recognition of its merits in its own right and relative to some alternatives. I judge it to be preferable to (194, 48), which is a poor paradigm because, for that pair, the algorithm terminates too soon. I would also avoid (144, 89) for a different reason: although it has good ‘length’, it conveys difference rather than division. Try it, if the intention of that remark is not self-evident. I would resist (97, 20) in recognition of my own liking for coprime pairs despite their particularity.

Much less common is the use of examples to explain why general relationships might hold: in short, to prove. One reason why this might be the case is clear enough—because
one or more examples cannot prove a statement about an infinite category of cases. Yet there is a sense in which the presentation of a single example can speak for some general truth, and for some general argument above and beyond the particularities of the example itself. Such examples, suitably structured to be not just a confirming instance but a chain of reasoning, are known as generic examples. As Balacheff (1988) so clearly and elegantly puts it:

The generic example involves making explicit the reasons for the truth of an assertion by means of operations or transformations on an object that is not there in its own right, but as a characteristic representative of the class. (Balacheff, 1988, p. 219)

The generic example serves not only to present a confirming instance of a proposition - which it certainly is - but to provide insight as to why the proposition holds true for that single instance. The transparent presentation of the example is such that analogy with other instances is readily achieved, and their truth is thereby made manifest. Ultimately the audience can conceive of no possible instance in which the analogy could not be achieved.

Un peu d’histoire

The story (probably apocryphal, but see Polya, 1962, pp. 60-62 for one version) is told about the child C. F. Gauss, who astounded his village schoolmaster by his rapid calculation of the sum of the integers from 1 to 100. Whilst the other pupils performed laborious column addition, Gauss added 1 to 100, 2 to 99, 3 to 98, and so on, and finally computed fifty 101's with ease. The power of the story is that it offers the listener a means to add, say, the integers from 1 to 200. Gauss’s method demonstrates, by generic example, that the sum of the first 2k positive integers is k(2k+1). Nobody who could follow Gauss’ method in the case k=50 could possibly doubt the general case. It is important to emphasise that it is not simply the fact that the proposition 1+2+3+...+2k = k(2k+1) has been verified as true in the case k=50. It is the manner in which it is verified, the form of presentation of the confirmation.

Paul Hoffman recounts the story in his best-seller The Man Who Loved Only Numbers (Hoffman, 1998). His comment on it (quoting mathematician Ronald Graham) is a telling testimony to the genericity of Gauss’ method.

What makes Gauss’ method so special .... Is that it doesn’t just work for this specific problem but can be generalised to find the sum of the first 50 integers or the first 1,000 integers ... or whatever you want. (p. 208)

In introducing the notion ‘generic example’ to audiences of all kinds - undergraduate and graduate students, mathematics education conference-goers, ‘general audiences’ - I routinely choose Gauss’ method as a paradigm of the genre. We should not be surprised that Gauss, of all people, should have provided it. Ironically, his Disquisitiones Arithmeticae established the ‘modern’ standard for generality in number theoretic proof arguments.
By contrast, Pierre de Fermat (1601-65) was notorious for stating number theoretic results in the absence of formal proof. In particular, it was Euler who gave a general proof of the ‘Little’ Theorem (if \( p \) is prime and \( a \), an integer, \( p \) divides \( a^p-a \)) some decades after Fermat stated it. In a recent article, Burn (2002) offers some suggestions concerning the kinds of reasoning that Fermat himself might have used to establish the truth of some claims associated with his Little Theorem, made in a letter to Mersenne in 1640. These claims were developed in the course of Fermat’s search for perfect numbers. A natural number (such as 6 or 28) is said to be perfect if it is equal to the sum of its divisors including 1, but not itself. Around 300BC, Euclid had established that the set of perfect numbers can be identified with integers of the form \( 2^{n-1}(2^n - 1) \) where \( 2^n - 1 \) is prime. In his letter to Mersenne (after whom such primes are named), Fermat claimed that if \( n \) is composite then \( 2^n - 1 \) is not prime. The proof amounts to the observation that \( 2^n - 1 \) divides \( 2^{ab} - 1 \). The converse, however, is false: in 1536, Hudalrichus Regius had shown that although 11 is prime, \( 2^{11} - 1 \) is composite, and so \( 2^{10}(2^{11} - 1) \) is not a perfect number.

Fermat made a claim which was to transform the previously Herculean task of determining whether or not \( 2^p - 1 \) is prime for a given prime \( p \). In effect, Fermat claimed that if an integer of this form has a prime factor, then that factor is of the form \( 2kp + 1 \) (the factor 1 is covered by \( k=0 \), and it follows from Fermat’s Little Theorem that \( 2^p - 1 \) itself is of the form \( 2kp + 1 \)). Thus, to decide whether a proper factor of \( 2^{11} - 1 \) exists, we only need to consider 23, since this is the only prime of the form \( 22k + 1 \) with square less than \( 2^{11} - 1 \). In fact, \( 2^{11} - 1 = 23 \times 89 \). (Note that 89 is also of the form \( 22k + 1 \), as expected).

In his letter, Fermat exemplifies this statement about prime factors of \( 2^p - 1 \) with reference to this case i.e. when \( p = 11 \). Burn (ibid.) reconstructs the argument that Fermat might have given with reference to this particular-but-generic case. Burn then continues: “Now we generalise the generic example of factorising \( 2^{11} - 1 \) by expressing the argument algebraically”. Of course, this accords with good modern practice, although Burn does not suggest that Fermat, having established the generic, then required the general formulation to be convinced of the general case.

**Teaching and learning Wilson's theorem**

The obscure Cambridge mathematician John Wilson is remembered to this day on account of a theorem stated in 1770, a century after Fermat’s demise:

\[
p \text{ is prime if and only if } (p-1)! = -1 \pmod{p}
\]

To be precise, it was Edward Waring, Isaac Newton’s successor (and Stephen Hawking’s predecessor) as the Cambridge Lucasian Professor of Mathematics, who stated the result of his former student, Wilson. In the best traditions of the time, neither Wilson nor Waring managed to prove the theorem: its status seems to have been a conjecture, the outcome of inductive reasoning from examples. It fell to Lagrange to give the first proof of Wilson’s theorem, in 1773. How then, might we approach the genesis of the theorem and the construction of its proof with the hindsight and didactic insights of the twenty-first century? What might a generic proof of that theorem look like?
As a preliminary, we would need to know that ±1 are the only self-inverse elements under multiplication modulo \( p \). Now consider the prime number 13 (17 or 19 would do equally well) and list the reduced set of residues modulo 13:

\[
1 
2 
3 
4 
5 
6 
7 
8 
9 
10 
11 
12
\]

Pair each of the numbers from 2 to 11 with its (distinct) multiplicative inverse mod 13: (2, 7), (3, 9), (4, 10), (5, 8), (6, 11). 1 and 12, of course, are self-inverse. [I usually link the elements in the inverse-pairs with lines on a chalk board]. Clearly, the product of these integers from 2 to 11 must be congruent to \( 1^5 \), i.e. 1, modulo 13. Therefore \( 12! \equiv 1 \times 1 \times 12 \) (=12) mod 13. The argument is generic, since 13 was in no way an untypical choice: the pairing would work equally well with any prime.

The scene now shifts to a session with class of about 20 first-year undergraduate joint honours mathematics-with-education students. I could have stated Wilson’s theorem and proved it formally in five minutes. In fact, it took an hour to make some conjectures and to work on proof. This is what happened.

First, I asked them to evaluate \( 4! \mod 5 \), \( 6! \mod 7 \), \( 10! \mod 11 \), and to write down a conjecture. The most common version of the conjecture was \( n! \equiv n \mod (n+1) \). The ‘for all \( n \)’ seemed to be implicit. I asked them to evaluate \( 5! \mod 6 \). They did, and they were visibly surprised by the refutation. I asked whether they could modify the conjecture. At first they homed in on the even/odd distinction between moduli, but \( n=8 \) led to further refutation and eventual restriction to prime values of \( n+1 \). \( n=12 \) provided a further confirming instance. I proceeded to an interactive presentation of a generic proof, inviting Sonia to pick a prime between 11 and 19. She chose 19. I got them to list 1 to 18 and work on inverse pairs in table-groups, during which Simon spontaneously explained to his colleagues why \( 18! \) had to be 18 mod 19. I asked him to repeat his reasoning to the class, and wrote his explanation on the whiteboard. He picked out eight inverse pairs, and explained why the product of the integers from 2 to 17 inclusive would have to be 1 mod 19. They dutifully copied Simon’s argument. Later, I enquired what would have happened if we had looked at \( 28! \mod 29 \), and Abby explained why it would have to be 28, again referring to inverse pairings of the integers from 2 to 27, although without feeling the need to identify the pairs this time. “Does everyone agree?”, I asked. They agreed. One shouldn’t read too much into such consent, however pleasing; nevertheless, Abby, at least, had convinced me that she had appropriated the proof-scheme.

The next day, at a tutorial meeting, I asked five members of the class to write out the proof (that, for primes \( p \), \( p! \equiv p - 1 \mod p \)) in conventional generality. Their responses were unaided and individual. It should be borne in mind, as I indicated earlier in this paper, that these students will have had little experience of composing formal proofs. Nevertheless, they all indicated in their writing that the genericity of the case \( p=19 \) had been apparent to them. Moreover, their argumentation and use of notation would have satisfied any examiner. Hannah’s response, which was typical, was as follows.

\[
(p-1)(p-2)(p-3)(p-4) \ldots 2 \times 1
\]
Every element of $M_p$ has an inverse, because $M_p$ is a group.

We know (from work on primitive roots) that only $p-1$ has order 2. Therefore $p-1$ is self-inverse. All other members of $M_p$ apart from 1 must have a distinct inverse.

Each inverse pair when multiplied gives $1 \mod p$.

This gives $(p-1)(1^{1/2(p-3)}) \equiv (p-1)! \mod p$

Therefore $(p-1)! \equiv (p-1) \mod p$

Only Zoë gave evidence of some insecurity in this intangible world that lies beyond examples. Her proof was much the same as Hannah's, but began with identification of the inverse pairs in the case $p=11$ (transfer to other examples) and concluded the comment:

I tried to find a formula for the inverses, for example $p-2$ has inverse $p-6$ (but only for $p=11$). I have been unable to do this.

For Zoë, mere knowledge of the existence of distinct inverses in the range 2 to $p-2$ is not enough. What is not clear is whether it leaves her cognitively insecure, or whether she believes that I (in my role as assessor) will expect more.

Abby's proof was elegantly and lucidly expressed, but stated that there are $\frac{1}{2}(p-1)$ inverse-pairs rather than $\frac{1}{2}(p-3)$. A case an error of manipulation, but not one of conception.

Generic arguments and cognitive unity

The domain of elementary number theory lends itself remarkably well to generic argument, presented with the intention of conveying the force and the structure of a conventional generalised argument through the medium of a particular case. One reason for this might be that, in the choice of examples, one seems to be spoiled for choice: there are an awful lot of integers (or primes, or whatever subset is called for) compared, say, with groups, or topological spaces. This is not to say that the choice of a generic example is an arbitrary one: it can be (and in a sense, it ought to be) a conscious pedagogical act. Some examples work better than others do for particular purposes - they carry and convey the generalisation rather better because the salient operations on the variable(s) can easily be tracked through the argument. Some tentative principles for the selection of generic arguments and the construction of generic arguments in number theory are given in Rowland (2002). I conclude, however, with some cautionary remarks.

First, the proof of Wilson's theorem given above crucially depends on knowing and being certain that 1 and $p-1$ are the only self-inverse elements under multiplication $\mod p$. How shall we establish that result? It emerges readily (as a conjecture, of course) from examples, especially when the contrast is made with non-prime moduli. The usual proof runs as follows: if $1 \leq a \leq p-1$, and $a^2 \equiv 1 \mod p$, then $p \mid (a-1)(a+1)$ and so $p \mid (a-1)$ or $p \mid (a+1)$. Whence $a=1$ or $a=p-1$. The essence of this argument is the solution of a

---

1 $M_p$ denotes the group $\{1, 2, 3, ..., p-1\}$ under multiplication $\mod p$. 

PME26 2002
quadratic equation in a multiplicative modular group, which seems to rule out a generic presentation entirely free of algebraic symbolism. It is true that I could take \( p \) to be 13, and argue that \( a \) must be 1 or 12, but I can’t seem to side-step arguing from (and with) \( 13 \mid (a-1)(a+1) \). Perhaps someone will delight me by convincing me that I’m wrong on this point.

Secondly, the converse of Wilson’s theorem [if \( n \) is composite then \( (n-1)! \neq n-1 \mod n \)] appears to lend itself wonderfully well to generic exposition. Take the case \( n=10 \). Now \( 9! = 362880 \), so \( 9! \equiv 0 \mod 10 \). Yes, but why? Because \( 9! \) includes factors 2 and 5. Since 10 is composite it can be decomposed into the product of two factors, both strictly between 1 and 10, so both occur as terms in 9! It is thus apparent that if \( n \) is composite then:

\[ (n-1)! \equiv 0 \mod n \]

However, whilst this conclusion is certainly true, the argument does not, in fact, transfer to all composite numbers. In those special cases when \( n \) is the square of a prime \( p \), the only possible decomposition of \( n \) into the product of two factors, both strictly between 1 and \( p-1 \), is \( n = p \times p \). The factors are not distinct and it is not the case that both occur as terms in \( (n-1)! \). It is not difficult to make a separate argument for these cases, but they can easily be overlooked, and caught in the shadow, as it were, of the earlier generic argument.

Notwithstanding these cautionary words, there seems to be a good prospect of developing and offering a systematic didactic technology of formal proof in number theory, building on skilfully-constructed generic examples. There is evidence that such an approach to proof is supportive of the cognitive unity of theorems, that is to say “the continuity ... between the process of statement production and the process of its proof, as well as providing meaningful examples”. (Mariotti, Bartolini Bussi, Boero, Ferri and Garuti, 1997).

DISCUSSION GROUPS
Imagery and Affect in Mathematical Learning

Coordinators: Lyn English, Queensland University of Technology (Australia)  
Gerald A. Goldin, Rutgers University (USA).

Traditional views of mathematics as an abstract, formal discipline have tended to relegate visualization, metaphor and metonymy, emotions, and the relation between feeling and mathematical imagination to incidental status. Continuing the discussions begun at PME-24 in Hiroshima and at PME-25 in Utrecht, our primary focus is on imagery, affect, and how they interact: their interplay with natural language, formal notations, heuristics, beliefs, and especially with each other. Representation in learning mathematics includes not only external structured physical configurations, but also internal systems that encode, interpret, and operate on mathematical image and symbol configurations (Goldin, 2002). We have a strong case for the centrality of imagistic reasoning, analogies, metaphors, and images in such representation (English, 1997; Presmeg, 1998). Lakoff and Nunez (2000) even (controvertially) seek to recast the foundations of mathematics in terms of conceptual metaphors. Essential roles of affect in encoding information, influencing learning and performance have also been noted and studied (Evans, 2000; Goldin, 2002; McLeod, 1992).

For PME-26, we will extend our discussions on the nature and role of affective and imagistic representational systems in mathematical learning and problem solving. In doing so, we will explore an embodied perspective on perception, cognition, affect, imagination, and reasoning. This issue generated much discussion at PME-25 and participants expressed a keen interest to pursue the topic.

In the first session, we will review the Discussion Group’s progress to date, and then continue our discussion on the embodied perspective and other perspectives that participants raise. In the second session, we plan to focus on specific classroom examples of the issues in question and consider some of the difficult points in their empirical investigation. Intending participants are asked to bring along problem-solving data (including videotaped activities and transcripts) in which the group can identify examples of imagery, affect, and especially their interplay.

STOCHASTICAL THINKING, LEARNING AND TEACHING

Co-ordinators: Brian Greer, San Diego State University, USA
Chris Reading, University of New England, Australia

In general, the group will continue to discuss the relationship between stochastical and mathematical thinking, learning, and teaching from multiple perspectives. Specific themes to be addressed will be:

- curriculum issues – syllabus, textbooks, software, assessment
- making connections within mathematics and with other subjects
- the wider social significance of stochastics education

We will begin with a commemoration of the contribution of John Truran to stochastics education, in particular his leadership of this Discussion Group.

Participants in the Sixth International Conference on Teaching Statistics and in the Second International Research Forum on Statistical Reasoning, Thinking and Literacy will report on those meetings.

Short contributions to initiate discussion will include:

- Andy Begg (New Zealand) talking about rich learning activities in syllabuses, textbooks, and assessment linking statistics with other parts of mathematics and with other subjects
- Chris Reading (Australia) talking about the “Profile for Statistical Understanding”
- Swapna Mukhopadhyay (USA) talking about the use of statistical data for critical analysis of social issues
- Chris Nisbet (Australia) talking about students’ graphical representation of statistical data
DISCUSSION GROUP
SEMIOTICS IN MATHEMATICS EDUCATION RESEARCH

Coordinators
Adalira Sáenz-Ludlow, University of North Carolina, USA
Norma C. Presmeg, Illinois State University, USA

For at least ten years, mathematics educators have incorporated different theoretical semiotic frameworks into an already rich set of psychological, anthropological, linguistic, and sociological theories to analyze the teaching practice and the learning of mathematics in-and-out of the classroom. The purpose of the group is to continue the discussion on how different semiotic perspectives contribute to our understanding of cognitive, linguistic, and social issues in the teaching and learning of mathematics. Six scholars, who have been using semiotics as a theoretical framework in their research activities, have been invited to contribute to the discussion.

In the first session, the contributors will discuss different semiotic aspects of classroom communication namely the role of signs for coding, indicating, and constructing mathematical knowledge; the semiotic reciprocity between referring, expressing, and addressing in educational settings that takes into account curricula, textbooks and classroom in a holistic manner; and the power of Buber’s “I-Thou-We” triad to coordinate the wide spectrum of students’ experiences and arguments in undergraduate and graduate courses on problem-solving and design.

1. The communicative and cognitive role of mathematical signs: An epistemological perspective on mathematical interaction
   Heinz Steinbring
   Universität Dortmund, Germany

2. From utterances to genres in mathematics education (and vice versa): A dynamic triadic (socio-) semiotics exemplified
   Sigmund Ongstad
   Oslo University College, Norway

3. The significance of dialogue in problem-solving using Buber’s triad “I-Thou-We”
   C. Jotin Khisty
   Illinois Institute of Technology, USA

In the second session, the contributors will pursue different semiotic venues to offer an enriched view that balances social and individual aspects of mathematical knowing and the role of signs in learning and doing mathematics. The papers will discuss the nature of the writing activity of mathematical text on the part of mathematicians in contrast to that of secondary school students; the complementarity of diagrammatic reasoning and conceptual thinking; and the pivotal role of signs in reading, writing and thinking mathematically.

1. What does social semiotics offer to mathematics education research?
   Candia Morgan
   University of London, UK

2. How diagrammatic is mathematical reasoning?
   Willi Dörfler
   Klagenfurt, Austria

3. A semiotic perspective on mathematical activity
   Paul Ernest
   University of Exeter, UK

At the beginning of June 2002, the papers will be posted in the web site <http://www.math.uncc.edu/~sae/> that was established for the PME25 discussion group on semiotics so that participants will have the opportunity to read them beforehand. Contributors will give the participants a birds’-eye-view of the main ideas in their papers and will elicit discussion on different issues. Each presenter is allowed 25 minutes to achieve these two goals. Five minutes are saved for transition between presenters.
RESEARCHING THE SOCIAL AND POLITICAL IN MATHEMATICS EDUCATION FROM A CRITICAL PERSPECTIVE: DILEMMAS FOR RESEARCHERS

Co-ordinators: Tansy Hardy and Hilary Povey
Sheffield Hallam University, England

Researching the social and political in mathematics education from a critical perspective raises a particular set of dilemmas for researchers. These may include the choice of what to research and who decides; the purpose of the research and the purposes to which it might be put; the methodology of research, traditional or alternative; the practice of the research, particularly as it relates to the people involved; and the reporting of the research, the format, the language, the authorship.

It is the intention to continue the work that was undertaken on this subject last year at PME 25. A number of individuals offered the whole group a response to the invitation to reflect on their own research into political and social issues in mathematics education and to highlight some feature of the research which had been problematic for them. Issues considered included

- researching sites which promote values opposed to those of the researcher;
- reporting in the language of the participants? the language of the researcher? the most powerful language in mathematics education?
- resisting the attribution of the ‘label’ expert northerner researching the south;
- the centrality or otherwise of a narrowly defined focus on mathematics education in the research;
- reporting to and with the participating community;
- the importance of seeking strategies that impact on policy;
- contributing to a shift within the dominant discourse of the mathematics education research community itself.

The co-ordinators will bring to the first session some specific and focused, possibly fictitious, dilemmas on which small sub-groups will work. Depending on their complexity, these may be circulated electronically before the conference. The second session will be adapted to meet the outcomes of the first session. It may include sharing reflections on the first session; writing reports of dilemma resolutions; considering dilemmas which are actual for the group members; or planning continuing work for the group.
The crucial idea in the conceptual change is the radical reconstruction of prior knowledge which is not very well observed in traditional teaching. The theories of conceptual change (see Vosniadou 1999; Duit 1999; Reiner, Slotta, Chi & Resnick, 2000) define two levels of difficulty in the learning process. The easier level of conceptual change means enrichment of one’s prior knowledge structure. In this case the prior knowledge is sufficient for accepting the new specific information. The student needs only to add the new information to the existing knowledge. The more difficult conceptual change is needed when the prior knowledge is incompatible with the new information but needs a reconstruction. There seems to be at least two basic kinds of directions for problems in conceptual change. The one is the knowledge and operations which are relevant on a certain domain, but need to be revised on the other. This is the case with the mistaken transfer from natural numbers to the rational numbers. For example the students seem to face considerable difficulties in struggling to sort fractions (Hartnett & Gelman 1998) because of their spontaneous use of the logic of natural numbers. The other kind of problems are the beliefs and conceptions caused by experiences with mathematics. The need to make drastic changes to the prior thinking may not even occur to the students unless the needed change is made very explicit in the teaching.

The purpose of the discussion group is to explore the specificity of the nature of conceptual change in mathematics concept formation (wide conceptual field needed, different representations used etc.), to discuss about the role of prior thinking and to find ways to facilitate this conceptual change.

References

The production of a thesis is the major task in most Ph.D programmes in mathematics education. Very often the work is closely supervised by one individual although in some institutions a committee is provided, for this purpose. Ideally the student could be working within a research project and calling upon the support of a number of individuals. The responsibility for producing the thesis rests with the candidate but the supervisor influences the work at all levels and so also bears a responsibility. The work is eventually judged by others, probably members of the mathematics education community. On what bases are these judgements made? Does a student know how the work will be assessed?

The discussion group plans to consider criteria for judging the worth of a thesis and also to engage students in the conversation to find their preferences and experience.
DISCUSSION GROUP: SYMBOLIC COGNITION IN ADVANCED MATHEMATICS

Principal Co-ordinator: Stephen J. Hegedus,
University of Massachusetts Dartmouth, USA

Assistant Co-ordinators: David Tall, University of Warwick, UK.
Ted Eisenberg, Ben-Gurion University, Israel

The study of Symbolic Cognition builds upon the work on representations in mathematics learning and communicating in the classroom (Janvier, 1987; Cobb, Yackel & McClain, 1997). We refer to symbolic cognition as the construction of mathematical signs and symbols and the processes involved in manipulating such objects into meaningful concepts, procedures and representations.

Following our very first meeting of the group at PME25 in Utrecht, rich and varied discussion has continued through the implementation of an on-line email forum.

At PME26, we aim to continue discussion focusing on seven important areas of interest which arose out of preliminary inquiries. These include:

1. The mediation of human experience by purposeful use of symbol systems;
2. The co-evolution of language and symbol systems;
3. The role of orality and literacy in the development and use of mathematical symbols;
4. The inter-relationship of signs and symbols (e.g. the work of Pierce);
5. On producing the symbolic – processes, actions and manipulation;
6. New technologies, new representational structures;

Each day discussion will be led by two or three short and focused presentations of 10 minutes each by members of the group aiming to further concentrate our ideas. Our aim is to generate specific lines of inquiry, which lead to the formation of a working group at the next meeting of PME. We see the group working in small sub-groups, concentrating on some of the main themes already outlined and new ideas deemed important and significant. This set-up will support the formation of special interest groups, which reflect the individual members’ lines of expertise in symbolic cognition.

On-going work can be found at the group’s website at www.symcog.org.

REFERENCES

The aim of organising a discussion group about learning disabilities in mathematics is to share research results and perspectives concerning this topic. Learning disabilities in mathematics seem to become an increasing problem in many countries. Too often these problems are assigned to experts who are not specialized in mathematics education. We intend to establish more contact between mathematics educators who work in this field.

The following aspects should be discussed:

- Is there a common understanding of learning disabilities in mathematics?
- What are the experiences in different countries and school systems?
- Are there new research findings concerning the diagnosis of learning disabilities in mathematics?
- Do children with learning disabilities in mathematics need a specific curriculum?
- What kind of teaching and instruction is appropriate for these students? Which standards of actual research in mathematics education are valid as well for low achievers as for high achievers? Which standards can be adapted?

During the sessions some specific thesis will be discussed. Moreover a reaction of experts is planned (asked: Rene Parmar/USA; Anne Watson/UK).
WORKING SESSIONS
AIMS

The principal aim of the workshop is to pursue conjectures concerning the psychology involved in the construction of mathematical objects meeting specified conditions. Participants will engage in mathematical tasks which involve the construction of objects, which, although familiar in general, may lead to extending their sense of classes of objects.

A subsidiary aim of the workshop is to demonstrate in practice how it is possible to learn from reflection upon and abstraction from, your own experience, informed and supplemented by accounts offered by colleagues.

TOPIC

Our starting point is that one characteristic of an expert is the ability to re-construct what they need, suitably modified and adapted to the current situation. This is in contrast to remembered and recited phrases, incantations and techniques. Our concern is with the construction of mathematical objects. We have discovered that many teachers at all levels report that they sometimes get their learners to construct mathematical objects for themselves. We are collecting examples of how learner-generated-examples alter the learners’ relationship with mathematical objects and affect the kind of understanding which they display.

PLANNED ACTIVITIES

Activities will be based around mathematical tasks constructed on the basis of studies currently in progress and so are not specifiable in detail at this stage. They will be appropriate for a wide range of participants.

Participants will be invited to work individually and then in groups on a minimum of two different tasks per session, and to engage in small-group and plenary reflection and abstraction from that experience.
LEARNING FROM EACH OTHER.

Breen, Chris, University of Cape Town, South Africa
Hannula, Markku S., University of Turku, Finland

AIMS
The workshop aims at increasing researcher sensitivity in the interpretation of classroom incidents. Participants will engage in analysis and role-play in order to generate different emotional and critical interpretations of a chosen classroom interaction.

ACTIVITIES
The working session will use both group work and whole class discussion methods. The seed for the working session will come from a classroom incident, which will be accessed through either videotape or transcript. Several groups of participating researchers will be asked to role-play the same situation. Our aim is to facilitate the creation of different interpretations of the thoughts and feelings of the teacher and students during the episode and use this as a platform to discuss the various interpretations. In addition, we will try to get the class to identify some critical teacher decisions in the excerpt and then generate the possibilities contained in alternative possibilities for teacher action.
This working session will focus on the problem of how to compose a path on a plane given two functions over time (e.g. x(t) and y(t) in a cartesian plane), or, the inverse problem of decomposing a given path into two functions over time. The problem of composing and decomposing planar paths have been the subject of recent individual and classroom teaching experiments conducted by the coordinators and their colleagues. Through these activities we tried to enrich high school students’ capability to imagine motion in space as defined by parametric functions. Gestures, utterances, and tool-use were focal aspects of our analysis.

The working session will be divided in two parts. During the first half the participants will work with tools and activities that involve the composition and decomposition of paths on a plane. During the second half the participants will analyze selected episodes filmed in individual and classroom teaching experiments. The coordinators will bring videotapes and transcriptions for the selected episodes.

The research questions for the session will be about the roles of physical experiences in mathematics learning and about the development of imagination. This question will be explored through the participants’ engagement with the tools and activities as well as through the analysis of classroom interactions.
Gesture, Metaphor and Embodiment in Mathematics

Coordinators:
  Laurie Edwards, St. Mary's College of California
  Janete Bolite Frant, PUC-Sao Paulo
  Jan Draisma, Catholic University of Mozambique, Nampula

One perspective on mathematics as a form of human cognition is that its roots lie in common human experience, both social and biological. In particular, our experiences as embodied, conscious beings provide the "raw material" needed to construct mathematical concepts. From the perspective of embodied mathematics (Lakoff & Nunez, 2000), both mathematical objects and processes can be analyzed in terms of more basic conceptual structures such as image schemata and conceptual mappings (Fauconnier, 1997). A common type of mapping is the conceptual metaphor, in which the logical and inferential structure of a source domain is utilized in making sense of a target domain (an example would be the embodied understanding of how objects can contain each other which underlies, unconsciously, the mathematical notion of set inclusion).

A complementary perspective on cognition and communication utilizes the analysis of gestures to help reveal how people think about mathematics. Coming out of the work of David McNeill and other psychologists and linguists (McNeill, 1992, 2000), this perspective views gesture as an integral part of language, not simply an embellishment. In advance of the session, readings on embodied mathematics as well as the analysis of gesture generally and in mathematics teaching and learning (e.g., Goldin-Meadow et al. 1999) will be made available via a website. During the session, videotaped data will be analyzed interactively in terms of embodiment, as expressed in both metaphorical language and gesture. Through the discussion group, we hope to continue building a common vocabulary, theoretical perspective, and methodology for understanding mathematics as an embodied phenomenon.

This Working Session will aim to engage participants in discussion and activities concerned with various aspects of writing for publication. In particular we shall try to work on the following issues.

**What are the key elements of a research paper?**
What is the nature of such elements? How can they be presented effectively? What issues are involved?

Should all papers include some theoretical framework? What forms does/can such a framework take? What would be included? What are the associated issues?

What kind of examples of data should be included? How would they be selected? How are examples related to findings and results?

**In what ways might a research paper be structured?**
What do readers need to be told, how, and in what order?

*e.g.*, dealing with the complexity of findings: use of bullet points, subsections, tables etc.

**What is involved in a review process?**
How do reviewers look at papers? What are the key criteria? What guidance is given? What questions are asked?

We hope that PME members who are editors and/or reviewers for the main research journals with which PME is associated will join this group and contribute to activity and discussion. Special issues of a journal arising from work at PME could be a consideration.

The two sessions will be based around detailed examination and discussion of a number of issues of relevant journals. Participants will be encouraged to work in small groups identifying characteristics of articles and raising questions.

Participants will be given an article or articles to read between sessions and asked to analyse this in terms of the questions and characteristics raised. Discussion of this activity will follow in the second session.
CHANGING ENGINEERING STUDENTS ATTITUDES IN CALCULUS
Roselainy Abdul Rahman (UTM), John H. Mason (OU) & Yudariah Mohd. Yusof (UTM)

This presentation will give the preliminary results of an on-going research on changing students’ attitudes towards Calculus. The main objectives of the research were to identify suitable approaches to encourage students to use their mathematical thinking powers and develop materials to further support these activities. The research was conducted on a group of first year engineering undergraduates taking Basic Calculus.

This research was motivated by the main findings from research conducted on mainly engineering undergraduates in Universiti Teknologi Malaysia (UTM) which found that these students had difficulties in coordinating procedures and manipulating concepts (Liew Su Tim & Wan Muhamad Saridan, 1991; Tall & Razali, 1993) and that they could not organise known facts effectively as well as master the mathematical language and symbols (Mohd. Yusof & Tall, 1994; Khyasudeen, et al, 1995). Furthermore, Yudariah (1995) found that the lecturers in UTM had little confidence in their students’ abilities to cope with a formal mathematics course and designed their teaching accordingly. Students were encouraged to learn procedurally and given routine tasks to ensure success in examinations. However, they felt that there was a need to develop students’ mathematical thinking and problem solving abilities.

The study adopts suitable qualitative research methods that studies the learning situation in context, in particular, an action research perspective of “practitioner as researcher”.

Here we will report on some of the findings which includes changes in the teaching methods to invoke students’ mathematical thinking powers such as specialising and generalising, the use of symbolic and multiple notations, technical terms and unfamiliar examples and expressing mathematical ideas. Difficulties encountered in the research implementation will also be discussed.

REFERENCES
This presentation will review a substantive theory explaining different students' progress in learning Real Analysis, and thereby integrate established theoretical constructs in this area.

This theory was developed through inductive analysis of interview data. Participants were attending either a lecture course, or a new, classroom-based course in which they worked in groups through a sequence of problems in order to prove results themselves (based on Burn, 1992).

Learning outcomes are characterized as demonstrating instrumental, relational, logical, or formal understanding, where these are closely related to how the student justifies statements about sets of mathematical objects (Skemp, 1979, Tall, 1995). Factors found to be causal in student development are their visual or nonvisual reasoning style (Presmeg, 1986), and their sense of authority regarding the mathematics, where this is characterized as internal or external (Copes, 1992, Skemp, ibid.). The new course did not precipitate changes in these predispositions, but did promote improved student reasoning in restricted ways. Hence, the relationship between these factors may be represented as below:

The presentation will define the terms in more detail, and provide illustrative examples demonstrating the ways in which these factors interact to lead to the different types of understanding.

SECONDARY TRAINEE-TEACHERS’ KNOWLEDGE OF STUDENTS’ ERRORS AND DIFFICULTIES IN ALGEBRA
Mohammed Al-Ghafri, Keith Jones and Keith Hirst
Centre for Research in Mathematics Education, University of Southampton, UK

This study investigated trainee-teachers’ explanations of students’ errors in algebra and their suggested ways for addressing such errors. The theoretical framework for the study is derived from Shulman’s (1986) idea that teachers’ knowledge consists of several types of knowledge. In the model developed for this research, and informed by the work of Askew et al (1997) and Ma (1999), teachers’ knowledge about students’ errors and difficulties and teachers’ belief about mathematics and how it can be taught have been incorporated.

Data gathering involved administering an open-ended questionnaire to a national sample of 251 trainee-teachers of secondary mathematics in 12 institutions in the UK, followed by a small number of semi-structured interviews for the purpose of validating and extending the data from the questionnaire survey.

The analysis of the completed questionnaires revealed that the majority of trainee-teachers explain students’ errors in terms of the incorrect application of the procedures for working out algebra problems. Hence, they recommend re-teaching these procedures to the students so that the students might overcome their difficulties. Other parts of the analysis showed that most secondary mathematics trainee-teachers are able to suggest a teaching sequence that takes into account the hardest and the easiest algebra problems. Finally, most of the trainees were able to predict the most likely errors in a set of five algebra problems. However, less than fifth of them obtain $R^2>0.6$ when correlated with Küchemann’s (1981) suggestion in regards to the facility level (percentage) of some algebra problems. This indicates that only a small proportion of trainee-teachers understand the sort of characteristics that determine the complexity of an algebra problem such as the number of variables in the problem, the nature of the elements involved and, importantly, students’ interpretations of the letters.

REFERENCES
Three levels of mathematics curriculum were identified: the intended, the implemented and the attained curriculum (Dirks and Robitaille, 1982). Alexander (1992) suggested a framework for aspects of practice in primary classrooms that serves as a useful prompt to those involved in the judgement of that practice (the implemented curriculum) which are the content, the context, the pedagogic process and the management of teaching and learning. This study focuses on the similarities and differences in the context and the pedagogical practices of teaching primary mathematics between the English and the Qatari classrooms.

Eight primary classes in each country were selected to cover the entire primary age range from classes whose teachers were willing to participate in the study in both countries. Each classroom was observed for three lessons using a structured observation schedule.

The box-and-whisker plot and one-way ANOVA were performed in order to assist the analysis and comparisons of the duration of different activities used in the two countries. In contrast to the findings of the TIMSS (Third International Mathematics and Science Study) with regards to England (Wiliam, 1998), the analysis of data showed that teachers in both countries devote a high proportion of lesson time to whole class activities. Individual, group work and off-task activities were experienced in both countries, while paired work was evident only in the English lessons. The most salient differences between the two countries were in the differentiation by setting (despite the current trend in England of reducing the range of pupils’ attainment in a class), seating arrangement and using information technology.

THE TALL-VINNER PROBLEM. AN OPERATIVE REFORMULATION

Jairo Alvarez G.; César Delgado G.

Centro de Estudios Avanzados en Psicología, Cognición y Cultura. Departamento de Matemáticas Universidad del Valle Cali, Colombia.

In order to identify conceptual comprehension problems, Tall & Vinner [1], [2] introduce the notions of concept-image, evoked concept image, and the differences between the formal definition and the personal definition (PD) of a mathematical concept. We will define these problems as the Tall-Vinner problem (TVP). This problem is manifested as incoherencies among the meanings associated to the concept or when the meanings associated with the name of the concept do not agree with its formal definition. This is observed when the subject responds to cognitive demands in different situations.

In [3], we construct an operative definition of the basic comprehension of function (BCF), inspired by Vergnaud's definition of concept [4], in order to identify the measure in which a student possesses a comprehension level of function that would allow him to successfully overcome the TVP.

We will present and discuss quantitative indicators which make the definition of the BCF operative, defining the concepts of a stable PD, a mathematically well-adapted PD, the coherence of a stable PD in relation to function. Our purpose is to provide an instrument of TVP analysis that can be generalized to the study of other concepts.

ALGORITHMIC MENTAL MODELS AND METACOGNITION

Aviva Barash
Beit-Berl College & Tel-Aviv University

Research in mathematics education has focused in recent years on students' conceptions and reasoning processes in mathematics. One explanation to students' mathematical misconceptions is the existence of intuitive mental models acting uncontrolled in the reasoning process (Fischbein, 1987). Dealing with algebra, we refer to algorithmic mental models, basic algebraic procedures that tend to become mental models. For instance, students who know the correct formula: \((a + b)^2 = a^2 + 2ab + b^2\) consider, inspired by the model of the distributive property, that \((a + b)^2 = a^2 + b^2\) (Fischbein & Barash, 1993).

Relying on recent research dealing with the affect of metacognitive methods on mathematical performance (Tirosh & Tsamir, 1997; Swan, 1998), we tried to rule out students' mistakes made due to the influence of tacit algorithmic mental models, by using metacognitive skills. For instance, using the “conflict method” (analysing the incorrect answers, raising a conflict, solving similar problems), to increase students' awareness of the existence of the models and control their impact. This was the main idea of our study unit: “Multiplication formulae and their use in reducing algebraic fractions”

One hundred and ninety four students in the 9th grade answered a pre-test to explore their formal knowledge of multiplication formulae and their error frequency in reducing algebraic fractions. Then, the study unit was applied. The same students, answered, a year later, a mathematical knowledge questionnaire, in order to examine the influence of the intervention program. The findings assert the hypothesis that learning by metacognitive methods, improves the formal knowledge of multiplication formulae and reduces the use of mental intuitive models which conflicts with formal knowledge.

I believe it is very important, that algebra teachers are aware of the impact of algorithmic mental models and recognise the importance of metacognitive skill applications. In my presentation I shall deal with the theoretical frame, the findings and some examples from the study unit based on general and specific psycho-didactical aspects.

INSTRUCTIONAL STRATEGIES AND TASKS DEVELOPED IN A TEACHING EXPERIMENT ON PROBABILITY MODELING

Carol T. Benson
Illinois State University

This study developed probability tasks and used them in a teaching experiment to investigate the impact of instruction on the modelling strategies of children in grades 3 and 4. Instructional strategies that were used are reported.

The research addressed the void in research-based knowledge of students' thinking in probability modelling by investigating the thinking of 6 students in grades 3 and 4 on contextual tasks that incorporated probability modelling. The teaching experiment consisted of 7 sessions: pre-assessment; 4 instructional sessions; short-term post-assessment; and long-term post-assessment. During the teaching experiment, the students' own cognitive strategies were used as a basis for planning and implementing instruction. The teacher-researcher posed tasks developed from this process, with some probes from the witness.

Instruction and tasks were influenced by four main teaching/learning patterns found in analysis of the transcripts and artefacts: (a) subjectivity in probability reasoning, when it exists, is difficult to counteract through instruction; (b) having students record their matchings of sample spaces for generators and tasks made the correspondence strategies they used more transparent for these students; (c) students use and think about discrete models differently than continuous models; and (d) two-dimensional modelling requires substantial accommodations for children.

Results indicate that young children use idiosyncratic and correspondence strategies, and that even a student whose idiosyncratic reasoning is deeply lodged can progress to using correspondence strategies with assistance from carefully designed tasks and probes. External representation may play a role in students' flexible use of correspondence strategies and probability generators, both discrete and continuous.

REFERENCES

The focus of this preliminary study was to examine the growth of prospective teachers’ understanding of high school mathematics while engaged in “lesson plan study” [LPS]. The tasks of LPS were used as research tools to examine pre-service teachers’ growth of understanding of what and how to teach high school mathematics. It is the intent to show the importance of engaging pre-service teachers in the conceptually rich mathematical tasks of LPS as the tasks relate to teaching high school students. Two frameworks were used in this study to examine the growth of mathematical understanding. One provided a frame for the growth of understanding (Pirie & Martin, 2000) and the other provided a frame for the school mathematics (Berenson, Cavey, Clark, & Staley, 2001). In this study, prospective teachers were asked to connect their lessons on rate of change to ideas of ratio and proportion. Four to five weeks were needed to complete one cycle of LPS and included the following tasks:

- Preliminary LPS Interview – Individual (20 min.). The pre-service teachers fold back to their primitive knowledge of algebra 1, linear functions, and slope to begin making their images of rate of change.
- Lesson Planning – Individual (45 min.). This activity promotes collecting other ideas of rate of change, and teaching activities to modify and change images of content and pedagogy.
- Post Planning LPS Interview – Individual (30 min.). Through explanations, pre-service teachers clarify their images to begin having images and noticing properties related to the content and pedagogy of LPS.
- Preliminary Group Interview – Group of 4 (10 min.). Pre-service teachers review their notes from the individual lesson planning to formalize their understanding.
- Lesson Planning and Post Planning Interview – Group of 4 (90 min.). Pre-service teachers share their LPS images and recursively collect and make new images of their understanding of what and how to teach rate of change.
- Lesson Plan Presentations – Four Groups (30 min each). Listening to the ideas of other groups, the pre-service teachers collect additional understanding at the formalizing and observing level of understanding.
- Written Lesson Plan – Individual (Variable time). Each pre-service teacher writes a final plan, formalizing the ideas collected over five weeks of LPS.

LOOKING AT A SQUARE THROUGH ANOTHER LENS:  
A SQUARE AS A LOCUS

Karni Shir, Irina Bershadsky, Orit Zaslavsky  
Technion – Israel Institute of Technology, Haifa

Locus is a salient mathematical concept that reflects one of the basic and general ideas of modern mathematics. Thus, the aim of our study was to identify sites in the geometry curriculum where the notion of locus can be interwoven, in particular with respect to definitions of geometric objects. There are various ways of defining geometric concepts (Shir and Zaslavsky, 2001). The most common way of defining a geometric object in school mathematics, as appears in most textbooks, is by a structural definition, namely, by characterizing properties of the object. Another way to define a geometric object is by a common property of its points, namely, as a locus.

There are several geometric objects that are usually associated with the notion of locus. Some are actually defined as a locus (e.g., a circle) while others are not ordinarily defined as locus, however, are looked upon as locus in terms of a unifying property of their points (e.g., a angle bisector, and a mid-perpendicular of a segment). On the other hand, most geometric objects are not normally associated with locus at all, let alone defined as one.

A square is an example of a concept that is not usually treated as a locus, although it can be defined as one. In our study we examined how mathematics educators (teachers, graduate students and researchers) think about the possibility of defining a square as locus. More specifically, we studied the following three questions: 1. To what extent do they think that it is possible to describe a square as a locus of points? 2. For those who think it is possible, to what extent can they describe a square as a locus? 3. To what extent is a (given) statement describing a square as a locus acceptable as a definition of a square?

Data was collected through written questionnaires and group discussions. There were a total of 74 participants in our study, who worked in two groups in two separate workshops. Our findings point to the reluctance to accept the proposed definition of a square as a locus, mainly for the participants’ unfamiliarity with such approach and for their views of the notion of locus as an abstract concept not within reach for students. In our presentation, a detail account of the findings will be reported. In addition, implications to teacher education and curriculum development will be discussed.

UNDERSTANDING NUMBER MEANINGS AND REPRESENTATIONS OF DIRECTED NUMBERS*

Rute Borba & Terezinha Nunes

Universidade Federal de Pernambuco, Brazil & Oxford Brookes University, U.K

An initial study (Borba and Nunes, 2000) - using Vergnaud’s (1982) theory of acquisition of mathematical concepts - showed that number meanings, conceptual invariants and symbolic representations affect reasoning about directed numbers. Controlling for number meanings and invariants, solving problems orally was significantly easier than having to make the representations of numbers explicit and operating on these explicit representations. Thus, performance in written assessments might lead to underestimating what children understand about directed numbers.

A second study investigated the possibility of teaching young children to represent directed numbers explicitly, enabling them to attain the same level of performance they showed orally. The participants were 80 children (mean age: 7y8m), pre-tested on problem solving using explicit representations of directed numbers. The children were matched for pre-test performance and then randomly assigned to four taught groups and one control group. The instruction the children received differed in number meaning (measure x relation) and form of explicit representation (writing x use of manipulatives). At post-test the taught groups performed significantly better than in the pre-test, but the control group did not. Children instructed on relations improved significantly more than the children instructed on measures. At post-test, the children transferred what they had learned in one form of explicit representation to other forms, and the representation used (writing or use of manipulatives) had no significant effect on performance.

Instruction was effective in teaching children to make explicit their implicit understanding of directed numbers. Instruction was more effective for the number meaning children had more difficulty in understanding. This suggests that instruction does not always have to start at the lowest level but rather that starting at an intermediate level children can build on their previous understanding of a concept.

* This research was sponsored by CAPES (Fundação Coordenação de Aperfeiçoamento de Pessoal de Nível Superior) as part of the first author’s doctoral studies.
This contribution presents part of a study with the aim to investigate how a mathematical network as it is stated by teachers to have been presented in middle grade classes is transformed when carried over into students' minds. The study particularly focused on the topic “sets of two equations in straight form” and restricts on the investigation of some network relations according to subject systematics and a special relation according to the application of mathematical objects, the model relation. (For the definition of main network categories with relevance for mathematics education in school see Brinkmann, 2001.)

The participants of the study were 3 experienced and proficient teachers of different schools in Germany and altogether 137 of their students. The teachers' statements in respect to the network they implemented in classroom were investigated by interviews. In order to map out the networks learned by students, there were developed tests demanding from students activities closely related to those of concept mapping.

The figure below shows the network teachers stated to have taught. Those linkages that turned out in the tests to be achieved only by less than 50% of the students are drawn with interrupted lines. The different links according to subject systematics are marked with S, model links with M.

The study reveals the incompleteness of the transfer of implemented networks into students' minds. The mainly learned connections by students are part of the links according to subject systematics, model links are hardly known. Conclusions in respect to the teaching of the different sorts of connections have to be drawn.

IT'S NOT WHAT YOU DO, IT'S WHY YOU DO IT:
REFLECTIONS ON THE ROLE OF TEACHERS IN RESEARCH
ON ALGEBRA

Laurinda Brown and Alf Coles
University of Bristol, Graduate School of Education and Kingsfield School,
South Gloucestershire, UK

Generalisation is accepted as an activity supporting students' use of algebraic notation
and language. One class of such problems used in the research literature involves
finding a general rule for, say, the number of matches used to make a row of n
squares. There seem to be four styles of research with such problems:
1) students' responses (problems given without teacher intervention, but often with
support of interviewer or teacher) are analysed (e.g. Friedlander et al, 1989)
2) a large-scale survey testing mathematical reasoning which, after analysis, is to be
followed up with case studies of effective outliers (Küchemann & Hoyles, 2001)
3) discussions of personal pedagogical practice (e.g. Hewitt, 2001, Mason, 1988)
4) exploring details of teaching strategies alongside student work (Radford, 2000,

How is it possible for us, as researchers, to question assumptions that we are making
and to become aware of different teaching approaches? Reading research papers does
not seem to be sufficient experience. At the recent 12th ICMI study conference, in a
discussion amongst researchers from many countries, it was possible to surprise each
other as we discussed the research and teaching related to this class of problems. The
surprises came as we experienced the detail of the teaching practices of others. At the
heart of research are the developing awarenesses and actions of teachers and their
students. If the aim of research is to improve teaching and learning, then we need to
report on what is possible and include the complexities of teachers' purposes,
knowing that these cannot be copied but with the hope of extending our practice. This
paper comes with a plea that we make the role of the teacher and the related students'
work central to our research projects and that we report, in some detail, case studies
of examples of practice that surprise us.

COGNITIVE PROBLEMS OF UNIVERSITY STUDENTS WITH THE CONCEPT OF DISTRIBUTION

María Inés Cavallaro- Marta Anaya

Facultad de Ingeniería, Universidad de Buenos Aires - Argentina

The concept of distribution, and specifically the notion of the Dirac’s Delta Distribution, was found to be difficult for university students who deal with it in the advanced course of Mathematical Analysis. It is shown that these difficulties are related to mental models and schemes that the students have or develop at the moment when the concept of distribution is first presented to them.

In this study carried out with a group of 30 students from the Engineering Faculty of the University of Buenos Aires, those difficulties are described and discussed within the framework of the cognitive theory of intuitive models (Fischbein, 1987).

A modelling activity was presented to the students with the aim to observe how they established the isomorphism between the mathematical theory and a physical model. A questionnaire and interviews allowed us to study the students’ beliefs, their ways of reasoning, and the intuitive models evoked during the problem-solving.

From the data analysis we could conclude that the use of the distribution for modelling has turned out to be unacceptable for the majority of the students. The students preferred to conceive the Dirac’s Delta as a function of numerical variable – null everywhere except at zero where it is infinite, but which at the same time has a non-zero integral. However, their misuse of the familiar model of numerical function became an obstacle in understanding such general ideas as function spaces and functions defined on these spaces. The students have ignored these contradictions by giving the Dirac’s Delta a status of “special” or “different function”.

In designing didactical interventions, it seems highly recommendable that teachers know students’ intuitive models. Modelling activities of real situations seem to be highly helpful to get this information and make the students to be aware of their own intuitive models, enhancing their meta-cognitive skills.

References

Alan Bishop has studied values in mathematics for more than two decades (Bishop, 1988). Recently, he says (2001, p.245) “... there had been so little research attention paid to values teaching, and none related to student teachers’ values. ... the sooner we have more research focusing on values education in mathematics the better”. In 1997, invited by Fou-Lai Lin, Alan’s student, I joined their values research group as a director on junior high school level. In the previous case studies (Chang, 2000, 2001), it was found that the Taiwanese inservice junior high school mathematics teachers believe and value Platonism or absolutism in mathematics, score-ism in education, specialism in mathematics education. These beliefs and values the teachers held are incompatible with constructivism, and become the main obstacle for teacher to teach mathematics from a constructivist perspective. Hence, the research problem of the present study was how to change teacher’ conventional beliefs and values in mathematics education.

The purpose of this article was to present how one teacher’s beliefs and values in mathematics education changed over a period of two years. In this case study, a junior high school mathematics teacher, I-Fen, joined the program of in-service teacher education and the project of values teaching, and conducted a collaborative action research of value teaching with researcher in her mathematics classrooms. Data collection included classroom observations, interviews, questionnaires, and self-reports, teaching journals, teaching material or tasks designed by I-Fen. The findings showed that her teaching improved, and her beliefs and values in mathematics education changed.

The affective domain and the achievement of the school children under two different mathematics instruction

Jing Chung, Dep. of Math. Edu., National Taipei Teachers College, Taiwan, R.O.C
Tien-Chen Chu, Dep. of Mathematics, National Taiwan University, Taiwan, R.O.C.

In Taiwan, the school mathematical curriculum and the associated textbook used to be unified. The new curriculum stressed student centered discoursing while all the previous curriculums stressed teacher centered lecturing instruction. The reformation was so great that it needed special justification for the sake of politics and education. Therefore, the main researcher, being a member of the curriculum develop group and the principal of the National Taipei Teachers College (NTTC) laboratory school carried out this minimum pair comparison of the two curriculums on 1998 and 1997 class students of NTTC lab school. We made a questionnaire on Mathematics Learning Attitude (MLA) to test students of both graduation years from grade 3 to 6. We also used a battery of Mathematics Achievement Test (MAT) based on the 1997 class grade 5 textbook to test all students at grade 5 and 6.

The test results made us to conclude that:
1. All the students thought that they all learned a lot of mathematics.
2. Experiment students (1998 class) liked more to do mathematics independently and to discuss with classmates.
3. Experiment students were more critical on the solution strategies and more aware of the written mathematical expression of the solutions.
4. All students showed equal achievement in taught scopes. For the experiment students, if the test items were not taught yet, they first showed inferior scores at grade 5, then jumped to the level equivalent to the compared students (1997 class) as long as the test items were then taught.

Based on the above conclusions we could carefully argue that the new teaching mode that the teacher poses a problem, then the students solve it voluntarily, then the students announce and defense the solutions, then the teacher steers the students to some sound patterns and the needed measures of restructuring of the materials to write a completely new textbook was an advance in school mathematics education. This study was a biproduct of six years of action research in NTTC lab school from 1992 to 1998 (Chung, 2000; Chung & Chu, 2001) to help teachers to cope with the challenge of teaching new curriculum. The scope and the depth of this curriculum reform, and the wisdom of the researcher to mobilize NTTC lab school to carry out this minimal pair comparison of the curriculums made the case of the curriculum reform in Taiwan worthwhile.

Argumentation in the context of a didactic sequence in elementary algebra
Selma Leitão, Jorge Tarcísio da Rocha Falcão, Cláudia Roberta Araújo, Mônica Maria Lins Lessa, Mônica Oliveira Osório

A growing number of researchers accept the view that the teaching-learning process is about the development of some shared understanding that comes out through discourse (Leitão, 2000; Douek & Scali, 2000; Steinbring, 2000; Yackel, 2001). The aim of the present work is to contribute to the discussion about the interest of discursive-argumentative activities for the conceptual development in mathematics.

The analysis of an excerpt from a teacher-led argumentation will illustrate an analytical procedure designed to capture the process of knowledge updating through argumentation. This analytical procedure is based upon the analysis of three types of discursive actions: pragmatic actions, concerning the offer of necessary psychosocial conditions to the emergence of divergence among pupils, as well as the encouragement of debate as the way to negotiate divergence and attain a consensus; argumentative actions, concerning the presentation of opinions / points of view, with their respective justifications, as well as the consideration of opposite arguments; and epistemic actions, referring to certain forms of reasoning and informational topics specific to an epistemic domain, like mathematics. Starting from these views, we analyze a fragment of a didactic sequence for the early introduction to algebra among 7-8 year-old Brazilian students (Da Rocha Falcão, Brito Lima, Araújo, Lins Lessa & Osório, 2000). This analysis seeks to demonstrate that this fragment of didactic sequence can be characterized as a process mainly oriented to formulation and justification of points of view, the counter-argumentation being present in only one utterance of the teacher. A possible general conclusion allowed by the analysis above is that the argumentative process remains partly implemented in the discursive fragment of didactic sequence that is reported here. This is a relevant aspect for research concerning didactic and conceptual development in mathematics.

Linear (proportional) relationships are undoubtedly one of the most common models for representing and solving both pure and applied problems in mathematics. But according to several authors, the attention given to linear models in current elementary and secondary mathematics education creates in students a tendency to use these linear models also in situations wherein they are not applicable, e.g. the belief that if the side of a square is doubled, the area also will be doubled (NCTM, 1989). This phenomenon is referred to as the illusion of linearity.

This short oral communication reports the results of a review of the literature about the illusion of linearity in the domain of probability. This literature survey has shown that there are several probabilistic misconceptions that have a remarkable common feature: the fallacious reasoning can be conceptually linked to and possibly explained by an improper application of proportions or linear functions when approaching probabilistic situations. The obtained inventory of linearity-related misconceptions contains both misconceptions that have already been studied intensively before as well as phenomena of a more anecdotal nature found in the literature.

Within the inventory of linearity-related misconceptions, we identified a special category of very closely related erroneous reasonings, wherein there is an improper assumption of a linear relationship between the determining variables of a binomial chance situation. This framework appeared to be a powerful tool to analyse the possible linear reasoning that might be elicited in binomial chance settings. It offered a new viewpoint for looking at some historical and well-known misconceptions and for seeing conceptual links between these - apparently very different - struggles with the laws of probability.

In a next step in our research, we set up an empirical study aimed at investigating to what extent the overreliance on the linear model is indeed the mechanism underlying students' faulty thinking when they suffer from the probabilistic misconceptions that we described in this short oral. The preliminary results are reported in Van Dooren, De Bock, Depaepe, Janssens, & Verschaffel (2002).

I consider students' 'simplification' of trigonometric expressions and present an operational model of how they simplify expressions. The model has three components: recognising, recalling and doing. I describe the interaction between these components and link this model to other models, e.g. Saxe (1991), of doing mathematics.

Data on students' manner of simplification was obtained using concurrent verbal protocols as students solved simplification items to gain an insight into their thinking. revealed a uniformity of approach with regard to approaches to simplification.

Students begin by reading the question and then focus on a subexpression or an algebraic form – I call this 'recognising'. They then 'recall' trigonometric or algebraic properties. In the schematic of my model (see Figure 1 below) read, recognise and recall are grouped together under the term 'recognition' because they all rely on sign association. Students then 'rewrite' the given expression with some form substituted for another. They then examine the rewritten form and recognise/recall another subexpression/property and enter a further manipulate/rewrite phase or accept their rewritten form as the result, the simplification. Recall, manipulate and rewrite are group under the term 'doing' because they all rely on transforming signs. The model, in its current form, has 'recall' in both the 'recognition' and 'doing' groups which reflects the dialectic between recognition and doing in this context.

Figure 1 Schematic model of students' simplification of trigonometric expressions.

The context of this study was development of teaching leading to development of students’ conceptual understanding in secondary school mathematics classrooms in Pakistan. The aim of this study was to explore teachers’ learning in their classrooms as they participated in a co-learning partnership (Wagner, 1993; Jaworski, 2000) with a teacher educator. Collaborative work with the teachers focused on supporting the teachers in developing their teaching while investigating both the teachers and the teacher-educator’s learning. The teacher participants taught secondary school mathematics and had resumed teaching in their schools after attending a ‘Visiting Teacher’ mathematics education programme at a university in Pakistan. Data was collected through maintaining field notes from the classroom observations, audio-recording interviews in pre and post-observation meetings and written comments in reflective journals. The analysis uncovered issues of practicality and limitations of a co-learning partnership in teacher development in the real classroom context.

This study shows that responsibility of a teacher educator to teachers’ developing teaching cannot be ignored in a context where teachers have never been encouraged to question or analyse their own or others’ actions within their school. In addition, teachers have limited knowledge and understanding of mathematics relating to new practice, and might not be aware of their own mathematical misconceptions. Therefore, nature of collaborative partnership cannot be achieved by the singular influence of any ideology or the theoretical assumptions of collaborative work. It is utterly dependent on the needs of the teachers and the reality of their context. Developing an attitude in which teachers see and experience questioning as learning should be integrated with the provision of adequate interventions.

This study suggests conceptually, that a commitment to learning establishes a teacher educator as a learner along with the teachers. The teachers’ commitment to learning activated their understanding of change incorporation in the practical reality of school. The teacher educator revisited her theoretical principles of collaborative partnership within the school’s reality in order to support teachers struggling with issues that impede change. The differences in knowledge and understanding were not viewed as teachers’ deficits or a teacher educator’s superiority but were appreciated as resources of co-learning. However, issues relating to differences in knowledge and understanding between partners, and the constraints of school encouraged the teacher educator to take a leading role in the teachers’ learning.

MATHEMATICAL ROMANCE: ELEMENTARY TEACHERS’ AESTHETIC ONLINE EXPERIENCES

George Gadanidis, Cornelia Hoogland, Bonilyn Hill
Faculty of Education, University of Western Ontario

We explore the aesthetic as an integral dimension of mathematics education and we report on our study of elementary school teachers’ experiences with the aesthetic dimension of mathematics in an online mathematics teacher education course. The study examines the online transcripts of the thoughts and discussions of 20 teachers participating in the online course. We look primarily at the first of six modules of the course, which offered teachers the opportunity to reflect on the nature of mathematics and mathematics pedagogy. The readings for the first module included three interviews with mathematicians who related their love for mathematics, two articles on the value of children inventing personal algorithms for arithmetic operations, and a text reading of problem-based mathematics activities. In the online discussion for the first module, teachers shared their personal views of mathematics, to describe the methods they used to mentally solve the arithmetic problems 16 x 24 and 156 + 78 + 9, and to reflect on the implications for teaching.

Our research depends on teachers’ stories about mathematics, particularly their romantic stories. How they came to love math, or hate it, and in some cases, how an old passion was sparked and re-ignited. We rely on the idea of romantic story with its ideas of overcoming difficulty and finding happiness (or wholeness) at the end of the day. We suggest that research on the dialectic relationship between teachers’ beliefs and practice may be expanded to include their stories about childhood and other experiences of mathematics. As well, we look for the mathematics stories embedded or perceived by teachers in curriculum documents, in classroom practice, and in mathematics activities. Learning about, and being in tune with our aesthetic sensibilities, may in part guide and bind us to stories of mathematics and to our underlying beliefs and practice.

The stories of mathematics articulated by teachers in our study were based on personal experiences with mathematics that were aesthetically informed. This was manifested in statements such as “I LOVE math. I always have. I, like many of you, had many problem-solving car trips. I still get excited when I see a licence plate that I can make ten with (using any means).” Note the teacher’s verbal expression of delight and the use of capital letters to convey her emphasis. Teachers appear to have been affected by the online course experiences with mental arithmetic in conjunction with the journal article readings. As their personal views and beliefs were enlarged some teachers interpreted curriculum through ‘new spectacles’. These new insights into mathematics and mathematics teaching were aesthetically informed and story-based. The interplay between the various stories that were available in the online course is a first step in incorporating new--hopefully romantic--plots.
Local magnification and theoretical-computational conflicts

Victor Giraldo¹, Luiz Mariano Carvalho²

Universidade Federal do Rio de Janeiro, Brazil,
Universidade do Estado do Rio de Janeiro, Brazil

The aim of this research is to understand how conflicts between computational and non-computational representations can contribute to enrich students’ concept image of derivative and limit. We consider theoretical-computational conflict as any situation where a computational representation for an object is (at least potentially) contradictory with the associated mathematical theory. For example, numerical calculation with machine accuracy cannot be performed in a way which corresponds exactly to mathematical theory of limits.

To perform the investigation, we designed a computer-based Calculus course having the notion of local straightness as a cognitive root for the derivative concept, as suggested by Tall (2000). On this approach, we give emphasis to theoretical computational conflicts, instead of avoiding them, particularly those related with the impossibility of computational representations for limits and infinite processes in general. This course was tested with a first year undergraduate class and a sample of six students was selected for weekly clinical individual interviews, when they are given theoretical-computational conflicts.

Partial results show that students develop different mental strategies to cope with this kind of situation. The experiment also seems to indicate that, in general, students can build up more sophisticated theory and establish richer links between cognitive units to answer questions that emerge from theoretical-computational conflicts.

MATHEMATICAL LANGUAGE AND PUPILS' PERFORMANCE
Godwin Hungwe and Ebert Nhamo Gono
Midlands State University and Ministry of Higher Education and Technology

This paper reports on an investigation that was carried out to establish the effects of specialised mathematical language on the performance of pupils at secondary school level. Since Zimbabwe's independence in 1980, the lowest pass rates in national examinations at secondary school level, have been in English and Mathematics (Riddel and Nyagura 1991). The pedagogical question arising from this scenario is whether or not the performances of pupils in these two subjects are related. Official syllabus documents, stipulate that one of the aims of mathematics education is to make pupils understand, interpret and apply mathematical information. The question of interest here is whether this is being achieved. The majority of students in Zimbabwe fall into the category which Barwell (2000) called English Additional Language. This means that mathematics is taught in English, to pupils whose first language is not English. In such situations there is always a possibility of lack of equivalents in the pupils' language for some mathematical expressions. In addition to this, a mathematical fact that appears obvious to adults may be a highly structured and stylised statement to pupils Southwell (1994).

Two mathematics tests were administered to Form 3 classes (15-16 year olds) in four randomly selected secondary schools in Harare, Zimbabwe. The first test established how pupils interpreted specialised mathematical terminology, while the second one tested the applications of the interpretations in word problems. The question-by-question analysis of the pupils' performance, revealed that many pupils used the same interpretation in answering corresponding test items in the two tests. Thus most of the pupils who failed to interpret mathematical expressions correctly, also failed to solve the corresponding application problems. For such pupils, incorrect interpretations led to incorrect application solutions. On the other hand correct interpretation resulted in correct application solution strategies. Therefore the study concluded that specialised mathematical language has an effect on the performance of pupils.

Improper integrals constitute a concept of great utility for Mathematics degree students. However, it appears that students are unable to assimilate this concept within the wider system of concepts they learn in their first year of Mathematics studies. In this oral communication we describe a competence model used in a preliminary and exploratory study of the kind of understanding students possess about improper integral calculus when two registers of representation come into play. We understand competence to be the coherent articulation of different semiotic registers: to be competent in mathematics is to be able to articulate coherently the different representations of a mathematical concept when having to solve "non routine" problems. According to us, the evaluation of our students' knowledge means that this should be analysed on the basis of activities that aim to clarify possible connections (articulations) made by them while constructing a given concept. In order to design our competence model we adapted different stages of development noted in cognitive representation systems in the case of algebraic language (Socas, 2001) to our own concept. After analysing the results to a questionnaire, six students were selected to be interviewed on the basis of their overall results and the significance of some of their answers. The main difficulties we detected are due to the lack of meaning or of knowledge of previous concepts. We can also see that, although some of our students have managed to make representations in the graphic register to some extent, going from graphic to the algebraic remains more difficult than going from the algebraic to the graphic. We will also discuss the formal competence model used.

Hand-held personal technology (H-hPT), e.g. calculator, can be used as a cognitive and mathematical tool in enhancing mathematical understanding, and give the opportunity to the user to confront with the real life mathematics. As a result, students at each grade level achieve a higher degree of mathematical thinking and save time for problem solving. In the present study, which is an ongoing project on H-hPT, a group of teachers’ and teacher trainees’ perceptions of calculators as a cognitive tool in mathematics instruction is searched, and their views were reflected to some extend. In the study, the researchers have looked for the answers to following two questions: (a) What are the differences between the perceptions of teachers and teacher trainees about the use of calculators, (i) calculators as a cognitive tool, (ii) using calculators in maths classroom, (iii) use calculator in problem solving? (b) What are the differences between the development problem-solving skills of teachers and teacher trainees before and after the seminar and workshop in mathematics teaching and learning? In the first year, the planned activities were programmed and scheduled as seminar and workshop for the participating mathematics teachers from various schools, teacher students and teacher trainees from Balikesir University in Turkey. A rather detailed questionnaire was administered in the two-days seminar and workshop to the participants, and an interview protocol was designed and applied after the activities. In the interview, 6 teachers and 12 teacher trainees were participated.

The statistical analysis of the designed questionnaire is in the process, and some results have been obtained. The first result shows that although the teachers and teacher trainees had negative opinions about the use of calculators in mathematics instruction and student-centred activities at the beginning of the seminar and workshop, their attitudes and beliefs were changed towards positive at the end. Interview results are also supporting this notion. The detail of two-day seminar and workshop and their reflections to the interview will be reported, and teachers’ and teacher trainees’ perception and views will be reflected in presentation of the paper.
IMAGERY IN GEOMETRICAL PROBLEM SOLVING

Eugenia Koleza, Elisabeth Kabani
Department of Primary Education, Ioannina, Greece

The essential role of imagery on students' geometric reasoning has been researched extensively (Bishop 1989). Different types of imagery have been proposed (Owens & Clements 1998, Persmeg 1986). Usually students are not restricted to only one type of imagery, they use or combine different types of imagery simultaneously, according to the situation.

Nevertheless, the school system discourages visualization and imagery as proper tools for the formal solution of mathematical problems, especially after 9th grade, giving emphasis to abstract thought and typical proofs. As a consequence, "geometric-type" students (according to Kruteskii's typology) are assessed as "low-ability" ones.

The present contribution is based on the case study of a 10th grade student with a poor theoretical background, whose mind is "dominated by images". Faced with four geometry problems, demanding different types of construction, she is led to unexpected solutions. This ability is altogether unknown both to her school and her, since she is assessed as one of the weakest students of her class and she believes she has no aptitude in Geometry.

Analysis of the student's responses shows that imagery can function positively both for the understanding and solving of geometrical problems, even in cases of students with a relatively poor theoretical background.

HOW THE GEOMETRIC CONSTRUCTIONS HELP THE UNDERSTANDING OF COMPLEX NUMBER?

Estela Kaufman Fainguelernt  
UNESA/ UNIVER CIDADE  
estelakf@openlink.com.br

Franca Cohen Gottlieb  
Universidade Santa Úrsula  
ogottlieb@abc.org.br

Introduction. The objective of this research was to analyze how the geometric constructions used in activities of dynamic geometry help students and teachers to produce meanings for the body of complex numbers. The research took place during the 2000 and 2001 years in an institution that prepares undergraduate teacher located in the western part of Rio de Janeiro, Brazil.

Participants of the research. Participated in the work two students and two teachers from the Undergraduate Course in Mathematics of the University. The two students had different preparation levels. One already knew complex numbers in an algebraic and automatical way and the other one never had studied this subject. The two teachers were engaged in mathematical investigation and were much interested to learn new methodologies for the construction of the meanings of mathematical concepts.

The framework. To analyze the development of the activities we used Tall (1981) who treats the formation of concepts of mathematical objects and also Hershkowitz (1994) who formulates an outline about use of the definition of concept to students. We tried to understand how the learner appropriates the mathematical concepts. We observed that human mind do not act exactly in accordance with symbolic logic. The concept is built by different experiences and approaches arriving to what Tall calls the "Conceptual Image". Tall created also, joining the words “procedure” and “concept”, the name “procept” to designate the process to the construction of a concept. Since we worked with dynamic geometry we created activities using, as a tool, Cabri Géomètre II software. The environment provided to students the possibility to create, to conjecture, to elaborate and to represent contents.

Conclusion. The student who had not previously learned about complex numbers built its concept better and in more appropriate way than the other one. We conjecture that use of visualisation in the geometrical approach is more effective than the algebraic approach. The teachers were glad to learn a new way to introduce complex number in the classroom.

References.
A new curriculum for teaching elementary school mathematics is being developed in Israel. The new curriculum stresses (in light of the NCTM 2000 standards) inquiry and investigation in learning mathematics, learning for understanding, using connections among mathematical ideas, applying a variety of appropriate strategies for problem solving and developing number sense.

The ministry of education requires that from now on all mathematics teachers be specializing in mathematics (mathematics being the main subject they are teaching) starting already at the first grade of elementary school.

In light of all the above, a broad in-service program for the empowerment of elementary teachers is being processed aimed at disseminating the reform. In a former PME paper, Becker (2001) pointed out that there is little information available about the design features of in-service programs which maximize changes in teacher practices.

A model for enhancing teacher development was designed for the in-service program. In our short oral presentation we will describe this teaching model that we use throughout the in-service program for each teaching unit. This model will be demonstrated on a specific unit dealing with numbers and operations. A task (of an inquiry type) will be presented. We will describe the mathematical objectives and content and its suitability to the various goals of the new curriculum.

The process the teachers underwent will be described, starting with working on the given task, finding various appropriate strategies for solving it, using different types of reasoning, methods of proof and documentation, recognizing and making connections among mathematical ideas and reflecting upon the process of problem solving. Then, adapting the problem to their class level, presenting it in class, evaluating students' work and documentation, promoting students' discourse and monitoring students' discussions and debates.

Teachers' activities as well as students' work will be presented and linked to the knowledge required for teaching (Shulman, 1986).

http://www.nctm.org/standards/standards.htm
In order to understand the process of understanding mathematics, Koyama (1992) presented the so-called “two-axes process model” of understanding mathematics as a useful and effective framework for mathematics teachers. The model consists of two axes, i.e. the vertical axis implying levels of understanding such as mathematical entities, relations of them, and general relations, and the horizontal axis implying three learning stages of intuitive, reflective, and analytic at each level. By analyzing an elementary school mathematics class in Japan, Koyama (2000) demonstrated the validity and effectiveness of this model and suggested that a teacher should make a plan of teaching and learning mathematics in the light of “two-axes process model” and embody it with teaching materials of a topic in due consideration both of the objectives and the actual state of students, and that she/he should play a role as a facilitator for the dialectic process of individual and social constructions through a discussion with students.

The purpose of this research is to examine closely the 38 second-graders’ process of understanding concepts of triangle and quadrilateral in a classroom at the national elementary school attached to Hiroshima University. These students are characterized to be at transitive stage from the first to the second level of geometrical thinking in terms of van Hiele Model (1986). In order to promote and improve their understanding concepts of triangle and quadrilateral, with a classroom teacher, we planned the teaching unit of “Let’s make figures with geo-board” and in total of 11 forty-five minutes’ classes were allocated for the unit in the light of “two-axes process model”. The data was collected in the way of observation, videotape-record, and pre- and post-tests during these classes, and analyzed quantitatively and qualitatively to see the change of students’ thinking level and the dialectic process of individual and social constructions through discussion among them with their teacher in the classroom. First, as a result of first two classes of them, the quantitative analysis of pre- and pre-tests showed the remarkable improvement of students’ understanding concepts of triangle and quadrilateral from the first to the second level. Second, as a result of the qualitative analysis of students’ discussion on whether a “concave quadrilateral” is triangle or quadrilateral in the fifth class, we found that students could investigate and communicate the reason of their own judgment with geo-board, geo-paper or matchsticks, and that such a new idea/definition was emerged that a “concave quadrilateral” is not triangle but quadrilateral because it is divided into two triangles by the line segment connecting two opposite vertices.

PROBLEM SOLVING THE CHALLENGE FACING SOUTH AFRICAN MATHEMATICS TEACHERS

Daniel Krupanandan,
KZN, Department of Education, South Africa

Mathematics Curriculum reform in South African classrooms has been on the minds of mathematics teachers since the introduction of Curriculum 2005, South Africa's version of Outcomes Based Education. The curriculum has introduced new perspectives and challenges on the teaching and learning of mathematics. Amongst others the shift to a problem centred or constructivist approach to the teaching and learning of mathematics is implied in the new curriculum documents.

Despite the rigorous training provided in the implementation of Curriculum 2005, affecting change to teacher's philosophies or beliefs about the teaching and learning of mathematics has been marginal.

Although a few teachers have engaged in problem solving as a context for teaching mathematical concepts, the vast number of teachers still rely religiously on routine textbook problems, for the introduction or consolidation of mathematical concepts. These teacher's classrooms are dominated by traditional teaching practices.

As a response to the need to promoting mathematical problem solving in schools, a project was initiated to providing training and support materials to teachers in selected schools. This report will present the results of this initiative. The research conducted makes an exhaustive analysis of the attitudes and responses of both learners and teachers involved the project.

The results of the project have had significant implications for future training initiatives for Curriculum 2005, and writing of learner support materials to be used in the mathematics classroom.

DIFFERENT VIEWS OF KOREAN AND GERMAN TEACHERS
BELIEFS ABOUT MATHEMATICS
Jeeyi Kwak, Kristina Reiss

Department of Mathematics, Carl von Ossietzky University of Oldenburg, Germany

Since the eighties in mathematics didactics, a branch of research so-called Beliefs ("Mathematische Weltbilder") is developed (cf. Törner, 1998). Results of the "Beliefs"-research have showed a further possible reason of the difficulty in proving and solving the mathematical tasks. (Pehkonen, 1995) According to Pehkonen, the competence of the problem solving does not depend on the students' mathematical knowledge or mathematical competence, but also on the beliefs about mathematics. In his opinion, beliefs about mathematics should be included as an explaining factor, which influenced on problem solving.

Our research aims are to find the role of beliefs in problem solving, specially related with proving as followed:
(1) Are beliefs the factor for the mathematical competence of proving? (2) Do the teachers Beliefs about mathematics influence student to develop their Beliefs about mathematics? (3) How differences do Korean and German teachers have in Beliefs about mathematics?

We asked 58 Korean and 27 German middle school teachers and 192 Korean and 659 German 7th grade students. We used the questionnaires of Klieme (2001) who refined and categorized the questionnaire of Grigutsch (1996). We have identified them as three broader categories, Application, Formalism (Exactness) and Process (Process as creativity). The view of German students about mathematics is dominated with the fact that mathematics is Formalism (F), Application (A) and Process (P) in the order named, the view of Korean students is similar as them, however, we can find quite different of their value. For German students, A=0.30, F=0.54, P=0.21, for Korean students, A=0.58, F=0.63, P=0.55. While Korean students and teachers both have similar views about mathematics, German teachers have quite different view from students. We did not identify a significant effect concerning the influence of Beliefs about mathematics on mathematical competence of both Korean and German students.

MAKING AND PROVING CONJECTURES: CIRCLES
Eva Tsz Wai, LAM

This study explores how the Sketchpad environment may help in developing students’ mathematical thinking in relation to proof. My intention is to create situations in which students make a conjecture from what they have discovered and then try to prove it. This approach is supported by Bell, Mason, Burton, Stacey and Cockcroft (as described in Hoyles, 1997). They all argued that students should have opportunities to test and refine their own conjectures, thus gaining personal conviction of their truth alongside the experience of presenting generalizations and evidence of their validity.

Five Secondary 4 students (age 16) participated in this study. Their mathematics abilities were average. In the workshops, students learnt some basic properties of circles. They interacted with the relevant dynamic figure, then made conjectures and finally tried to prove them deductively. A video camera was set up to record the participants’ behaviour. Three sets of worksheets were given to all participants to guide them how to do the task and write their proofs. An in-depth interview was conducted after each workshop. In this study, the following questions were addressed:
1. How do students discover and form conjectures using Sketchpad?
2. How do students prove their conjectures?
3. How do students interact with each other and with the computer?
4. What do students feel about this approach?

From my observations, students went through the following process as they made and proved their conjectures: Intuitive Observation (based on the impression of one figure to make a conjecture), Inductive Hypothesis Making (based on some common properties of many figures to make a conjecture) and Deductive Explanation (based on theorems to prove a conjecture). It was found that Sketchpad can motivate students to learn and helps them to think inductively. However, there was no evidence that Sketchpad can help the students to think deductively. They all needed some hints from the teacher. Moreover, students working as a pair on one computer seemed to have more courage to drag the points around, thus it might be the most effective situation to carry out such activity.

AN AVERAGE WITH UNIMAGINATIVE WEIGHTS
WHEN THE WEIGHTS EQUAL THE VALUES
Avital Lann and Ruma Falk - The Hebrew University, Jerusalem, Israel

The self-weighted mean, denoted $SW$, is a weighted mean in which the weights are the values themselves:

$$SW = \frac{x_1^2 + x_2^2 + \ldots + x_n^2}{x_1 + x_2 + \ldots + x_n}$$

where $x_1, x_2, \ldots, x_n$ are $n$ positive numbers.

It is easy to see that $SW$ is greater than the arithmetic mean ($A$), because in $SW$ the larger values get larger weights. $SW$ is linearly (and positively) related to the variance of the $n$ values. Lack of distinction between the two means is sometimes referred to as "sampling bias" (Stein & Dattero, 1985).

$SW$ is called for whenever the probability of sampling a given value is proportional to its size, that is, under self-weighted sampling (SWS), usually known as "size/length-biased sampling". SWS is encountered in diverse areas: demography, medicine, management science, and many others (Patil, Rao & Zelen, 1988). Therefore, understanding this concept, and gaining reasoning ability about the mean in SWS situations is important for both information consumers and data producers.

Our research focuses on learning and analysing people's intuitions: How do people intuitively fare in different SWS tasks (e.g. assessing the expected waiting time for a bus that arrives at varying intervals, or the mean class size obtained by questioning students)? Are there typical fallacies, and how could they be overcome? We first hypothesised that some people might fail to understand the need to weight the averaged values, thus calculating $A$ instead of $SW$. This hypothesis was confirmed in our experiments. The implicit assignment of equal weights to all the values is compatible with Tversky and Kahneman's well-known description of heuristic principles that people rely on when assessing the value of an uncertain quantity. In particular, tacitly assuming uniformity is in harmony with people's predilection for symmetry and equality (Zabell, 1988). We also found that experiencing the problem's procedure — even only via a thought experiment — provides a useful corrective instrument, as does emphasising the weights by using a roulette with variable angles, and asking about the mean of these angles, for repeated turnings of the roulette.

THE USE OF STUDENT QUESTIONING FOR ASSESSING MATHEMATICAL UNDERSTANDING

Huk-Yuen Law
University of East Anglia

Abstract of the Study

The issue I am most concerned with is how to enhance the mathematical communication that helps the students acquire mathematical concepts better. Conceptualization of thinking serves as an instance of communication, which in turn provides useful insights for an understanding of human cognitive process (Sfard 2000). Self-questioning defines an active role for the students to construct the solution strategies based on their own personal knowledge during the process of solving mathematical problems. In this study, I intend to make use of student questioning for assessing mathematical understanding.

The Methodology

Two groups of students (aged around 14-16, Fourth Formers) would be asked to solve a set of mathematical problems. The number of students included in each group would be decided on the basis of time constraints, with one being classified as expert-student group (the top students in my class) and the other as novice-student group (the students with below-average performance in mathematics). During the problem solving episodes, the verbalization process of students' thinking would be recorded and the think-aloud protocol is analysed for identifying the key questions being raised. (Sample of data would constitute part of my presentation.)

The Significance of the Study

The mathematical communication is an essential component of curriculum reform in Hong Kong for enhancing the teaching and learning of mathematics. The present study serves the purpose of enriching our understanding of the phenomenon of communication in term of self-questioning during the problem solving episodes. Understanding the self-questioning processes provides us with a key to enhancing the effectiveness of students' learning strategies in doing the self-study.

ANALYSIS OF CHILDREN'S ARGUMENTATION WHILE MAKING SENSE OF FRACTIONS.

Amanda le Roux, Hanlie Murray and Alwyn Olivier
University of Stellenbosch, South Africa

Argumentation and articulation of ideas are viewed as important processes in the development of children's mathematical thinking. Analysing children's argumentation is therefore important.

Wood (1999) states that "...conceptual change and progression of thought result from mental processes involved in the resolution of conflict" and Yackel (2001) underlines the importance of challenging and justifying explanations. Our analysis of an episode where a group of three Grade 5 children are working on a problem to find a fraction of a fraction, shows an absence of disagreement or challenging of others' ideas.

We used Toulmin's scheme as a methodological tool. According to Toulmin, an argument consists of four parts. A claim is made and data is offered as grounds for the claim. A warrant explains why the data supports the claim, while the backing finally links the core of the argument to collectively accepted assumptions (Yackel, 2001).

In the episode, several claims were made and data and warrants offered as support. The claimants tried to find a backing, thereby trying to justify their claims, even though they were not challenged to do so by one another. They were unable to find backings for those claims that were mathematically invalid. The researcher then focused them on a mathematically valid claim that one of them had made earlier. This minimal facilitation enabled the claimant to provide a backing and she made an effort to have the backing accepted by the rest of the group. Eventually a frame switching, from a numerical backing to an iconic backing, made it possible for the whole group to accept the full argument.

We argue that it was the acceptance of the obligation to explain and justify explanations by the whole group that drove the discourse and kept the group from reaching early closure and not disagreement or challenging of others' ideas. It was clear from their claims, data and warrants that their fraction concept was not yet stable, making it difficult for them to challenge others' ideas.

REFERENCES

Research on graphing calculators has focussed predominantly on students with the teacher’s role being largely neglected. This study examines graphing calculator use from the perspectives of advanced-level mathematics teachers working in English schools; adding to recent research on teacher’s beliefs (Doerr & Zangor, 1999) and teachers’ perceptions (Simonsen & Dick, 1997) in relation to graphing calculator use.

Since the intention of the study is to elicit in-depth accounts of teachers’ perceptions and experiences of graphing calculator use in their classrooms, an interpretative framework has been adopted. Semi-structured interviews and lesson observations with six teachers from two institutions form the data corpus.

Findings from the study indicate a set of interrelated considerations and motivations for use. Moreover, the process of incorporating graphing calculators into their classroom practice involved several forms of teaching (technical, functional and conceptual), guidance (indirect and direct), and support. Teachers were found to develop knowledge of a range of pitfalls students were likely to encounter when using the graphing calculator, and from this a repertoire of troubleshooting techniques appeared to evolve.

DEFINING A RECTANGLE UNDER A SOCIAL AND PRACTICAL SETTING BY TWO SEVENTH GRADERS

Fou-Lai Lin
Kai-Lin Yang
Department of Mathematics, National Taiwan Normal University

1. Purpose of Study

§ What kind of activities could initiate 7th graders into defining?
§ How would the students reason when they involve in the defining activity?

2. Method: designing a Social and Practical Setting

§ Social: interviewers’ intervention and peer discussions
§ Practical: the swimming pool task

3. Findings

§ propositions: e.g., if two opposite angles are right angles in a quadrangle, it is a rectangle.
§ concept/theorems-in-actions (Vergnaud, 1998): e.g., stereotyped concept image of right angles is horizontal and vertical.
§ apprehensions (Duval, 1995): perceptual, operative, sequential and discursive

4. Conclusion

§ Students are stimulated to develop definitions by the innovative task.
§ Implicit theorems/concepts support students’ apprehensions of figures.
§ Defining can be the beginning of learning to prove.

A TIME OF CHANGE

Irene F Mackay

The Open University / Inverurie Academy, Aberdeenshire

Pupils' lack of progress in mathematics as they make the transition from primary to secondary school is well documented (Fullarton, 1996; Murdoch, 1986; SOEID, 1996) and often recurs as an emotive headline (Daily Mail, 2001; Daily Telegraph, 2001; Sunday Telegraph, 2000) following the publishing of reports or statistics.

This study is in the process of investigating:

- groups of pupils who may be affected by the transition and
- the effects on pupil progress from factors within the classroom/school

Factors considered are those over which mathematics staff have some control, and the power to adapt to meet pupil needs. The factors are those related to the classroom: classroom climate, teacher and curriculum.

The research study takes place over three years in two cycles, following two samples of pupils as they move from primary (9 schools) to secondary school (3 schools). In each cycle a sample of pupils is observed and tested during the last year in primary school and the first year in secondary school. All data will be available from May 2002.

In this presentation, results from both cohorts will be discussed. Pupil progress over the period will be considered and related to pupil and teacher perceptions of the classroom interaction. Groups of pupils will be identified linking their progress to influences in the classroom.

THE CALCULATOR'S ROLE IN PROBLEM SOLVING: A CASE STUDY IN A FOURTH GRADE CLASSROOM

Ema Mamede – University of Minho - Institute of Child Studies

In Portugal, the fundamental aims of mathematics teaching are based on the development of three skills: (a) reasoning; (b) communication; and (c) problem solving (DEB, 1998). The curriculum supports that the solving of problematic numeric or non-numeric situations should be proposed in all teaching topics. This document also refers the calculation methods that should be used in the classroom. Written procedures, mental calculation and the calculator should be present in daily routine classroom. It is important for children of this grade to be able to compute using one of these methods, as well as to be able to decide which means is more suitable for a specific situation (Abrantes, Serrazina & Oliveira, 1999; NCTM, 1991).

However, in the majority of Portuguese elementary schools, there is a certain degree of resistance to the use of calculators, which raises difficulties in its employment in problem solving situations. As a matter of fact, the Portuguese document “Matemática 2001”, which reports diagnostic and recommendations for mathematics teaching and learning, presents some results on the use of calculator in first grades. For instance, almost 74% of the teachers do not use calculators to solve complex problems, 71% do not use it to explore numerical concepts and 63% do not use it to verify results (APM, 1998). It seems that many elementary school teachers ignore how powerful a calculator can be in a problem solving context.

Making an effort to improve this situation, a qualitative case study research was developed in order to understand the role that pupils attribute to calculator as a support tool for computation in a problem solving context. The study was implemented in a ten years old class in Braga, Portugal. In this study the calculator’s use in solving tasks of estimation, numerical investigations and application of mathematics to real life situations was analysed, attending to strategies used and to interactions between pairs.

This presentation intends to show how was developed the research and to present and discuss its results.

PROMOTING STUDENTS' AWARENESS IN APPLYING BIJECTIONS IN ENUMERATION TASKS
Joanna Mamona-Downs & Martin Downs
University of Macedonia, Greece and U.C. Berkeley, U.S.A.

Much mathematical knowledge is retained in the mind in a factual mode that is not in the form that can be readily accessed for problem solving activities. This was noted as far back as 1929 when A. N. Whitehead talked about 'inert knowledge'. We conjecture that this phenomenon may occur for some very basic notions. In this communication, we will specialize in one such notion. A 1:1 and onto function cognitively corresponds to the pairing off of each element of the domain with one of the co-domain such that no elements are left unmatched after the process ends, so bijections preserve set order. (Here the more overtly definitional case of infinite sets is not considered.) However, if students are not aware of this knowledge as a potential problem-solving tool, they could not avail themselves of approaches involving the construction of bijections in enumeration tasks.

The study has two aims. The first is to provide some evidence that indeed the knowledge of the preservation of set order under bijective correspondence is inert. The second is to test whether the above situation may be ameliorated through a particular teaching approach. What motivates the teaching approach is the following. To try to make the students more aware of applications of bijections in enumeration tasks, we propose a general framework about developing techniques to address inert knowledge. A technique lays down several standard stages to achieve, but their accomplishment may require substantial problem solving. An important factor in a technique is a 'cue', i.e. a description of the circumstances where the technique may be regarded as being worth considering. The rationale behind the cue corresponds to the 'releasing' of some inert knowledge. When the understanding of why the technique works is transparent, the awareness of the technique depends mostly on the familiarization with its cue. The idea of the teaching approach is to prompt the students' attention to the cue (in its contextual form), and after this to (largely) leave the students to carry out the application itself. In our case, the cue would either be two sets whose orders we wish to compare, or one set whose order we wish to determine by identifying another (better understood) set for a correspondence.

In the presentation, we shall briefly indicate how the above aims were implemented in fieldwork conducted on college students, and shall outline the results and conclusions reached.
What should preservice teachers study during their college years in order to become good mathematics teachers in elementary school? Should we emphasize subject matter knowledge since “without adequate content knowledge student teachers spend much of their limited time learning content, rather than planning how to present the content.” (Brown and Borko, 1992).

Should we emphasize pedagogical content knowledge, since as we know, “...pedagogical content knowledge is unique to the profession of teaching [and] we expect it to be relatively undeveloped in novice teachers, and thus be a primary focus of their educational experiences” (Brown and Borko, 1992).

Should we emphasize field experience, since “this is the real practice” and “if novice teachers get too little practice or if they receive inconsistent feedback from their university teacher educators and classroom supervisor, their expertise may not be adequately developed” (Vacc and Bright, 1994).

Can we emphasize all three aspects, and if so to what extent? What, however, do teachers think about the way they were prepared to teach mathematics in the elementary school?

275 teachers (from three different colleges) in their first years of teaching, answered an open-ended questionnaire aiming to reveal their opinions about their preparation in college from the point of view of beginning teachers. The questions asked about: relevant and irrelevant courses that teachers studied, subjects that should have been but were not included in their preparation, difficulties and dilemmas of teachers in their first years of teaching mathematics, sources of help, participation in inservice courses and the involvement that should or should not have taken place to guide them in their first years in school. In addition they were asked to describe a good math teacher in elementary school.

Findings add valuable information from the teachers’ points of view, and should be taken into consideration when revising preservice programs.

Previous research has tended to focus on the development of separate number components (e.g. counting; addition; multiplication) and so, cannot comment on how development in one component affects development in others. In this study, 152 children from three different cohorts (aged 4, 5 and 6) answered to several maths tasks - three times along one school year - assessing their understanding of 5 separate number components, such as: counting and number-word sequence; structure of the decade numeration system; addition; multiplication; and written multi-digit numbers (place value). In the analysis, special emphasis was given to the separate role of each component and the developmental inter-relations amongst components, in children's understanding of progressively more complex ideas about number.

The evidence suggests that no progress seems possible without the inter-related development of several components, at key times. For example, no child could understand the structure of the numeration system without a previous combined understanding of advanced counting skills (i.e. continuation of counting), addition and multiplication. Also, children who failed to continue counting could not display understanding of addition or multiplication, although they all mastered the counting principles. Based on this longitudinal data, it was possible to outline a preliminary proposal about children's number development, which included the identification of important predictors. Evidence that over 97% of the participants fit the proposed model, suggests that the present approach is relevant and worth further investigation.

METACOGNITIVE DISCOURSE
IN MATHEMATICS CLASSROOMS

Bracha Kramarski and Zemira Mevarech
School of Education, Bar-Ilan University, Israel
Kramab@mail.biu.ac.il

Research in the area of mathematics emphasizes the importance of discourse as an integral part of doing mathematics (The National Council of Teachers of Mathematics, 2000). The discourse in mathematics classrooms includes at least two factors: mathematical discourse and metacognitive discourse. Mathematical discourse includes the abilities to construct mathematical conjectures, develop and evaluate mathematical arguments, and select and use various types of representations. Metacognitive discourse refers to using self-regulating behaviors.

The present study investigates the discourse in mathematics classrooms under two conditions: cooperative-learning with or without metacognitive instruction. The metacognitive instruction was based on the IMPROVE method (Mevarech & Kramarski, 1997). Under this condition, students were guided to activate metacognitive questions in small groups that focus on: (a) the nature of the problem/task (b) the construction of relationships between previous and new knowledge; (c) the use of strategies appropriate for solving the problem/task and understanding why; and (d) reflection on the solution process.

Participants were 122 eighth graders who studied in six heterogeneous classrooms. Data were video-taped and analyzed by using qualitative and quantitative methods. Discourse analyses indicated different discourse characteristics under these two conditions. Students who were exposed to the metacognitive instruction within cooperative settings were better able than their counterparts in the COOP condition to express their mathematical ideas.

Their mathematical discourse was more fluent and involved a richer battery of mathematical concepts. In addition, their discourse involved self-regulating behaviors (e.g., prove, check) than students who studied in cooperative settings with no metacognitive instruction. The practical implications of the study will be discussed on the conference.

REFERENCES
We believe that an essential aspect of improving the effective teaching of ratio involves raising teachers' awareness of their students' strategies and misconceptions. A good diagnostic test can be a helpful tool for evoking teachers' knowledge about their children (Williams & Ryan, 2001). This communication is part of a research project which involves the construction, analysis and scaling of two parallel forms of such a test for 10 to 14 year olds (sample, n=236), one in which children are provided with hypothetically helpful diagrams, models and referents and one without.

For instance, six pairs of parallel items differing in numerical structure and context were presented in two versions: one accompanied by a pictorial representation aid in the manner of Lamon (1993) and one without. Here we report the results for these items.

The analysis of the results shows that the addition of pictures in each task affected the kind and the frequency of strategies that students employ. A notable finding is that several students answered the items correctly, based only on the pictorial aid-as shows their work on the scripts. Equally interesting is the fact that, as Santos (1996) commented about illustrations in mathematics textbooks, pupils did not always see the accompanying pictures as aid.

STUDENTS' APPRECIATION OF 3-DIMENSIONAL SOLIDS: A STUDY IN HONG KONG

Ida Ah Chee MOK (iacmok@hku.hk)
Department of Curriculum and Educational Studies, University of Hong Kong

Betty Sui Wah TSE (a9430125@graduate.hku.hk)
Creative Primary School, Hong Kong

ABSTRACT

"Spatial sense” has always been seen as important. This is the case in Hong Kong as well as many other different places in the world. Hong Kong primary students, besides learning simple geometric figures and solids in their mathematics lessons, also have a chance to develop their spatial sense further in their experience of art appreciation in their art lessons. There are opportunities of employing skills such as identifying, describing and classifying 2-dimensional shapes and 3-dimensional solids; intuitive recognition of reflective/symmetrical objects in the visual art curriculum.

A teaching package “Buildings in the future” was developed. The package consisted of three parts. First, different kinds of buildings were presented in screen images and students were asked to recognize the geometric forms and shapes from the screen images. Second, students needed to draw a sketch of a building which they would like to construct. In this part, the students needed to present the concepts in their sketches. Finally, the students constructed models of their own buildings according to their sketches and present their models.

The package lasted for four lessons of 70 minutes each. The package was tried in 4 primary-four classes (age 9) and the lessons were videotaped. The subsequent analysis aimed to find out what roles the students’ understanding of the geometric concepts might play in their perception of the buildings in pictures, as well as in the design and construction of models. The framework developed by Gutiérrez (1996), in which visualization is seen as “a kind of reasoning activity based on the use of visual or spatial elements, either mental or physical, performed to solve problems and properties”, was used as conceptual tools in the analysis.

Some interesting results have been observed. For example, despite the fact that the students had been taught the basic geometric concepts, they had confusion between the shapes and the forms, prisms and pyramids. Some students made their mental image explicit in the presentation of their own sketches. In constructing their own buildings, a few modified their designs as a result of the difficulties in constructing a particular solid.

REFERENCES:

Traditional education of proportionality has a strong algorithmic orientation by Portuguese teachers. Rate and proportions makes part of the 6th grade students curriculum (11 years old) and most of the students show difficulties in using the equation $a/b = c/x$ to find the missing value.

This study was carried out with 4th graders pupils (9 years old), following a work project methodology. Children negotiated with the teacher the projects which they will be developing, they moved out in real world in order to find the information they needed, and returning to the classroom where they tried to answer the questions they had related to their problem. After that they had to communicate the project to their colleagues, explaining all the procedures.

The problem chosen by a group of 4 children which will be presenting in this communication is “How much cost to travel by car?” During the development of the project pupils were not taught by the teacher any formal or informal process to solve the problems that children faced. They just had to mobilised basic arithmetic skills they already had.

During this communication will be analysed students strategies as well as the development of ratio tables they invented to systematise the reasoning.

Rogoff (1984) argues that thinking is deeply related to the context of the problem to be solved which includes the problem’s physical and conceptual structure as well as the purpose of the activity and the social milieu in which it is embedded. This may explain the level of performance shown by these children in solving the proportion problems directly related to their lives and interests.

Lamon (1993) and Hart (1983) consider that formal instruction and conventional symbolism should take advantage of students’ invented strategies in solving rate and proportions problems and that the best time to teach a child a new skill or idea was when it was needed, because the child was faced with a situation that could not be dealt with using the previously used methods.

"I went by twos, he went by ones" Multiple Views of Graphs
Judit Moschkovich
University of California, Santa Cruz, CA U.S.A.

In this presentation, I use a situated and sociocultural perspective (Forman, 1996; Gee, 1996 and 1999) to examine a classroom discussion about graphs of motion stories. I address the following questions: What were the multiple perspectives and ways of talking about this mathematical representation? What resources did the participants use to socially construct an understanding of the scales on the graphs?

The data is taken from a series of classroom observations and videotaped lessons collected in a bilingual eighth-grade mathematics classroom. In this classroom students represented stories of bicycle trips using tables and graphs. I examine a mathematical discussion between two students and a teacher as they explained the scales on the graphs they had constructed for a problem about a bicycle trip.

The analysis shows that there were multiple views of the meaning of the marks on the vertical axes of the graphs and multiple ways to describe these scales. I use transcript excerpts to illustrate multiple meanings for the phrase "I went by" and to describe multiple ways of talking about the scales on the graphs. This discussion did not explicitly focus on different interpretations. Instead, each student described what he had done to construct his graph and how he saw the results of his actions. These two students developed an understanding of the scale on the vertical axis by engaging in a discussion detailing their different perspectives of the scales on the two graphs. The clarification and negotiation of these multiple views and descriptions was one way that understanding of this representation was socially constructed. The analysis also shows how the graphs, the teacher, the verbal descriptions, gestures, and the multiple perspectives themselves provided resources for socially constructing the meaning of this representation. When students are making sense of a problem and have some intellectual authority, then verbal descriptions can signal the times and places where views of a representation are or are not shared. In this discussion multiple verbal descriptions marked a place where inter-subjectivity broke down. But this break down was not an obstacle. In fact, the multiple views themselves were a powerful resource for constructing mathematical understanding.

References
Most people find school math disconnected from the reality of their lives. Word problems, that ostensibly are intended to make a connection, are (stereo)typically artificial and unrealistic. Yet it is also recognized that mathematics permeates the everyday life of common people. Jean Lave and others have shown how mathematics situated in daily activities, such as choosing the best buy at a supermarket, represents a very different practice from that of school math.

We carried out an investigation based on a mathematical problem that relates to a situation that most adults in contemporary society have encountered many times, namely: “If you buy something in a store on which you have to pay tax and there is a percentage discount on the item, does it make a difference to what you have to pay if they add the tax first and then take off the discount or take the discount off first and then add the tax?”.

This problem has been posed to 230 adult students in lower level college math classes designed to prepare them to be elementary school teachers. Students first give an immediate, intuitive, individual response and then work on the problem in groups. After whole-class discussion of the problem, the students are then set an assignment to interview five people, report on their responses, and reflect on those responses.

Less than 20% of initial responses among the students, and likewise among their interviewees, are correct. Incorrect answers are generally supported either by the argument that adding the tax first means that the discount is greater or, conversely, that taking the discount off first means the tax is less. The linguistic phrases “adding tax” and “taking off a discount” suggest that the problem is additive; in fact, if tax of 8% and discount of 15%, for example, are seen as equivalent to multiplication by 1.08 and 0.85 respectively, it is clear that the order of operations makes no difference.

When students discuss the problem in groups, or when the interviewees are allowed to work with pencil and paper or with a calculator, almost all calculate the results for one or two examples and on this basis conclude that the order does not matter. Almost nobody attempted a general proof using algebra.

The students comment on the impact that carrying out the interviews had on them, in particular their surprise that people with extensive knowledge of monetary transactions neither knew nor were able to logically infer the correct answer and were usually surprised by the result of carrying out calculations. The results have profound implications for the way in which people generally fail to perceive mathematics as a potential tool for analysis of aspects of their lives.
Establishing and maintaining knowledge-building communities of practice with Knowledge Forum and other Computer Supported Collaborative Learning (CSCL) software systems in the domain of mathematics has been found to be a rather intractable problem (Scardamalia & Bereiter, 1996).

In this study, the major aim was to investigate whether having students engage in model-eliciting mathematical problems (Doerr & Lesh, in press) with collective discourse mediated by Knowledge Forum would achieve the kind of authentic, sustained, and progressive knowledge-building activity that has been achieved in more content-rich discipline areas such as science, history, and geography.

The twenty-one participants in this study were students from a Grade 6 class at a private urban Canadian school for girls. The model-eliciting problem posed to the students was to devise an alternative model that could be used for ranking nations’ performance at Olympic Games which de-emphasizes the mind-set of “gold or nothing”. The production and improvement of the alternative models proceeded in five phases: 1) Warm-up Activity, 2) Initial model-eliciting, 3) Sharing of initial models, 4) Revision of Models, and 5) Dissemination and Revision of Models in Knowledge Forum database.

Four important elements of knowledge-building activity which have been noted in mathematical research communities were observed during the course of the study: (1) redefinition of problem, (2) inventive use of mathematical tools, (3) posing and exploration of conjectures, (4) incremental improvement of the mathematical models. Much of the success we had in establishing and maintaining the mathematics knowledge building community in this study can be attributed to the rich context for mathematizing provided by the problem and to the contexts and scaffolds for both intra- and inter-group discourse provided by Knowledge Forum.

ARGUMENTATION AND PROOFS IN MATHEMATICS TEACHING

NASSER, L. and TINOCO, L.
Instituto de Matematica – Universidade Federal do Rio de Janeiro – Brazil

In the last decades, the teaching of mathematics in Brazil at secondary school has been very superficial: students are not exposed to demonstrations, and are not asked to justify their answers, or the truth of an assertion. This happens in Geometry, when students are given ready definitions and are trained to apply formulas. In the Algebra classes it is even worse: the focus is on procedures – manipulation of algebraic expressions and solution of equations. As a consequence, students are getting to the University without being able to think or to discuss the solution to a problem.

Trying to change this framework, a group composed by two university teachers, five secondary school teachers in Rio de Janeiro and four university students from the Mathematics course carried on an investigation in order to:
- identify, at first, what kind of argumentation and justification students at various school levels, from 11 years on, are able to give;
- suggest trends and strategies to enhance the levels of argumentation of students, as well as of prospective and in-service mathematics teachers;
- develop activities based on these strategies to be tested by the teachers in the group;

This research has been motivated by the project developed by Professor Celia Hoyles, at the Institute of Education, University of London (Hoyles, 1997), and was based on well-known research about the teaching of proofs (Balacheff, Bell, Clements & Battista, De Villiers, Galbraith, Godino, Hanna, Hoyles, van Hiele).

As reported in Nasser and Tinoco (1999), the first trials of our investigation pointed that “the majority of Brazilian mathematics teachers do not require their students to justify their answers...”(p.303), which is the crucial point for the difficulties shown. Several questions asking for justifications have been developed and tested, based on the strategies adopted, in order to improve the ability of argumentation (Nasser and Tinoco, 1999). With these strategies, the teachers are getting great progress in the students’ ability to give justifications. Some of the activities used in the research, and samples of students’ justifications will be shown at the oral presentation.

The first conclusions show that there is a great relation between argumentation ability and content domain, as well as between that ability and good domain of the mother language; activities to develop the level of argumentation and logical reasoning must be included in the curricular planning since the first years of schooling, and at least two schoolyears of work are necessary to get students writing justifications.

Hoyles, C. (1997): The curricular shaping of students’ approaches to proof. For the Learning of Mathematics, 17 (1), 7-16;

1 Research partially supported by CNPq (Brazil)
One of the fundamental roles of the mathematics teacher is to provide learners with understandable explanations. 'Explanations are demonstrations of understanding and provide a window to a person’s thinking' (Zuzovsky & Tamir, 1999). Studies in explanatory frameworks reveal that they provide an avenue to enhance learners' understanding of scientific phenomenon. Regrettably, less has been written about the role of explanations in mathematics teaching and learning (Dagher and Cossman 1992, Horwood 1988, Martin 1970, in Treagust, 2000).

This paper presents an analysis of twenty-three lesson observations of 10 secondary mathematics teachers in three township schools. This is done with the aim of identifying, classifying and analyzing the spoken and written explanations of a sample of mathematics teachers. The analysis of results was guided by the framework of Curtis & Reigeluth (1984) and Ogborn et al. (1996). The findings revealed among other things that mathematics teachers explanations are influenced by various factors, that they often do not consider learners' prior knowledge, are incomplete and do not always lead to understanding. The findings will be used to guide professional development intervention programs to help teachers improve their mathematics instruction.

The teaching of area of simple geometric shapes (circle, rectangle) in elementary schools is characterized often by the difficulties that pupils face in understanding some basic concepts concerning them. For example, the confusion between perimeter and area of a shape or the “mysterious” number $\pi$.

Within the framework of teaching areas we tried to cope with two special didactic problems that are related to the $\pi$-estimation and the change of the area of a square or a rectangle when we alter their dimensions with the support of a computer. Specifically for the teaching of these matters in the 6th grade of an elementary school we used the Cabri-geometer, Excel and in some cases freeware like a Java applet. Especially for the $\pi$-estimation we used, in Cabri-geometer, a combination of inscribed and circumscribed normal polygons as we were increasing the number of their sides (Archimedes’s method), we used Excel for performance and recording relevant computations in a matrix and a Java applet for the Buffon’s needle experiment which is connected with $\pi$. The same software had been used for the processing of resultant data when dimensions of a square or a rectangle had been changed (e.g. they had been doubled or increased by adding a constant length).

Pupils easily accepted the notion that when we increase the number of sides of the inscribed and circumscribed polygons we could “approximate” $\pi$, namely we could find out that the average of the areas of the two polygons is “probably” the area of the circle, which divided by $r^2$, equals the desirable number. However some pupils claimed that when we increase the number of sides of the circumscribed polygon the area increases while others used perimeter instead of area. Of course this method doesn’t permit an accurate estimation of $\pi$ but we think it is important the fact that pupils could “use” (even with teacher’s guidance) approximating methods. We also simulated via a Java applet the Buffon’s needle experiment for the $\pi$-estimation. The simulation offered the opportunity to pupils to toss as many needles as they wanted.

In rectangles and squares pupils easily concluded that if we multiply their dimensions with a number, then the second power of this number indicates how many times its area increases. When they had to estimate such an area, they generally responded positively. Some of them wrote correctly the power (e.g. $4^2$) but they failed in calculating it (e.g. $4^2=8$). A difficulty showed up when we increased the dimensions of a square adding a constant length. The teacher had to guide them with Cabri-geometer’s help to find out graphically the similarity with the previous case.
WHAT IS GEOMETRY FOR FRENCH PRESERVICE ELEMENTARY SCHOOLTEACHERS?

Bernard Parzysz*, Françoise Jore**

* IUFM Orléans-Tours & Equipe DIDIREM (Université Paris-7)
** Université Catholique de l'Ouest & Equipe DIDIREM (Université Paris-7)

This communication describes the first results of an ongoing research about preservice elementary schoolteachers in French IUFM (Academic Institute for Teachers' Training). Concerning most of these students, trainers agree on their knowledge in geometry being far from sufficient for future teachers. This can be attributed partly to their previous curriculum: even if they all have spent at least three years at university, many did not attend scientific courses; however, all were secondary students, and as such had geometry courses until the age of 15-16.

Our theoretical frame, based on our previous researches [Parzysz 1991], distinguishes, among others, two geometrical paradigms which seem relevant to account for our students' relationship with geometry: roughly speaking, the first one (G1) deals with physical objects and perceptive proofs, and the second one (G2) deals with theoretical objects and deductive proofs (or, rather, 'informal deductive”, according to Godino & Recio [Godino & Recio 1997 p. 317]).

In order to find suitable means to improve our students’ training, we started with an investigation into their beliefs, through a questionnaire (N >700). A major aim of this part of our study was to get an insight into their knowledge in elementary geometry (especially about construction techniques) and more precisely about how they connect a construction (G1) to the underlying geometrical properties (G2). We also wanted to know whether—and how—they can use their geometrical knowledge (G2) to overcome a material difficulty (G1), in the present case, material constraints preventing them from using a routine construction technique.

The analysis of the results through various statistical techniques (among which implicative analysis) allowed us to find that, even if our students have a good knowledge of elementary geometrical construction techniques, many of them cannot relate these techniques to the corresponding geometrical properties. Moreover, the study of the techniques used by the best-performing students show that these techniques have more 'degrees of freedom’ and, as such, can be adapted more easily, when necessary, to overcome possible constraints.

REFERENCES

Mathematics is often considered to form a hierarchical structure where all the new concepts logically follow from prior ones, which allow students to enrich their knowledge step by step. The very fundamental idea of successor, for example, is necessary for learning the notion of natural numbers. It is, however, seriously conflicting with the understanding of the very character of both rational and real numbers (cf. Sowder, 1992). According to the theories on conceptual change (cf. Carey, 1985; Vosniadou, 1994; Duit, 1995) the relationship between learners’ prior knowledge and new information to be learned is one of the most crucial factors in determining the quality of learning.

The objective of this paper is to analyze the results of a level test in mathematics done by elementary teacher students at the University of Turku (Finland), and to explain these from the viewpoint of conceptual change theories. Elementary teacher students’ basic skills and attitudes towards mathematics were measured in November 2000. The results refer to serious problems in the understanding of basic concepts of numbers and to low level of students’ mathematical thinking. The thinking of whole numbers and everyday experiences seems to be restrictive to a higher level of thinking, which refers to the problems of conceptual change. This suggests also that the extension of the number domains has not been dealt with thoroughly enough from a theoretical viewpoint, but it has been rushed into practice with new numbers.

Within the theories of conceptual change, it has been recently emphasized how a process of a radical change seems to be very slow. One of the presumptions for the conceptual change is the increasing meta-conceptual awareness of one’s thinking. Thinking of whole numbers dominated the students’ answers that refer to problems of conceptual change. As a result, we suggest that the perspective of conceptual change would be profitable in the mathematics education of teachers’ pre-service and in-service training.

THE EFFECT OF THE SOCIO-CULTURAL FACTORS DURING AN INTERDISCIPLINARY APPROACH OF TEACHING MATHEMATICS & TECHNOLOGY

Eugenia Koleza*, Antonis Perivolakis*, Constantine Skordoulis**, Dimitris Dellaportas**

*Department of Education, University of Ioannina, Ioannina, Greece
**Department of Education, University of Athens, Athens, Greece

This research examines the effect of cultural factors during the implementation of an activity that was carried out by 6th grade students in the framework of an interdisciplinary approach of Mathematics and Technology courses. Two four-membered mixed teams formed the sample of students. The activity concerned the design of a window of the belfry of an Eastern Orthodox Church that laid nearby the particular High school. The students were asked to draw a window twice the size of the one appeared in an under scale photograph of the belfry. The activity was carried out by the students without the presence of the researchers and the discussions between the members of both teams were video and audio recorded. In the analysis of the discussions and the drawings collected, particular emphasis was given to the effect of the dominant cultural elements. The discussions as well as the drawings reveal the degree to which the cultural context of the problem activates previous experiences of the students. We find that during the implementation of the activity their discussion incorporated influences from themes that are related to modern television forms of entertainment. However, it is the traditional cultural factors that mainly influence the drawing proposals. With respect to the mathematical part of the activity, the students proceed with off-hand numerical calculations and with vague and spontaneous use of the notion of scale. The students do not appear to be familiar with this notion although they were taught this subject the previous year. The analysis of the recordings shows also that the boys are more familiar with the application of certain mathematical and technological ideas. The incorporation of "decorative" elements in the final drawing by the girls leads the first team to the adoption of this particular drawing and to the rejection of some other appreciable proposals that present remarkable harmonies. The second team does not manage to adopt a unique proposal since its members had been separated tacitly from the beginning in two subgroups: boys and girls. Thus, this team proposes two different drawings, both characterized by originality and by traditional cultural effects.

THE ROLE OF REPRESENTATION DEVICES IN THE ALGEBRAIC CONCEPTUALIZATION OF CHANGE: A study with 10 to 11-year-olds

Elvia Perrusquia and Teresa Rojano

Center of Research and Advanced Studies (Cinvestav) Mexico

Initiating the learning of algebra concepts by describing, exploring and analysing graphs, tables, and numbers without using –at first instance- the algebraic code is said to be likely. The aforementioned is possible by the use of representation devices generated by a mediation tool such as a simulator (in this case Math Worlds). In order to do so, an early-introduction-to-algebra model, applied to 10-11 year old students who have not received any former education on the subject, is tested. Motion backgrounds are employed profitably so as to introduce algebra concepts; i.e., the starting point is the mathematics of change by using simulations generated by computer environments such as SimCalc Math Worlds. The algebra concept being examined and reported in this article is the functional relation such as velocity, from reading the position and velocity graphs as well as creating tables; in other words, by exploring and elaborating different representation devices.

The methodology used is basically longitudinal case study developed throughout 3 stages: 1) Design and/or selection of teaching activities aimed at promoting cognitive activities of formation, treatment, and conversion among devices (according to R. Duval’s theory of representations), by using simulations of motion phenomena in Math Worlds. 2) An exploratory study aimed at testing a diagnostic instrument and the first sequence of teaching activities. 3) The main study aimed at analysing cognitive processes involved in the construction of algebraic knowledge, which is the result of conversion and treatment activities among devices.

We will discuss issues arising from two cases (Isabelle and Mario) within the framework of R. Duval’s theory, in relation to the use of different representation devices in an early introduction to algebra. In one case, the representation devices and the simulator were used to express concepts that the student (Mario) already had started to build up e.g. the velocity concept as a functional relation between distance and time. While in the other case (Isabelle) the devices were used to get information and to start constructing the velocity concept that will be strengthened in the future. In both cases, we will stress the role that a variety of representations played when constructing or explaining the notion of a functional relationship, in the particular context of motion phenomena (specifically, with a focus on velocity as a functional relationship).

Literature’s review was according to early introduction to algebra, the role of representation, and experimental studies with SimCalc Math Worlds.

We want to thank The National Council of Science and Technology in Mexico (Conacyt) for funding the research project "Incorporation of IT to the school culture: the teaching of math and physics in the secondary school" (grant No. G26338S).
CATECHETICS OBSERVED IN MATHEMATICS CLASSROOMS

Adrian J Pinel
University College Chichester

During an audit of the teaching of mathematics within a group of schools spanning the age-range 4 to 16 years, attention was paid to observing the 'catechetics' of the lesson, i.e. the use of question-and-answer interactions as a means of teaching, and its inverse, the students' use of question-and-answer with their teacher and their peers in order to enhance their learning. The incidence and significance of catechetical interactions in 12 mathematics lessons is the basis for this paper.

THE LESSONS OBSERVED

Lessons seen ranged from those with students aged 4 to 14 years, across 12 schools, all but one of which was implementing the English 'National Numeracy Strategy'. By then NNS had been in place for 4 terms, and the focus of much professional development for all of the teachers observed. Lessons lasted 45 minutes or so and were observed throughout, incidents being noted on a proforma derived from observable processes and from modes and styles (ref. Gardner, 93).

Each teacher interpreted the NNS' 3-part lesson differently. The 'mental/oral starter' sometimes involved high concentrations of catechetical teaching, sometimes almost none. In only a few lessons was the inverse-catechetical form observed: students leading question-and-answer episodes with their teacher, or with their peers.

DISCUSSION

Much emphasis has been given to such interactions within NNS, so it might be assumed that this aspect of lessons would play a significant part in observed teaching. This study suggests that a rather more complex set of practices is in use. Prior practices seem more enduring than out-of-classroom discussions would indicate. All these teachers seemed prepared to use NNS approaches in prior conversation and lesson-planning documents. There were catechetical-rich episodes in 3 teachers' lessons, but almost no catechetical activity in 3 lessons. Yet the latter teachers self-evaluated their lessons as following the NNS approaches as planned.

REFERENCES

The English national curriculum includes ‘time’ as a key element within the measures section with the expectation that seven year old children achieving above average in their Key Stage One assessment tests (attaining level 3) will be able to “use standard units of time in a range of contexts” (DfEE/QCA 1999). An initial analysis of the results of these tests shows that many children who attain level 3 are still unable to fulfil the requirements with respect to time, for example to draw the hands on a clock face accurately to indicate the time “half a hour after nine o’clock”, or to calculate a finishing time given the starting time and duration, where the calculation requires movement across the next hour. The conclusions drawn (e.g. QCA 2001) are that teachers are not teaching children sufficiently in the early years of schooling to read the clock face and to calculate time. However an alternative interpretation could be that we are asking something that the majority of children at this age are unable to understand.

Time is the measure of an abstract quality, which cannot be observed. It is difficult to assess the child’s understanding, as indeed Piaget found - resorting to activities which related more to speed than time (Piaget 1969). Experience of time is subjective, some hours seem to go on for ever, others pass in an instant, depending on activity. Secondly, ‘telling the time’ requires the interpretation of a complex continuous scale, which bears little relationship to any other measuring instrument. Reading the clock face requires attention to two separate markers (the hour and the minute hands) and the relationship between them and fixed marks (hours) interpreted as two different scales (hours and minutes). Thirdly, calculation of time requires calculation with a set of different bases (60 minutes in an hour, 24 hours in a day, etc.) which do not accord with base ten calculation that the children are learning at the same time (Cockburn, A. 1999).

The research sets out to analyse children’s understanding of time and to identify children’s procedural and conceptual misconceptions. Data collected and analysed from standard assessment test papers and from observations of classroom lessons will be presented and discussed and the implications for teaching ‘time’ to young children drawn out.

QCA (2001) Standards at Key Stage 1 English and Mathematics. London, QCA
The issue of how advanced mathematics students evaluate assertions with a false premise was considered in a study presented at PME25 (Rogalski & Rogalski, 2001). Seven items of a logical test proposed to 107 future mathematics teachers were analysed, all asking for the evaluation of the value of an implication. Students were classified depending on the orientation in their answers to three non computable assertions with a false premise: 'Logic' ('the assertion is true as the hypothesis is false'), 'Relevance' ('the assertion is stupid', 'non sense'), 'Falseness' ('hypothesis always false, then assertion false'), 'ND' (non dominant type of answer). When focusing on 'logic' students also answered logically to a social contract question. Both 'logics' and 'relevance' orientations led to correct answers to a mathematical computable assertion, and to the two Wason's selection tasks—but only 'logic' was related to correct answers to both items.

Are these results stable? Are the answers sensitive to changes in the wordings of implications? What is the role of the computability of a mathematical implication in its assessment? We shall report here on a new study aiming at highlighting these questions, with the general purpose of a better understanding of how future mathematics teachers use the logical tool.

In this new empirical study 71 students were asked to assess the truth of assertions in 4 identical items, 3 items where the canonical "if ..then" was substituted to the original formulation, and 4 new mathematical computable assertions with false premise. We observed the following results (numerical data in a related poster):

1) stability of the distribution of patterns and stability of the correlation between patterns and correct answers to similar items;

2) effect of wording only on the classical Wason's task (searching data for assessing an implication), due to an increased use of the contrapositive;

3) effect of the type of mathematical computation needed to derive the 'target' consequence from the false hypothesis: there were more logical answers to the item "if 1=2 then 2=3" than to items such as "if x^2+1\leq0 then (x^2+1)^2\leq0".

Globally, even if future teachers are reasoning more logically than generally observed in the psychological litterature, they are far from a mastery of the logical tool, while this use is a determining factor of how they will manage the teaching/learning process of this tool in their future classrooms.

From the perspective of the socio-cultural approach, learning is predominantly seen as the transformation of social practices and of individuals. This view raises three issues of particular importance: the relationship between knowledge and the value certain social groups attach to it, the positioning of the learners and the importance of contextual factors in learning (Bliss and Saljo, 1999).

Empirical research carried out so far within the socio-cultural tradition has been mainly focused on the understanding of skills in everyday use, paying very little attention to issues of valorisation of knowledge and conflict or resistance. However, these issues are essential, especially in understanding the difficulties encountered by both pupils and teachers when new learning frameworks, which make possible novel kinds of learning interactions, are introduced.

Recent research has shown that both children and teachers find it hard to adopt changes in the classroom. For example, in a study that set out to explore scaffolding strategies of primary teachers in mathematics among other subjects, it was found that scaffolding either did not exist or did not work in classrooms (Bliss, et al., 1996). The teachers interpreted or translated pupils’ contributions into their own thinking often in line with the task goals, thus requiring pupils to 'ignore' all they know or believe, thus minimising the role of pupils’ contributions.

The study reported here focuses on the transformations in teaching and learning practices, following the introduction of a new approach to teaching mathematics in a number of Greek primary schools. The activities introduced were mainly of an investigative character, and the teachers were asked to adopt a role that would keep them on the periphery of the learning process, providing support to the pupils only when necessary. The results of the study so far indicate that the majority of the teachers were unaware of many aspects of their practice and tended to fall back on traditional strategies, particularly when considering that the mathematical meaning constructed by the pupils was 'at risk'. Pupils, on the other hand, tended to pay little attention to the instructions provided in the activities, often looked for the teacher's approval of their work and were unable to see the overall mathematical scope of the activities.

REFERENCES
Several studies (Nunes, 1997; Meira, 1998; Da Rocha Falcão, Brito Lima, Araújo, Lins Lessa & Osório, 2000) have observed the importance of symbolic representations in mathematics conceptualization. We are here particularly interested in investigating the bars graphs comprehension among kindergarten in the exploration of additive-structure problems among six year-old children. We proposed a didactic sequence to children based on graphical representation of quantities derived from tridimensional histograms built with Lego©-blocks. Twenty-four children from a public school in Recife (state of Pernambuco-Brazil), working in pairs took part in a six-week long didactic sequence covering three modules of activities. In the first module, only tridimensional blocks were used to represent and compare quantities, in order to solve additive problems concerning combination, equalization and comparison. A set of blocks was used to construct bars serving as precursor representations of bar graphs. The second module explored aspects of the Block-histogram, like the notion of scale (the previously established relationship between each elementary piece and a specified quantity), and finally the third module explored the activity of passage from Block-histograms to draw and interpret representations in simplified Cartesian plans. In this oral presentation we will analyze the relationship between the previous activity based on blocks and the interpretation and construction of bar graphs on the paper, in the context of addictive structures (Vergnaud, 1985). Preliminary results seemed to suggest that the activity provided by modules 1 and 2 helped children to understand information represented by Cartesian graphs in terms of quantities, their relationship and eventually their pattern of change over time.

Children entering first-grade are expected to solve written addition and subtraction exercises early in the school year. Therefore, the quality of informal number knowledge which the children bring from kindergarten prepares them for initial success or frustration with school mathematics. Evidence has been found for differences in informal arithmetic understandings by kindergarten children from different socio-economic backgrounds (Ginsburg, Klein, & Starkey, 1998). A research-based program was introduced by our staff to enhance the development of mathematics in a group of children of immigrants, identified as being at-risk for school failure.

The program provided informal instruction to small groups of children, an hour a week per group of four children, including structured game-based activities for all four, or for two, three, or one child. The teachers were advised how to extend these activities over the week.

The project included up to 115 children each year in 16 kindergartens. The children participated in an initial interview with tasks of counting, identifying numerals and using a mental number line, knowledge critical for developing understanding of addition and subtraction (Griffin, Case, & Siegler, 1995). Data from the interviews were updated regularly for an “on-line” assessment of the children’s progress. The staff was engaged in a continuous process of examining together the children’s thinking about numbers, and exchanging ideas for appropriate activities to most effectively match the children’s development. The project was an adaptation of the “Classroom conceptual research” model of Fuson, Sherin, & Smith (1998).

Results at the end of each year (May, 2000 and May, 2001) showed significant improvement in the children’s arithmetic knowledge. A follow-up is planned to record the children’s experience in first-grade.

When solving word division problems children have to consider three basic elements: the size of the whole, the number of parts, and the size of the parts (quota) which must be the same for all the parts (Correa, Nunes & Bryant, 1998; Kornilaki & Nunes, 1997). It is important to know how children deal with these elements when solving word division problems presented under situations that involve different systems of signs (Nunes, 1997) and manipulative material, which are often present in classrooms. It is also important to explore the role played by formal and informal knowledge in children when solving word division problems.

This study aimed to investigate how children before learning division in school (Group 1: 20 children) solve word division problems by using informal knowledge. In this research we compared their solution procedures and representations to those used by children who had been formally taught about division in school (Group 2: 20 children). Each child was individually asked to solve two word division problems (partitive and quotitive) by using paper and pencil, and manipulatives (objects). The analysis of children’s performance took into account the graphic representation used, the solving procedures adopted and the types of errors presented. Differences were found between groups in relation to the graphic representations adopted (p<.01) and to the way problems were solved (p<.001) in each situation (graphic and manipulative material). The results suggest that in the classroom close attention should be given to: (a) the role played by different systems of signs children adopt when solving word problems; (b) the differences between formal and informal knowledge in children; and (c) the importance of informal knowledge to the teaching of division.

CHILDREN’S MISUNDERSTANDING OF AN INVERSE RELATION

SARAH SQUIRE

DEPT. OF EXPERIMENTAL PSYCHOLOGY, UNIVERSITY OF OXFORD

One difficulty that young children encounter in understanding division problems is in understanding the inverse relation between the divisor and the quotient. Recent studies (e.g., Correa, Nunes & Bryant, 1998; Sophian, Garyantes, & Chang, 1997) have shown that children find it difficult to judge that when a given quantity is shared out, the larger the number of recipients (divisor), the smaller each portion (quotient). The current studies investigated whether children’s understanding of this relation might partly be dependent on the numbers presented in the problems.

Children were presented with problems about two parties of rabbits (with the same total amount of food, i.e., the same dividend). Children had to judge whether a rabbit in one party would get the same (or more) food to eat as a rabbit in the other party. In some trials the number of rabbits (divisors) in each party was the same (e.g., 8) and in the others there was either a small (e.g., 6 vs. 4) or a large (e.g., 12 vs. 2) difference in size between the divisors. Previous research had not investigated whether a large size contrast between the divisors would aid children’s understanding of the inverse relation. It was found that children were successful in the same-divisor trials, but only 25% of five-year-olds performed significantly better than chance in the different divisor trials. A common mistake that children made was to say that in the party with more recipients, each rabbit would receive more to eat. There was no significant difference between the small and the large contrast conditions in either five- or six-year-olds. In a second study, children were again given problems involving small or large divisor contrasts but this time they were shown pictures of the resulting portions in each party and children had to decide which sized portion corresponded to each party. It was found that almost 80% of six-year-olds consistently matched the larger portion to the party with a greater number of recipients, i.e., they inferred a direct rather than an inverse relation.

These studies provide evidence that some young children actually have a misunderstanding of the inverse relation between the divisor and that this is independent of the size of the numbers in the problems. Suggestions for future adaptations of the tasks and possible educational implications of the results will be discussed.

PME26 2002 381
ABILITY GROUPING, SEX AND SOCIAL CLASS – EFFECTS ON ATTITUDE TOWARDS AND CONFIDENCE IN MATHEMATICS
Susan Steward, Faculty of Education, University of Cambridge, UK

The substance for the Short Oral will be based on results from a questionnaire given to Year 9 pupils (640 in total) in three schools to investigate attitudes towards and experiences of learning mathematics. The profiles of the three schools used in the survey are similar in that they are all successful, mixed comprehensives in a small English city and were chosen opportunistically. The statistical results presented therefore act as a snap-shot picture of particular pupils' attitudes and cannot be reliably generalised. The results appear to confirm existing research yet prompt further questions as to the extent of pupil disaffection, its causes and the particular groups of pupils affected.

There is a view that mathematics as a discipline is objective and value-free. Yet research at school-level shows that sub-sections of students have different experiences of mathematics lessons and can be prevented from realising their potential or from gaining ownership of the mathematics they do. In particular, the attitudes of pupils in two such sub-groups, namely girls and those from lower socio-economic groups will be presented. The effects of grouping by perceived mathematical ability will also be considered.

1) Girls
In the UK, while girls' performance compared to boys in mathematics examinations at age 16 has improved this improvement is relatively minor compared to other school subjects. More importantly girls remain under-represented in non-compulsory mathematics courses post-16. Much research around gender issues has shown that confidence is a key factor in determining attitudes to the subject and its choice. Leder suggested that 'bright' girls demonstrate 'fear of success' in mathematical situations more than boys. There is also evidence that girls 'experience' school mathematics differently and do not value the type of mathematics that is widely taught. (Boaler, 1997).

2) Social class and ability groupings
There is little research within mathematics education, into the effects of social class on pupil's experiences and attitudes. Cooper has suggested working class children perform less well on national tests at age 11 which results in these pupils being placed in lower ability groups with lower expectations of their mathematics potential. In England nearly all secondary schools teach mathematics to such 'setted' groups. Boaler, Wiliam & Brown have detailed the effects of this policy and argue that pupils' experiences of learning mathematics often depend on the ability group in which they are placed.

Boaler, J (1997) Reclaiming School Mathematics: the girls fight back. Gender and Education 9 (3)
EQUATIONS AS AN EXAMPLE OF A "PROCEPT"

Jonathan Stupp, College of Management and the Hebrew University, Jerusalem

Gray and Tall coined the expression "procept" as an amalgam of process and concept (Gray 1994). This amalgamation reflects a flexible way of representing mathematical notions and is characteristic of students' thinking. Sfard writes also about mathematical notions being at the same time a process and an object (Sfard 1991).

Piaget's theory about acquiring a concept and the connections between the concept and the actions, which are linked to this concept, are applicable also to mathematics (Piaget 1972). According to Piaget the abstraction (or conceptualization) is drawn not from the object that is acted upon, but from the action itself.

In my research I chose the concepts of "a root of an equation" and "equivalent equations." Both concepts have a formal definition but are naturally linked to a process, the process of solving equations. The main activity in algebra lessons is dedicated to solving equations. My research question was: After several years of practicing this action, are students capable of conceptualizing these mathematical concepts in a mental way or are they still bound to the process, thinking only through algebraic manipulations?

One hundred and ten 10th graders were given a set of seven pairs of equations and had to decide which of the pairs were equivalent. This was done after a discussion in class about equivalent equations.

The results show that when the answer was the outcome of standard algebraic manipulations, most of them answered correctly. But when there was no clear process to connect the two equations and one has to go back to the formal definition, students had difficulties. In this case there was no real interiorization in Piaget's sense. There is, of course, a certain justification to this behavior. In these cases the correct answer has to do with a semantically abstract meaning of the concept and is rather detached from the "real life" meaning.

RELATIONSHIP: SIGNS – OBJECT – CONCEPT
IN THE PROCESS OF THE CREATION OF THE CONCEPT OF
SIMILAR FIGURES (CASE STUDY)

Ewa Swoboda, University of Rzeszów, Poland
eswoboda@univ.rzeszow.pl

During my research lasting 3 years I analysed the process of forming of the concept of similar figures. One of the aims was connected with the problem of selecting a set of standard representations for the similarity. I tried to check the following criteria (in the frame of the “epistemological triangle”):

- Does the reference context and object capture the fundamental mathematical ideas underlying the given domain?
- Does the given sign (word, name, expression) is connected in the right way with the mathematical concept?

During the first stage of my research I used different tools for learning the meaning of the statement: “the same shape”. Among others there were the transparent sheet with the picture of a car. We have manipulated those sheet on the overhead projector and observed the picture on the screen. We used the expressions: “figure have the same shape”, or “figure has a changing shape”.

After three years I used the same tools during the investigation. This situation caused bringing up new associations. The tools were recognised, but the reference context was interpreted not in direction of ideas of similar figures. The representation, which give the possibilities of the action on the object does not open the way to the domain of similarity. They allow two different interpretations:

1. in the direction of non-proportional change of the figure (deformations);
2. in the direction of isometries.

Both of those domains are different. Similarity is not connected with any of them. The used object and reference context does not satisfy my expectations. Also the expression: “the same shape”, connected with such context does not help in creating the right intuitions – it has completely different meaning. Going after the children though – preservation of shape is connected with such action of the object which does not change the object as the whole.

It seems that the procedural change the one figure into the other one is not a basic root for that mathematical concept.

FROM NAÏVE DRAWING TO CARTESIAN REPRESENTATION
Donatella Iannece – Pasqualina Nazzaro – Roberto Tortora
Dipartimento di Matematica e Applicazioni, Università Federico II di Napoli, Italy

A very important goal in mathematical education is the ability to connect different representation registers (Duval); but this attitude, far from being spontaneous, must be promoted in pupils. In particular the ability to represent a link between two variables by means of a Cartesian diagram, exactly as happens for every mathematical object, is the result of a long process rooted in natural thinking and growing through successive structuring stages. But in order to grasp the “cultural” meaning of a representation, children must experience the necessity of proposing their own naïve representations, and possibly of modifying them, if they want to communicate, while sharing achievements and emotions.

Following this idea, we have proposed to 6-7 aged children to dramatize a short novel by D. Buzzati The seven Messengers. The aim was a) to promote collective discussions (Bartolini) and reflections about the conceptual space-time tangle involved in any experience of motion. Ilaria says: “Space and time run together because time goes on as I’m walking.”; b) to favour a natural evolution from spontaneous drawings toward bidimensional representations (the three selected pictures give an idea of this transition).

During the classroom activity a major care of the teacher was to let the pupils: a) evoke and utilize all their previous knowledge; b) freely go back and forth from a register to another (bodily, verbal and graphical), whenever useful to understand. As a result of this activity, focused on different levels of representations, a Cartesian diagram is understood not only as a descriptive tool but also as a powerful mathematical object (from a cognitive point of view).

A detailed account of the whole activity, together with theoretical background and samples of tape-recorded classroom discussions, will be the content of a paper in preparation and will be ready for the time of communication.
INTRODUCING REASONING IN EARLY CHILDHOOD

Marianna Tzekaki

Aristotle University of Thessaloniki, Greece

Argumentation and reasoning are introduced in mathematics education from early years. This demand the design of experience and activities that should help children to discuss their opinions, to explain their interpretations and justify their ideas in different situations (English, 1997). Based on this orientation, we explored the reasoning abilities of 4-5 years old children and implemented teaching intervention to improve these abilities.

The paper presents the results of a teaching experiment in pre-schoolers. First, the children have been tested in argumentation and reasoning activities including i) recognition of patterns and rules, ii) explanation and justification of their ideas iii) making conjectures (Hanna, G.& Janke, 1996). The intervention process lasted six weeks and consisted of 35 tasks. The designed tasks were problems, games, stories and constructions, extended in situations (such as shapes, space relationships and transformations, qualitative and quantitative characteristics and relations) that encouraged argumentation and reasoning procedures (Alexander, 1997, Edwards, 1998, Maher & Martino, 1996). After the end of the intervention, the children were tested again in the same abilities.

The results of how interventions of this kind can help young children enhance their reasoning abilities provide interesting evidence about mathematics teaching in early years. Pre-schoolers can be encouraged to reason based on their own life experience and their background knowledge, but their improvement in this field depends on the situations the educator will employ. This point will be discussed during the presentation of the research.

REFERENCES

We present issues arising from a national project [1], which aimed to incorporate new technologies to the middle-school (12-15 years olds) mathematics curriculum of Mexico. The use of Spreadsheets, Cabri-Geomètre, SimcCalc, Stella and the TI-92 calculator were researched with nearly 90 teachers and 10000 students, over more than 3 years. The project incorporated results from international research in computer-based mathematics education, to the practice in the “real world”. In particular, the pedagogy underlying the design of mathematical microworlds (Hoyles & Noss, 1992) was considered in the design. The computational instruments were conceived as mediational tools for students’ construction of concepts. The setting and classroom structure were also emphasized (Ursini & Rojano, 2000): from the physical set-up of the equipment, to the collaboration between students, to the role of the teacher, to the pedagogical tools (e.g. worksheets). The project was evaluated considering the role of teachers, headmasters and parents; and students’ learning and use of tools. Although it was groundbreaking in changing the role of the teacher and the traditional passive attitude of children, opening the door for richer ways of incorporating technology in schools, the project had challenges and difficulties. Factors not present in laboratory settings come into play, when implementing a project such as this one, “out in the real world”. The more outstanding issues were: lack of adequate mathematical preparation on the part of the teachers; lack of experience working with technology by both teachers and students; difficulties in adapting to the proposed pedagogical model; teachers’ lack of free time to prepare anything outside the established curriculum (all of these factors contributed to make the activities much more directed than we would have liked); bureaucratic difficulties: teachers and schools had to be provided with permits to fit in the project activities to the curriculum; and lack of communication between the different levels of authorities. We believe that a fundamental facet to emphasise for overcoming many of the above issues, is in the training and continuous support of teachers: to implement a project such as this one requires long-term training in the use of technology, in linking mathematics and technology, in the pedagogical approach expected; as well as creating a support link between teachers and experts.

[1] The project is known as EMAT (Teaching Mathematics with Technology). Its evaluation is financed by Conacyt: Research Grant No. G26338S.
WHAT MENTAL MODELS DO STUDENTS USE REGARDING THE STRUCTURE OF THE DOMAIN OF RATIONAL NUMBERS?

Vamvakoussi Xanthi, Vosniadou Stella
National and Kapodistrian University of Athens

In teaching mathematics, it is often assumed that, due to the hierarchical structure of Mathematics, new ideas about numbers will smoothly follow from prior ones. However, learning difficulties in this area suggest that the conceptual shift from prior to new mathematical concepts is not as smooth as often supposed. Theories of conceptual change suggest that the enrichment of a conceptual structure by simple addition of new information is not enough to achieve understanding of certain mathematical notions.

In this study, we monitored the changing understanding of "number density" while students acquire expertise on rational numbers. We claim that we detect the need of a radical kind of conceptual change.

We interviewed twenty students of the ninth grade. They were given tasks regarding the internal structure of the set of rational numbers. (e.g. "How many numbers can you find between ... and ...?'"). Both the prior knowledge about the natural numbers and their properties, and the use of the number line, influenced clearly the way the students responded. We report our first results in identifying and categorizing the mental models that students construct when dealing with questions about density of rational numbers.

Vosniadou, St., 1994, Capturing and Modeling the Process of Conceptual Change, Learning and Instruction, Vol.4, pp.45-69.
International studies, both large and small scale, have shown that students from Far Eastern countries such as Japan, Korea and China consistently outperformed their counterparts from the West. Some researchers have noted that the number words in those countries reflected the base-10 numeration system very closely, and such language structure may be a contributing factor for their superior performance. For example, Fuson & Kwon (1992) discussed how Korean language structure may have helped Korean children to develop efficient methods for simple addition and subtraction problems. Miura & Okamoto (1989) suggested that the Japanese children's cognitive representation of numbers positively affected their understanding of place values.

Although a number of researchers speculated that the number word structures in Far Eastern languages may have contributed to their children's performance, there has been no study that investigated Asian children's understanding of ten as a unit. Thus, a small scale, exploratory study was conducted to analyze Japanese young children's concepts of ten.

A convenient sample of 12 Kindergarteners, aged 5 years and 5 months to 6 years and 3 months, and 12 first graders, aged 6 years and 8 months to 7 years and 3 months, participated in this study. These students attended the Kindergarten and the Elementary School affiliated with the College of Education of a national university in Japan.

Each child was individually interviewed. There were four types of interview questions for children in both age groups. These tasks were adopted from Steffe and his colleagues' work (e.g., Steffe & Cobb, 1988) and involved individual counting squares and ten-strips. These interviews were semi-structured in that there were a set of common questions for each age group. However, based on children's response, the interviewer asked additional questions, and or or altered the size of numbers. Each interview took approximately 20 minutes. All interviews were videotaped for later analyses.

In our presentation, we will present our analysis of these interviews, focusing specifically on these children's understanding of ten as a unit.

References

The aim of this exploratory research was to identify, examine and draw recommendations from analysis of the similarities and differences between able and gifted 10-11 year-olds, where ‘able’ refers to high achievers, and ‘gifted’ to exceptionally high achievers. The research draws upon Szabos’ (1989) characteristics of ‘bright learners’ and ‘gifted learners’, and Krutetskii’s (1976) structure of mathematical abilities. It addresses the questions: What distinguishes a child who is gifted in mathematics from the larger group of able, above average children? Are these differences in degree or differences in kind?

Based on the above definitions, two schools were asked to identify an able and a gifted 10-11 year-old child. Using a case study methodology, clinical interviews were then conducted with each of the four children. The interviews were video taped, transcribed and analysed using a grounded approach.

Many broad similarities were found between the able and gifted, including their approaches to procedural tasks. The results presented here will focus on the more subtle qualitative differences in kind observed in the children’s approaches to conceptual tasks. Key differences appeared to be the tendency of the gifted to plan a strategy, solve problems in an efficient and elegant manner, and justify solutions for themselves. Drawing on the children’s responses to conceptual tasks, a model was developed to characterise the strategically based methods of the gifted. It will be presented and illustrated with examples of children’s work. This research supports the use of mathematically difficult tasks to enhance the identification of giftedness (Niederer & Irwin, 2001; Span & Overtoom-Corsmit, 1986). It also raises many questions, calling for further data collection and evaluation of the model.

REFERENCES

In this session I will report on the first year of a three-year research project in which I am working with a group of student primary school teachers through their one-year post-graduate training and then, I hope, the first two years of their teaching careers. The students and I are working to characterise their sense of their identity as learner and as teacher of mathematics and track how this changes and develops over time.

I am using concept mapping (Mwakapenda, 2001) as a methodological tool to provide a framework for representing, discussing and probing students’ developing pedagogic content knowledge and, from the perspective of situated cognition and identity theory, their developing identity as ‘teacher of mathematics’ (Lave and Wenger, 1991, Wenger 1997, Winbourne and Watson, 1998, Winbourne 2002). We have begun the process of accounting for development in identity in terms of students' participation in university mathematical and pedagogical practices and increasingly practices in their placement schools; later, the scope of these accounts will be expanded to include the practices of the schools in which students start work as newly qualified teachers (NQTs).

Through hermeneutic analysis of data (Van Manen 1990) emerging themes are identified, explored and used to construct biographical narratives that are represented to the students/NQTs themselves for further discussion and validation.

Amongst the questions I hope to consider are these: if students/NQTs become practitioners who are critical of their practice (meaning the mathematics teaching practices within which they are becoming experts) what in their experience may turn out to have been central in the development and maintenance of this disposition? If not, what features of their experience may be similarly identified?

Winbourne, P (submitted for publication 2002) Looking for learning in practice: how can this inform teaching?
The use of computer simulation in probability teaching raise questions about its use that is worthy to search. In this sense, Coutinho (2001) reports some difficulties the students had when several situations were given for building urns models for simulating some probabilistic games. These difficulties are associated with the use of the software, the resistance to use the simulation for solving a problem that can be solved directly by calculation and the difficulty on accept simulation data that has not obtained by themselves in order to estimate probabilities.

We are developing a searching for knowing the understanding that the students generate as a result of an instruction supported on the use of the computer simulation. The first part of this work, besides of looking for students’ intuitive ideas about probability, look for the spontaneous ideas they have about the frequentist approach and, in particular, the difficulties they face solving probability problems using the computer simulation. Furthermore, we pretended find the strategies they used for estimating the values of the requested probabilities. Some of the results obtained are the content of this paper (Yáñez, 2001).

Twelve university engineer students in Mexico City participated in this study. The activity was made in four sessions of three hours each. In the two first sessions we started working with Fathom solving some problems with computer simulation. In the third session the students worked in pairs for solving three problems of conditional probability; in the fourth session the students individually solved three problems of conditional probability.

For the results obtained, it is seen that the students have difficulties in the modeling of the random experiment and in its programming in the simulation computer language. Other difficulty deals with the interpretation of the graphics of the relative frequencies for estimating the probabilities.

Almost all of the students used the last value strategy that identifies the last value of the relative frequency with the probability requested. Another strategy deals with modeling for solving only the questions and not the random experiment, trying to transfer the theoretical analysis to the simulation computer language. It might be that the students make distinction between a theoretical probability and simulated one, even some of them believe there are as many probabilities as generated values of the relative frequencies.

POSTER PRESENTATIONS
One of the major objectives of mathematics teaching at schools is the development of advanced logical thinking in students. Pedagogical experience convinces us that the process of logical thinking development in students was and is the major weak point of mathematics teaching in school. Studies of the nature of students’ logical errors during solving mathematical problems show that such errors result from certain gaps in the students’ system of fundamental knowledge. Elimination of these drawbacks requires from the students assimilation of basic notions of mathematical logic such as: a necessary and sufficient condition, corollary, equivalence, etc. The proposed technique is based on the idea of students’ involvement in the research and expertise activity.

A student is offered: to check the “problem solution” proposed by the teacher and try to find the logical error in it; to highlight the error; to study the error nature; to offer correct solution technique; to formulate the rule preventing further mistakes of the kind.

This instruction technique promotes:
- Practical study of mathematical logic elements;
- Finding and elimination of logical errors;
- Development of critical thinking, which is the integral part of mathematical culture and scientific outlook;
- Maximal rapprochement between standard mathematics teaching process and the students’ teacher-instructed self-education;
- Realization of basic ideas of the collaboration pedagogic;
- Advancement of learning motivation (a student is warned against “the potential danger”, and he, naturally, strives to test his abilities).

The authors have tested the of the report major statements on high achievers of various grade levels for a number of years. The report indicates typical examples illustrating the technique, substantiates and demonstrates certain methodological types which are efficient for generating the respective teaching process.
INDIVIDUAL DIFFERENCES IN COGNITION AND AFFECT AND SECONDARY SCHOOL STUDENTS’ MULTIPLICATIVE KNOWLEDGE IN BASIC ARITHMETICAL PROBLEMS

Glenda Jean Ashleigh
University of New England, Australia

The study was set in a Brisbane metropolitan secondary school that draws students from a mix of demographic and socio-economic areas. Individual differences in cognition and affect in secondary school students’ multiplicative knowledge structures of basic mathematics problems were examined. Procedural and Conceptual knowledge aspects of multiplicative structures of basic mathematics problems were analysed within a proceptual framework described by Gray and Tall (1994). An expanded model of Proceptual Multiplicative Knowledge was proposed.

OVERVIEW

Four quantitative studies examined models of cognition, affect and knowledge structures of basic mathematics problems and their inter-relationships. Luria’s (1973) ‘whole brain’ theory describes how information is processed successively (sequential and primarily temporal) and simultaneously (continuous and primarily spatial). Marsh’s (1990) multi-dimensional model includes academic dimensions as measures of Self-Image. The academic dimensions of Maths and Verbal Self-Esteem can be linked directly to performance in mathematics problems. Students’ responses to basic mathematics problems provided student performance data on the arithmetic operations involving integers and non-integers. A qualitative study, incorporating semi-structured interviews, focussed on individual differences in cognition and affect and multiplicative knowledge structures that students use in solving basic mathematics problems.

Ten A4 sheets of paper in varied colours will be displayed in the allocated area. Text, tables and figures will show the findings of the study and the proposed expanded model. A one-page handout of the highlights of the poster will be provided.

REFERENCES

The purpose of this study is to analyse how teachers in mathematics understand the equation concept. Furthermore my goal is to investigate what kind of previous experiences the teachers have had of their own concept learning. Ten teachers in mathematics in the secondary school participated in the study. Five teachers were newly graduated and five were experienced. Data was gathered by interviews and questionnaires. Tapes were transcribed into protocols and interpreted to categories of conceptions by the phenomenographical research method (Marton and Booth 1997). The results indicate that the teachers have different kinds of misconceptions of the equation concept. They are insecure both to the mathematical symbols, the letter expressions and the solving procedures. Their experiences at school suggest that they have spent most of the time to develop procedural skills instead of mathematical understanding. Their acquired experiences of the concept learning have formed their concept images (Vinner 1991). These are not identical with the concept definition. For some of my teachers an equation does not constitute a mathematical statement. The equation concept is for them closely linked to other difficulties like variables, unknown factors, the roles of the equality sign, the meaning of the mathematical symbols, the role of the formal definition and the solving procedures. The process-object duality of the mathematical notation (Sfard 1991) creates fundamental problems for teachers. They have considerable problems in leaving the process level and entering the object level and there is no difference between the newly graduated and the experienced teachers. Concept definitions help us to form a concept image, but they do not guarantee understanding of the concept. Teaching mathematical concepts with understanding requires different kinds of metaphors, various examples, non-examples, language, situations and so on. It presupposes that teachers have mathematical and pedagogical knowledge and skills and a rich image of mathematical concepts.

EARLY EXPERIENCES IN DYNAMIC VISUAL REASONING IN A
COMPUTER ENVIRONMENT

C. COSTA
Escola Superior Educação, Coimbra - Portugal

Transformation geometry is considered of great importance for the elementary school by a number of researchers (Williford, 1972; Del Grande, 1990; Edwards, 1991; Johnson-Gentile & Outros, 1994) but there is some controversy about how children think about transformations (Shah, 1969; Kidder, 1976; Lesh, 1976). The learning of transformation geometry is intimately connected to the presence of dynamic visual reasoning. We are interested in the ways technology can enhance the dynamical visual reasoning of pupils. We designed a computer environment, microworld, to try to show ideas like translation, reflection and rotation, through the motions slide, flip and turn, to elementary school pupils. The microworld allows with some ease a number of actions on some visual representations. Two pre - built shapes can be moved (slide, flip or turn), some of its characteristics can be modified, a set of geometric concepts may be explored, discussed and communicated. The microworld will give opportunities to develop the ability to learn to imagine dynamically and to perform mental experiments of spatial reasoning. With this environment to learn mathematics children may combine the practical ways to mathematise those motions with higher mathematical activities.

The poster will: - elaborate on the types of learning sought; - explain the design of the microworld; - describe how the microworld works; - give details of the use of the microworld with pupils of 4th grade and in-service teacher training (grades k-4).

HOW DOES A TEACHING PRACTICE PROJECT INFLUENCE THE
TEACHER-STUDENTS’ ACTIONS

AUTHORS: Maria Solange da Silva – FFP - UERJ
Marco Antonio Costa da Silva – FFP - UERJ

AFFILIATIONS: University of the State of Rio de Janeiro

Inside all of disciplines of the Mathematics’ course to students who intend to be a teacher the teaching practice is responsible for the articulation between the pedagogic speeches and the formal speeches.

If we want to stimulate changes to teacher-students’ procedures we have to influence the future teachers that they need to develop their sensibility about the functions and purpose of mathematical speech. This implies a total change in the nature of their actions and concepts about mathematics teaching.

In Faculty of Teacher Training – FFP-UEI, a public University in Brazil, the Mathematics’ Department develop a new model of mathematics teacher training breaking the isolation of the individual subjects. For that the teachers’ preparation include a large reflection about how does the teaching practice influence the teacher-students.

This poster presents some favorable results about this project that gives priority to the didactical and methodological action of the mathematics students in their teaching practice.

DO INDIVIDUAL STUDENTS CONSISTENTLY APPLY THE SAME INTUITIVE RULE?

Dirk De Bock¹, Wim Van Dooren¹³, Dave Weyers¹ and Lieven Verschaffel¹
¹University of Leuven and ²EHSAL, Brussels; Belgium
³Research Assistant of the Fund for Scientific Research – Flanders (F.W.O.)

In recent years, the intuitive rules theory has received growing attention in the mathematics and science education research community because, according to its advocates, it can explain and predict various kinds of responses of students to a wide variety of tasks from scientifically different content domains (see, e.g., Stavy and Tirosh, 2000). Two major intuitive rules are manifested in comparison tasks and are called “More A – more B” and “Same A – same B”. A recent Belgian replication and elaboration study by De Bock, Verschaffel and Weyers (2001) has challenged the predictive power of that theory. Hundred-and-seventy-two students of grades 10, 11 and 12 solved five problems, stated in a multiple choice format with three alternatives: the correct answer, an incorrect answer in line with “More A – more B” and an incorrect answer in line with “Same A – same B”. The results showed that Belgian students are less affected by the intuitive rules than their Israeli peers: for most problems, the results in line with the intuitive rules were far below chance level and several other misconceptions proved to be at the origin of students’ erroneous answers.

A different kind of analysis on these data was executed to provide an answer to the following research question: are individual students consistent in their choice for one of the intuitive rules? We shifted from a data analysis at the item-level to an analysis of the answering profiles of the 172 participants. Theoretically, there are 21 ways to answer the five problems (e.g. two answers in line with “More A – more B”, two in line with “Same A – same B” and one correct answer is one of these ways). By means of three-dimensional frequency diagrams, the poster shows and compares the observed distribution of the students’ profiles and the theoretical (multinomial) distribution that would be expected if students answered at a random base. This analysis clearly indicated that the typical “More A – more B” or “Same A – same B” student does not exist (or is extremely rare). E.g., none of the 172 students answered more than three times in line with “More A – more B”. Confronted with a problem they cannot solve, students rather seem to guess than to apply a specific intuitive rule, a finding which once again challenges the predictive power of the intuitive rules theory.

Some preservice mathematics teachers reveal difficulties and negative attitudes when they study geometrical concepts and relations. Some years from now I’m having a problem: what can I do in the classroom to foster understanding and performance of students when they face proof in geometry? I need more knowledge about proof and teaching of proof. I have access to papers from Gila Hanna, Michael de Villiers, Tommy Dreyfus, P. Goldenberg, ... After that, I start designing environments where students play active roles in trying to develop geometrical habits of mind. The goal is to develop in preservice teachers reasoning processes, meaning that the variety of actions that students take in order to explain to themselves, to others, what they see, what they do, what they conjecture and why they do it. I decided to use The Geometer’s Sketchpad (GSP) with the students to contribute to experimentation, to conjecture, to convince of the truth of the conjecture and to help them come to see proof as a form of explanation and understanding why, rather than convincing. One aim of the study is to analyse the performance of preservice teachers in proving, in order to answer to the question: what level of performance reveal preservice teachers in doing proofs? The participants in this qualitative case study are a whole class of preservice teachers in the second year of the maths and science course in a School of Higher Education, during a whole year. Data has been collected through geometric problem solving tasks and observation. To solve the tasks the participants need to use GSP, to make conjectures, to examine and to reformulate those conjectures and to answer why they are true. We are in the beginning of data analysis, that is holistic, descriptive and interpretative. This presentation will try to answer the question and to draw some conclusions.

References

A group of students must “know how to determine the equation of a straight line in the form \( y = ax + b \) from its graph” (Intermediate 2 Mathematics, SQA, 1999). So starting with the particular and moving to the general, we begin with an example...

“\textit{It's hard to measure the length of a winding road on a map. Can we estimate its length by counting how many times it crosses a gridline?}” We each try out the idea by laying different lengths of string randomly on 1 cm squared paper and collecting data. “\textit{A graph may be helpful.}” We draw graphs by hand and, using a transparent ruler, we fit a line. “\textit{The line doesn't quite go through all the points but it's the best fit we can find.}” Find the equation of the line. Laurence gets \( y=1.1x \). “\textit{The equation doesn't quite fit all our data ...but it's the best fit we can find.}” “We all got more or less the same equation: \( y=1.25x \), \( y=1.1x \), \( y=1.2x \).” “\textit{Why weren't they the same?}” “\textit{Why is it a straight line again? Oh yes, all the pairs of numbers fit the equation / lie on the line.}” Natasha says she was told that a line of best fit couldn't go through the origin. “\textit{But a 0cm piece of string must cross 0 gridlines}”. We agree that length = crossings \( \times 1.2 \) (roughly). The graphic calculator gives the equation of the line as \( y=1.26344086x+0 \). “\textit{That looks different - oh no, if we round it's about the same.}” We try to predict the length of a string with 22 crossings. “\textit{So how far is it from Edinburgh to Perth on the M90?}” “\textit{We can often fit data to a straight line in this way. It allows us to predict...}”

(The roster includes illustrations of this activity)

From the particular to the general...

Some teachers like teaching (school) Mathematics because it is tidy and complete and logical. The experience of this group suggests that learning Mathematics is neither a linear nor a tidy process. Its very untidiness pushes it forward. (\textit{Why is the equation on the GC different?}) Learners work to assimilate new ideas to the concepts they are building (eg a linear relationship can be used for prediction) and accommodate the concepts to make sense of the inconsistencies they find (eg. a best fit line can go through the origin). Using a holistic approach to bring together different concepts motivates the learner to tidy up, reconcile, rationalise, understand better. It is not possible to ‘tick off’ the linear relationship as completely ‘understood’ by a learner. Intelligent learning (Skemp,R.(1987) Psychology of Learning Mathematics) involves building a network of links between concepts. This is an ongoing organic process.

By the way...

We also covered co-ordinates, graphing, gradient, ratio, decimals, rounding, algebra, substitution, why Maths is a powerful language, why Maths might be worth learning... And we joined up our thinking.
The awareness of students with special needs is getting more and more central in educational decision making. Students with learning disabilities are a significant group within this population because they share some qualities which may contribute to their society. The definition of learning disabilities refers to students that show a gap of almost 2 years between their actual ability and their potential. Most of them have an average and even more intelligence quotient and one of the most problematic subjects is mathematics. Mathematics is a very unique subject matter because of its special language, its inquiry systems and its rigid and step by step concepts and principles construction. Students who are diagnosed having dyslexia or ADHD or writing difficulties suffer much from mathematics demands. Some of these learning disabilities are due to psychological aspects and also to teaching disabilities.

I developed, tried and evaluate a humanistic model for teaching mathematics to students with learning disabilities at grade 7 -12. The model is based on mutual reflection between the coach and the student. The components of the model are in initials: M.I.R.R.O.R: M- for Mathematics; I- for Interaction; R for Relevance; R for Realistic; O-for Openness; R- for Respecting; The rational for this model us base on psychological-educational theory of Dewey(1933), Piaget(1969) and Rogers (1963).

The poster will show graphically the M.I.R.R.O.R model. In the middle of the poster there will be a mirror, student and teacher with connections to the 6 phases in the margins of the poster: Mathematics; Interaction; Relevance; Realistic; Openness; Respecting - with examples for each phase and explanations

Rogers, C. R., 1963, Learning to be free. Journal of reading, 36, 3
FORMING COGNITIVE SCHEMES IS ONE OF THE CONDITIONS OF DEVELOPING STUDENTS' INTELLECTUAL ABILITIES

E. Gelfman, Tomsk State Pedagogical University,
M. Kholodnaya, Institute of Psychology of RAS, Moscow

Educational process is the system of constructing links between teaching and learning. Its contents, methods, skills and techniques should be, first of all, directed to exposure and usage of every student's experience. M.A.Kholodnaya (Kholodnaya, 1997) singles out such forms of intellectual experience as cognitive, metacognitive and intentional. Cognitive experience includes such mental structures as the ways of information coding, cognitive schemes, semantic structures and, finally, conceptual structures. Cognitive schemes are responsible for receiving, collecting and transforming information. Here arises a question: "What are the conditions which help students to form cognitive schemes in process of teaching?"

In the course of long experiment we have pointed out the types of school texts, which help forming a repertoire of students' cognitive schemes. First of all, we pointed out some types of cognitive schemes. These are, for example, "focus-examples" (Bruner, 1971). Focus-examples are schematized images, which are used as the starting point by a person who solves this or that problem. To create generic focus-examples is necessary to have a set of specific focus-examples, which are used to form a concept.

Another variety of cognitive schemes is a frame (Minsky, 1979). On the one hand, to create frames is possible with the help of texts, which form students' ability to perform the procedure of identifying objects, phenomena, properties and links between them. On the other hand, there should be school texts, which could develop students' flexibility of thinking and ability to reconstruct a frame.

Special attention in our research was paid to forming controlling cognitive schemes-plans of actions in a problem situation (Pascal Leon, 1970, 1987). Here we pointed out the types of texts which help students to construct plans of their activity, their fixation, pointing out separate elements of these plans, correlation of different plans and so on. It is very important for a teacher to be well aware of the activity, which is connected with forming cognitive schemes: if the familiar cognitive scheme becomes stronger, larger and reaches or a new cognitive scheme is created.

Success of students' school activity depends on the repertoire of student's cognitive schemes and how a student can analyze them in a certain situation.

THREE MEASURES FOR CONFIDENCE IN MATHEMATICS

Hannula, Markku S.; Maijala, Hanna; Pehkonen, Erkki; Soro, Riitta

University of Turku, Department of Teacher Education

In this poster we shall report some preliminary results of the research project ‘Understanding and self-confidence in mathematics’. The project is directed by professor Pehkonen and funded by the Academy of Finland. It includes a two-year longitudinal study for grades 5-6 and 7-8 with two quantitative surveys for approximately 200 mathematics classes and a qualitative study of 40 students. In this poster we will present the instrument and some results of the first survey.

We designed a survey to measure the level of self-confidence and understanding of number concept in a large population. The survey was administered by teachers during normal 45-minute lessons during the fall term 2001. It consisted of five parts: student background, 19 mathematics tasks, success expectation for each task, solution confidence for each task, and a mathematical beliefs questionnaire.

The students’ confidence was measured with three different measures. Before the students did the actual tasks, they estimated on a 5-point Likert scale whether they can solve the task or not (‘success expectation’). After solving each task they answered on another 5-point Likert scale on their confidence on their solution (‘solution confidence’). Furthermore, the 25 items in the mathematical beliefs questionnaire included ten items that were adopted from the confidence scale of the Fennema-Sherman Attitude Scales (Fennema & Sherman, 1976) (‘self-confidence’). Success expectation and solution confidence responses tended to be skewed (high confidence), especially for seventh graders. For further analyses we chose eight (most difficult) tasks that produced less skewed responses.

As expected, the three confidence measures were correlated. The success expectation and solution confidence had a correlation of 0.67. Self-confidence correlated with the other measures on the level 0.44 – 0.50, weaker correlations being for the fifth grade. Somewhat surprisingly correlations between confidence measures and success in test were weaker, more so among fifth graders and there especially for girls (0.06-0.09).

Another interesting result was found in gender differences. On fifth grade the differences in both success and confidence favoured boys. However, on seventh grade no gender differences were found.

Semantic types of an anchored addition and subtraction
Milan Hejný, Charles University, Prague

The poster will be split into six main sections: illustrations of fundamental terms; definitions; tasks; student's solutions; examples; didactic applications of theoretical ideas.

As a continuation of G. H. Littler’s poster about semantic types of numbers (Ad = address, St = state, Co = comparison, Ch = change) the most frequent semantic types of the addition and the subtraction are discussed:

<table>
<thead>
<tr>
<th>Type</th>
<th>Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>St + Ch</td>
<td>I had 10 Kč. I found 5 Kč. How many Kč do I have now?</td>
</tr>
<tr>
<td>St - Ch</td>
<td>I had 10 Kč. I lost 5 Kč. How many Kč do I have now?</td>
</tr>
<tr>
<td>St + Co</td>
<td>Ed is 124 cm high. Eva is 3 cm higher. How tall is Eva?</td>
</tr>
<tr>
<td>St - Co</td>
<td>Ed is 124 cm high. Eva is 3 cm lower. How tall is Eva?</td>
</tr>
<tr>
<td>St + St</td>
<td>Here you see 5 girls and 4 boys. How many children are here?</td>
</tr>
<tr>
<td>St - St</td>
<td>Here are 9 children. 5 of them are girls. How many boys are here?</td>
</tr>
</tbody>
</table>

We asked pupils to indicate the semantic inverse of these cases. There were no problems with the issues St ± Ch and St ± Co, since words to lose and to find as well as higher and lower have been identified as opposite by all pupils. However the issue St ± St was a difficulty. The most frequent opposite to put together was identified as to part the whole or do not touch it. And the most frequent opposite to take the complement was identified either take the whole or take the starting part or do not take the complement.

Consequence. To be prepared to grasp the idea of subtraction a child has to be familiar with cases St + Ch and St + Co. If the majority of his/her semantic experiences with the addition is of the type St + St a child is not well prepared to understand subtraction.

Types Ad ± Co (I live on the 5th floor and Fred lives 2 floors above/below. On what floor does Fred live?) or Ad ± Ch (Our family moved from the 5th floor 2 floors up/ down. On what floor do we live now?) are of the same difficulty as St ± Ch and St ± Co. A child must to meet these cases as well.

More demanding are types Co ± Co and Ch ± Ch (Ann is 2 years older than Bert and he is 1 year older than Cindy. How many years is Cindy older than Ann?) Here some children ask for the starting state (the age of Ann). Even more demanding are the cases Co ± Ch and Ch ± Co (During the last year Mark grew 4 cm taller. Now he is 1 cm shorter than the table. How many cm was Mark shorter than the table before?)

OLD TUNES, NEW TECHNOLOGY: HOW COMPUTERS MEET HISTORY IN THE MATH CLASSROOM

Ronit Hoffmann
Kibbutzim College of Education
and Tel-Aviv University, Israel

Technology and especially computers are essential when teaching and learning mathematics; they influence the mathematics that is taught and enhances students’ learning (NCTM 1989, 2000). In addition, mathematics educators have long emphasized the importance of integrating the history of mathematics into the curriculum (Arcavi, 1987; Freudental, 1981). The integration of computers and historical aspects contribute to the understanding, interest and enjoyment in learning mathematics.

The poster will demonstrate a teaching topic that combines historical and computational aspects: The number π and its computation to a desired accuracy (Hoffmann, 1996), intended for elementary and secondary school mathematics prospective teachers. The calculation of π is characteristic of the history of mathematics in general and, according to Beckmann (1971), “The history of π is a quaint little mirror of the history of man”. Its importance goes beyond its historical origin in geometry, and expands into the various fields of mathematics. Calculation of this number has engaged the greatest mathematicians from the dawn of history (Kline, 1972). Today, using computer power, more than 200 billion digits of the number have been extracted.

There exist several numerical methods to calculate π which cover a range of mathematical and computer-science concepts. Each method generates beneficial by-products: Analysis of the effect of round-off errors, rates of convergence (Breuer & Zwas, 1993), probabilistic reasoning, computer simulation (Hoffmann, 2001), the uses of series and so forth. We will show how current technology enables integrating these methods into the school curriculum and review our experience in teaching the topic in teachers' colleges and to university students.

Implementation of Content and Language Integrated Learning (CLIL) in Mathematics Classroom

Jarmila Novotná, Marie Hofmannová, Charles University, Prague

The work was inspired by the European project TIE-CLIL developed over the past four years. CLIL refers to any teaching of a non-language subject through the medium of a second or foreign language (Pavesi et al., 2001). It aims to create an improvement in both the foreign language and the non-language area competence.

The described experiment is one of the outcomes of an optional CLIL course aimed at the Faculty of Education students wishing to enhance their teaching qualifications from the original Diploma in Mathematics (to be taught in Czech) and English (as a foreign language) to a new, integrated competence of teaching mathematics through English to Czech learners.

Four final year teacher trainees were placed at two upper secondary schools – one in Prague and the other in Olomouc. The Prague school provided a typical learning environment. Students, experimental group (n = 30), learn all the subjects in Czech. The Olomouc school, control group (n = 29), belongs to the network of twelve schools where selected subjects are taught in a foreign language. For the period of two weeks both groups were exposed to the same subject matter (graphs, ellipse) in English. The aim of the experiment was to monitor the teacher’s role and specify the amount of his/her verbal and non-verbal support through the stages of the students’ cognitive development. Observation sheets, videotapes and questionnaires became the primary source of data. The nature of support could be seen partly in the interaction of three languages of information processing: Czech (L1), English (L2) and the language of mathematics (L3). Teacher talk as an insufficient instrument was combined with a variety of pedagogical practices including the use of teaching materials and aids.

FOCUS ON MEDIATION OF ACTIVITY TO DEVELOPING CLASSROOM DISCOURSE

Verónica Hoyos

CAEM, Universidad Pedagógica Nacional (MÉXICO)

Abstract. In this work is endeavoured to contribute in the search of significant tools to learn mathematics (significant in the sense that they necessarily alter the character of knowledge, in according to Confrey, 1993). We are presenting the results of some empirical observations about performed activity of a group of 18 student’s 14-aged, who were working on certain scenarios of learning. The pupils were mainly handling certain cultural artefacts for the elementary geometric transformations learning. Here, our main concern was to analyze, using a communicational learning approach (Sfard, 2001), the way that learners approach to mathematical terms using scripts for the activity and describing their accomplished tasks.

INTRODUCTION

Some recent research results show that in sessions of practical work, secondary pupils, using recent processing development, are acting to access to notions, properties or mathematical procedures that were previously subjects of access for no one but professional Mathematicians (Hoyos, 1999; Hoyos, Capponi and Geneves, 1998; Moschkovich, Schoenfeld, and Arcavi, 1993).

On the other hand, theoretical expectations and alternative approaches in didactics of mathematics (Bartolini, 1998; Bartolini and Boero, 1998; Boero et. al., 1997; Mariotti et. al., 1997) argue for introducing “voices” or historical contexts of recreation of scientific experience in the classroom, as a way to generate ideas or complex mathematical notions.

Here, we attempt to contribute further information in a perspective of research related to the use of computerized scenarios and the introduction of historical contexts in the search for significant tools for mathematical learning. Particularly, it was interesting to analyze the different descriptions that pupils are effected at the end of performed activity. The analysis of the advancement of students was based in a communicational approach to learning (Sfard, 2001). From our point of view, those pupil descriptions reflect how they coordinate obtained experiences.

Acknowledgments: The work presented here was based in a research partly supported by the National Council of Science and Technology (CONACyT) of Mexico, No. 30430S.
COMPUTER-BASED MATHEMATICAL GAMES FOR PRESCHOOL CHILDREN

Jenny Pange, Maria Kaldrimidou
University of Ioannina-Greece

Computer games play nowadays a significant role in the culture of children and adolescents. Given the strength of their influence, it is likely that these games may affect the knowledge children could get either from school or at home (Bruner 1985, Wark, 1994).

The spread of computer software as mediator in the development of mathematical concepts (Anderson 2001) and the Internet as a teaching tool (Pange 1998), provide an extra chance to children to play and learn mathematics using computer-based games either at home or at school, as most of these computer-based games are easily accessible to children and there are at no extra cost.

A survey was conducted amongst Greek pre-school teachers and children aged 5-6 years, to examine whether they use computer-based games in the Internet to teach mathematics.

Results revealed that very few Greek children are using the Internet and also very few Greek pre-school teachers know how to use computer-based games, in order to teach mathematics. From a group of 500 pre-school teachers only 10 knew how to use the Internet at school. These teachers found that computer games allow children maximum freedom in approaching mathematical tasks in their own manner. But, mathematics have to be the main stage of the software, the software has to encourage children to play again the computer game, all children with any learning style, can enter into the computer game, and children can explore new mathematical ideas from the game. Without these characteristics of the software, children become bored and non-enthusiastic in playing the mathematical computer game.

This study concludes that the use of Internet computer-based games from pre-school children has to be guided by an experienced teacher. All teachers have to be well acquainted with computers and also to be quite experienced with Internet in order to be able to teach mathematics to children and to evaluate the computer-based games.

3. J. Pange, 1998, Using web as a tool for teaching, Proceedings of the BITE, Maastricht,

In this paper, elementary mathematics teachers’ beliefs about the use of technological tools in mathematics teaching in rural and urban areas were analysed. The researchers develop a questionnaire. The questionnaire was conducted in Balikesir, Turkey. An interview protocol is also developed. An interview is conducted with twelve mathematics teachers in both rural and urban areas. Initial findings show that mathematics teachers in rural areas said: “technological tools are insufficient”. Mathematics teachers in rural areas have also lack of knowledge about how to use technological tools in mathematics teaching effectively. Although, teachers in urban areas do not keen on to use technological tools, even though technological tools are available.
The primary aim of the mathematics curriculum in Singapore schools is to enable pupils to develop their ability in mathematical problem solving. The conceptualisation of the mathematics syllabuses is based on a framework that emphasises the interplay of five components — Concepts, Skills, Processes, Attitudes and Metacognition to achieve this aim (MOE, 2000). Prior to the year 2000, Processes in the framework referred to Deductive reasoning, Inductive reasoning and Heuristics (MOE, 1990).

In 1997, responding to the Prime Minister’s launch of the THINKING SCHOOLS, LEARNING NATION vision (Goh, 1997), the Ministry of Education initiated changes to curricular subjects to implement the Thinking Programme in schools (MOE, 1998). A revision of the Mathematics syllabuses in 1998 saw a significant change to the component Processes in the framework. It now referred to Thinking Skills and Heuristics. At the secondary level, the list of Thinking Skills suggested include: Classifying, Comparing, Identifying Attributes & Components, Sequencing, Induction, Deduction, Generalising, Verifying and Spatial Visualisation. However, there was no change to the list of Heuristics.

To support this change a 30 hour in-service course: Activities to Promote Thinking in the Mathematics Classroom is conducted by the author twice a year for secondary school mathematics teachers. Participants come together once a week for 3 hours to design mathematical tasks that infuse thinking skills and also to share their experiences about tasks they have attempted to use in their classrooms.

The poster presents the outline of the course, tasks designed by the teachers’ and findings of a questionnaire administered to the teachers at the beginning and end of the course.

OPENING THE MATHEMATICAL HORIZON USING OPEN-ENDED TASKS

Hari P. Koirala
Eastern Connecticut State University, USA

Boaler (1998) claims that open-ended tasks and projects help students develop conceptual understanding of mathematics. Zevenbergen (2001) supports Boaler's claim with a caution that if the tasks are too open-ended it might lead to confusion and ambiguity. Because of a huge potential to enhance student learning, I have been using open-ended tasks in my teaching of elementary and secondary school preservice teachers. This poster focuses on how open-ended tasks can convince preservice teachers that mathematical problems can have multiple correct solutions. This is very important for preservice teachers because many of them believe that a mathematical problem has one right answer and there is usually one correct way to solve it.

In this poster I will provide how preservice teachers struggled and eventually learned a great deal from the following problem. It is noteworthy that one of the preservice teachers claimed that there are 32 solutions to this problem, all of which will be provided in this poster in a pictorial format.

**Problem.** Use the 9 digits 1, 2, 3, 4, 5, 6, 7, 8, 9 to fill the nine squares below. Each digit may be used only once to make a true addition statement.

A TEACHING EXPERIMENT ON HOW CHILDREN UNDERSTAND THE MEANING OF ½ FRACTION.

Dimitrios Kontozisis, Maria Kaldrimidou
University of Ioannina

Our purpose of this paper is to describe a teaching experiment conducted in an "early childhood mathematics classroom" about teaching fractional-related concepts. The paper describes the responses of 16 children of four and five years old to a problem requiring the sharing of a square pattern. Data analysis is focused on the material and its properties and on the situations created by experimenting with it in order to enhance children's knowledge about fractions.

Fraction learning is a major obstacle for children. It seems to be a very complicated issue in the teaching and learning mathematics. Despite the wide range of research reports many issues are still to be answered.

While a certain number of researches dealt with the epistemological nature of fractions, most researches focused on the material elaboration and the methods used. Most of these approaches tried to teach fractions either with partitioning of continuous and discrete quantities or with subdivision of sets, length, area and volume (Miller, 1984, Davis et al, 1993). Regarding to early childhood education, there is limited research on children's knowledge about fractions (Hunting and Davis, 1991). The material used in these approaches refers to sharing of discrete and continuous quantities.

In our teaching experiment the task was designed to establish a conceptual field for the ½ fraction. The task, which seemed to be a powerful and challenging activity, is the one we call “Fill in the square”. Four different material sets were used to “Fill in the square”. The uneven material (6 triangles 1 square) using during the episode resulted to be the most effective in generating the notion of the half fraction and the patterns’ equivalence among different shapes of the material.

Results support the conclusion that where some fractional knowledge exists, the use of well-organized and challenging activities can promote and develop children's previous knowledge.

Following the poor results of Austrian high school students in the TIMSS achievement test, a research project was set up in which the results were analysed and additional investigations into the situation of mathematics and science teaching were started. As a consequence, the initiative IMST² – Innovations in Mathematics, Science and Technology Teaching was launched to support teachers’ efforts in raising the quality of learning and teaching in mathematics and science. In the school year 2000-01, 126 Austrian schools participated in total with about one quarter collaborating more intensively with the IMST²-team and documenting one or more innovations.

Four priority programmes – S1: Basic education, S2: School development, S3: Teaching and learning processes and S4: Practice-oriented research – have been established. The four teams support initiatives at schools as well as develop corresponding theoretical concepts. Innovations are the key feature of IMST². They are not regarded as singular events that replace an ineffective practice but as continuous processes that lead to a natural further development of practice. Participation in the initiative is voluntary, teachers and schools have the ownership of their innovations. Writing down the experiences in a systematic way means a second cycle of reflection and opens the opportunity for more people to learn from those experiences. Another important feature of IMST² is the emphasis on supporting teams of teachers from one school.

Evaluation is an integral part of IMST² whereby three different functions have been defined:
- The process-oriented evaluation should generate in a continuous feedback process steering knowledge for the project management and the project teams.
- The outcome-oriented evaluation should work out the impact of the project at different levels of the educational system.
- The knowledge-oriented evaluation should generate new theoretical and practical knowledge which will form a basis for improving support to innovations at schools.

The poster shows the first outcome of the process-oriented and the outcome-oriented evaluation.

DIFFICULTIES ARISE WITH IDEA OF COMPLEMENT
Jana Kratochvilová, Charles University, Prague, Czech Republic

On the basis of experiences from long-term experimental teaching in a primary school and other experiments M. Hejný suggested that further research on the phenomenon of a complement with pupils needed to be carried out. The aim of my poster presentation is:
1. To show several concrete examples where the phenomenon occurs.
2. To outline prepared research.

Illustration of the Idea of Complement
Many areas of mathematics need the idea of the complement to reduce the work involve in the normal arithmetic or measuring circumstance. I list below three such possibilities.

A. Pupils are given Fig. 1 and they have to find the number of triangles. The pupils count it in the following way: 2 x 5 = 10. Then when given Fig. 2 they have to find the number of triangles as well. They count each triangle separately and the black dot is disregarded. Most pupils at 8 years do not discover the idea of complement, that is to find the number of all the triangles and then to subtract the one black dot.

B. Most pupils do not use the idea of complement in the processes of addition and subtraction even though they are aware it. For example the task 14 + 29 using the idea of complement could be solved as 14 + (30 - 1) but pupils usually solve these tasks using decomposition of the second number as in this example 14 + (20 + 9) or even 14 + (20 + 6 + 3).

C. The idea of complement is also present in the finding the area of triangles on squared paper. Pupils getting Figure 3 find the area by a cutting method – two 'half square' triangles give one square and one plus one square gives two squares. However with Figure 4 pupils see that the cutting method does not work and they usually struggle to find a solution. It is difficult for them to discover the idea of complement – the triangle lies in a 2x2 square and when we cut the marked triangle from this square pupils can more easily find the area of remaining parts. They then subtract these from area of the 2x2 square to get the required area of the triangle.

I intend to develop the research which I have already undertaken involving the Abracadabra problem (Polya, 1966). This research did not involve the phenomena of the complement. To be able to research ideas of the complement it will be necessary to reconstruct the research tool so that it is suitable for pupils in the age range 9 to 14 years.

Levels of understanding of letters in the word problem solving processes
Jarmila Novotná, Marie Kubinová, Charles University, Prague

In (Arcavi, 1994) the deep analysis of manipulations with symbols is being discussed: “Even those students who manage to handle algebraic techniques successfully, often fail to see algebra as a tool for understanding, expressing and communicating generalisations, for revealing structure, and...”

In this contribution, we are comparing the levels of dealing with letters during the period of grasping the meaning of the assignment (encoding phase), and the period of mathematisation of the solving process (transformation and calculation phase). The use of letters in students’ written records are analysed and classified in two concrete situations.

**Situation 1 – The assignment does not contain algebraic elements** (Novotná, 1997): The following four stages of the transition from an arithmetical to an algebraic way of using letters in the written record of assigned information were identified:

1a) Solvers use one letter for labelling several values, the letter is a symbol of a general unknown for them.
1b) Solvers use one or more letters in the encoding stage without working with them in the transformation stage, the unknown is only used as a label for something that is to be found.
1c) Solvers consciously use letters for labelling required values and for describing assigned relationships, arithmetical models are more important and thus the arithmetical solution is used.
1d) Solvers use letters for labelling the values and algebraic operations are carried out and solved. The conditions for the successful use of algebraic methods have already been created.

**Situation 2 – The assignment contains algebraic elements** (Novotná – Kubinová, 2001): The following four stages of dealing with the assignment were identified:

2a) Solvers ignore data which are not assigned as concrete numbers, their ability to work with algebraic representations is not developed.
2b) Solvers use letters only as labels for something that is to be found by calculations, the value assigned by a letter is handled as an unknown.
2c) Solvers are aware of the nature of data assigned as letters; by substituting a concrete number a letter, they change the problem into a pure arithmetical one. The symbolic algebraic description of the situation is not yet fixed in their knowledge structure.
2d) Solvers are able to work successfully with data assigned in both arithmetical and algebraic languages.

The correspondence between the two situations will be documented by concrete examples of students’ solutions.

A WEB-BASED MODULE ON FRACTIONS FOR PRE-SERVICE TEACHERS

Amanda le Roux, Hanlie Murray and Alwyn Olivier
University of Stellenbosch, South Africa

This presentation outlines and analyses a web-based module for pre-service elementary teachers on the learning and teaching of fractions. The objectives of the course include developing their mathematical content knowledge, pedagogical content knowledge, and their beliefs about teaching and learning.

The course is structured to elicit optimal reflection. Students work through the course material in their own time (and to a certain extent at their own pace), but are required to attend contact sessions where whole class discussions are held and uncertainties clarified. Students have to submit assignments (which include several group assignments) by e-mail and can participate in on-line discussions throughout the module. Individual feedback to assignments is given electronically.

The content of the course includes reflection on the nature of understanding (Carpenter and Lehrer, 1999), studying research articles describing children's informal knowledge of fractions (Murray, et.al., 1996) and their misconceptions about fractions and the analysis of learning materials and video clips of children working on these materials (MALATI, 2000).

Almost the whole class indicated that they had not previously understood the underlying rationale for the rules for performing the operations with fractions and it only became clear to them during the course. There was a marked improvement in the students' formulation of their ideas which may be an indication of improved understanding. The electronic medium made more communication between lecturer and individual student possible, which lead to an increased awareness of students' misunderstandings.

The Web-based Inquiry Science Environment (WISE) offers software designers a flexibly adaptive learning environment that implements the scaffolded knowledge integration instructional framework (Linn, M. C. and S. Hsi (2000). Computers, Teachers, Peers, Lawrence Erlbaum Associates.), incorporates proven technology features, and supports promising instructional patterns. This presentation describes WISE mathematics projects (see http://wise.berkeley.edu), illustrates WISE data analysis tools, reports results from classroom trials, and discusses how WISE projects might improve mathematics instruction.

By supporting flexibly adaptive design, WISE can empower instructors and curriculum designers to test alternative ideas, analyze weaknesses in instruction, and redesign instructional materials to meet student needs. Teachers can also easily customize WISE projects, adding relevant data – such as water quality information from a local stream – and adjusting mathematics demands – by using qualitative or quantitative tools. WISE offers designers graphing tools, real time data collection options, connections to data collected by PDA and more.

The Scaffolded Knowledge Integration Framework has four main tenets that jointly support knowledge integration (Linn & Hsi, 2000). WISE has developed features such as discussion tools and patterns that combine the features to implement the framework. Research with WISE shows that students learn more when instruction combines making thinking visible using a graphing tool with making predictions, reconciling results with expectations, and testing ideas against established criteria. Figure shows data collection options for an earthquake project:
SEMANTIC TYPES OF NUMBER

G.H. Littler, University of Derby, UK.

The poster will be compartmentalised to contain illustrations of fundamental terms; the table given below; student’s tasks and solutions and didactic applications of the theoretical ideas presented.

The world of numbers emerges from children’s everyday experiences. During the first years at school this world reaches its autonomy, a natural consequence of mental development, very often loosing its linkage to the real world - a cause of low quality future mathematical knowledge in students. This paper classifies different types of anchored numbers, - numbers linked to the real world, using a slightly improved version of the classification defined in Hejný, Stehlíková (1999), as follows:

<table>
<thead>
<tr>
<th>Class</th>
<th>Sub-Class</th>
<th>Examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>Identifier</td>
<td>name</td>
<td>Bus number 15. Telephone number 37. (is observed)</td>
</tr>
<tr>
<td></td>
<td>address</td>
<td>Newton was born 1643. Beethoven’s fifth symphony.</td>
</tr>
<tr>
<td>State</td>
<td></td>
<td>Six apples on the plate. Mary is 152 cm tall.</td>
</tr>
<tr>
<td>Quantity</td>
<td>Comparison</td>
<td>Tom has £5 less than Ed</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Doug is 7 cm taller than Debby</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Michael did 3 times more steps than Karin</td>
</tr>
<tr>
<td></td>
<td></td>
<td>The Rhine is twice as long as the Seine.</td>
</tr>
<tr>
<td>Operator</td>
<td></td>
<td>I put two more apples into the basket.</td>
</tr>
<tr>
<td></td>
<td></td>
<td>She shortened her hair by 10 cm.</td>
</tr>
<tr>
<td></td>
<td>Change</td>
<td>The number of participants was four times those expected</td>
</tr>
<tr>
<td></td>
<td></td>
<td>During the flood, water in this brook increased 90 times.</td>
</tr>
</tbody>
</table>

A - additive; M- Multiplicative.

An anchored number is either an identifier or a quantity.

A number as an identifier is used to denote some object, person, time, location, event, ... If it is part of a structured set like the scale on a thermometer, a seat in a theatre we will call it an address. If there is not a structure to the set, numbers on ice-hockey player’s shirts, bus destination numbers, it is a name.

A number as quantity can be classified from the points of view of its function and of its quality. As a function a number describes either a state – it quantifies some object, situation, event.. or an operator – which is either a comparison, comparing two different states or a change, turning a given state to another. The quality of a number expresses either a magnitude – such as length, weight, pressure, etc. which is measured by means of some unit, or the count of the elements of a set. Boundaries between the classes, sub-classes are not well defined.

Hejny, M., Stehlíková, N. (1999) *Ciselne Predstavy Deti* Charles University, Prague
This paper describes the design process of a computational environment created to explore the development of 5 and 6 year-old children’s understanding of place value, particularly their ability to explain the relations between the units of different sizes (i.e. hundreds, tens and ones) used in written multi-digit numbers.

The goal of the game was to integrate the epistemological principles involved in children’s understanding of place value in order to (1) discriminate their conceptual development, and (2) promote their reflection about the relations between the different units in the multi-digits, in a meaningful way. Children’s conceptual development was explored through the refinement of several number-comparisons categorising the span of relations between different units (“200-300” and “235-245” are examples of different categories), while the use of multimedia promoted their reflection about these categories dynamically.

After a series of game-playing sessions, all participants were able to explain the relations between the different units in multi-digits, and used place value correctly, according to post-task assessments. The analysis of case studies suggests that this computational environment can help to describe individual trajectories of development by opening a window into children’s thinking-in-change, from idiosyncratic ideas to more sophisticated conceptions about place value.

THE CALCULATOR’S ROLE IN PROBLEM SOLVING: A CASE STUDY IN A FOURTH GRADE CLASSROOM

Ema Mamede – University of Minho - Institute of Child Studies

In Portugal, the fundamental aims of mathematics teaching are based on the development of three skills: (a) reasoning; (b) communication; and (c) problem solving (DEB, 1998). The curriculum supports that the solving of problematic numeric or non-numeric situations should be proposed in all teaching topics. This document also refers the calculation methods that should be used in the classroom. Written procedures, mental calculation and the calculator should be present in daily routine classroom. It is important for children of this grade to be able to compute using one of these methods, as well as to be able to decide which means is more suitable for a specific situation (Abrantes, Serrazina & Oliveira, 1999; NCTM, 1991).

However, in the majority of Portuguese elementary schools, there is a certain degree of resistance to the use of calculators, which raises difficulties in its employment in problem solving situations. As a matter of fact, the Portuguese document “Matemática 2001”, which reports diagnostic and recommendations for mathematics teaching and learning, presents some results on the use of calculator in first grades. For instance, almost 74% of the teachers do not use calculators to solve complex problems, 71% do not use it to explore numerical concepts and 63% do not use it to verify results (APM, 1998). It seems that many elementary school teachers ignore how powerful a calculator can be in a problem solving context.

Making an effort to improve this situation, a qualitative case study research was developed in order to understand the role that pupils attribute to calculator as a support tool for computation in a problem solving context. The study was implemented in a ten years old class in Braga, Portugal. In this study the calculator’s use in solving tasks of estimation, numerical investigations and application of mathematics to real life situations was analysed, attending to strategies used and to interactions between pairs.

This presentation intends to show how was developed the research and to present and discuss its results.

Igliori et al. (2000) checked, in a late study, that 5th graders restricted the meanings of the relations *come before than* and *not come after than* in solving problems. For these students, *come before than* meant *come immediately before than* and, in the ordering relation *not come after than* (equivalent to *come before than* or at the same time as), they did not admit *come at the same time as* as an ordering. The authors also checked if it was possible to see an improvement in the knowledge of students subject to a didactic intervention. Bearing in mind that establishing relations is adamant for the learning of mathematics in the various teaching levels, the authors elaborated the present study, which widened the former, based on the following question: Did 5th to 8th graders have the same problems diagnosed in the late research? And if they had, was the evolution of a restricted conception to a broader one different for each grade for the same didactical intervention? To this end, questions about enunciations of the following kind were proposed: *A teacher could not figure out the exact order of her students' arrival. Give the possible orders of arrival according to the statements students gave her:* João said that he came to school before Eni. Eni said that she came before Bia. Rita could not remember the arrival of her mates, but she was sure she came before Eni. The research was conducted among 4 groups of 5th to 8th graders (10 to 14 years old), totalling 64 students, from a school in the state of São Paulo, Brazil. There were students of the same grade in each group taking a pre-test, a class and a post-test dated a week apart, based on Brousseau (1997). These 3 phases were conducted by the same researcher. The pre-test results highlighted no difference in the answers' standard among the grades for all students. They presented the restricted meaning of the investigated relations. This proves that the existent difficulties disregard the grade. Furthermore, a single class could improve the students' knowledge. For all instances, the values for $t_{crit}$ were regarded highly significant. This means that there actually was a statistical shift in the students standard answer in favor of a better comprehension of the broader meaning of the relations under study. This poster will present the pre and post test data organized in tables for each group, including the statistical analysis for discussion and reporting some debates developed in the aforementioned class.

What is between Lafontein's quarter and the rational number quarter? or What is the difference between math justice and jungle justice?

Shoshy Millet, Achva College of Education, Israel
Dorit Patkin, Hakikibutzim College of Education, Israel
Hanna Ezer, Levinsky College of Education, Israel

This study is focused at the positive effect of integration of fables as literary genre for improvement the math language, reduction in the fear of math teaching, increase in the satisfaction and strengthening of the relationship between use of daily language and math language.

Professional literature emphasizes that teaching math along with literacy activities enables teachers to reach a variety of students (Fulwiler & Young 1990; Ackerman 1993).

Also, a study among different populations of math teachers reveals that integration of literacy in teaching may contribute to the understanding of this subject and reducing fear of it (Ezer, Patkin & Millet 1999).

This concept is integrated in the call for strengthening the interdisciplinary connections in different systems including the educational one.

This approach emphasizes that understanding of the subject is achieved by multi-disciplinary systems.

The research is consisted of 60 student teachers for elementary school.

At the beginning of this study 75% of the participants testified that to teach the subject of quarter is considered difficult.

Following learning of the term fraction using the fable of "The Lion and the Hunting" by Lafontein, 90% changed their position and said that they feel more confident in teaching of the term fraction.

The findings indicate that the use of intriguing fables that stimulate the math thinking and lead to an educational lesson promotes the positive approach to teach math and the use of math language.

The knowledge of mathematics that elementary teachers bring to their teaching is recognised as a significant influence on how successfully they teach mathematics (Fennema and Franke, 1992; NRC, 2001) yet this is more complex than simply requiring a grasp of mathematics content (Ball, 1990; Ma, 1999). A number of studies have examined trainee elementary teachers’ knowledge of number, and how this knowledge is related to their teaching competence (for example, Rowland et al, 2000). This study extends this work to examine graduate primary school trainee teachers’ knowledge and understanding of spatial concepts.

The theoretical framework being developed for this study builds on suggestions that Shulman’s (1986) model of teacher knowledge may be too simplistic (see, for instance, Cochran, DeRuiter and King, 1993) and incorporates Ma’s (ibid) notion of “profound understanding of fundamental mathematics” (PUFM). One aim of the study is to determine what form of geometrical knowledge is needed for the effective teaching of spatial concepts.

Data comes from audits of trainee teacher knowledge and confidence together with assessments of their teaching competency. Initial analysis of this data indicates that the trainees’ knowledge of geometry is quite poor, certainly poorer than their knowledge of number or algebra. They appear not to recall some topics, may never have met other (for example, the nets of solids), and are unable to solve relatively simple problems such as calculating the surface area of a triangular prism.

CONCEPTS OF OPERATIONAL SYMMETRY IN THE THINKING OF FOUR ELEMENTARY SCHOOL STUDENTS

Norma Presmeg and Jeff Barrett
Illinois State University

The research described in this poster is part of a 4-year longitudinal study of the thinking of four students who are presently in grades 4 and 5. We describe some of their concepts of symmetry, defined broadly as iteration of patterns, and involving rotation and translation as well as ‘mirror reflection’. Interview tasks with these students included working in 2 and 3 dimensions. Preliminary results suggest that degrees of symmetry (in the sense of “this is more symmetrical than that”) is a natural idea for these students; that moving from the metaphor of folding to point-wise operations in reflective symmetry is a complex but necessary process; that notions of rotational symmetry in two and three dimensions are less well developed but may be fruitfully taught at this age; and that all of these developments facilitate and enhance performance on tessellation tasks.

Our objective is the establishment of a cognitive basis, through literature review and clinical interviewing of students, for investigating how symmetry and pattern recognition may be used as generative processes in the teaching and learning of mathematics at various levels. Here we focus on the notions of symmetry that evolved in the four students as evidenced by data collected in the fall semester of 2001, based on interviews using the following tasks. Preliminary results are reported.

Interview tasks

1. Compare six clay solids and rank them in order of apparent symmetry: a spherical ball; a cylindrical “snake”; a coiled basket made by spiralling a long, thin, cylindrical piece; a rectangular prism; a triangular pyramid; and an irregular lump of clay.

2. Compare pair wise, four large photographs of landscapes. In each of these six comparisons, decide which picture is more symmetrical than the other, giving reasons for your choice.

3. Two-dimensional symmetry:

(a) Given a drawing of a geometrical figure, can you “make the figure symmetrical” (rotation or reflection) and draw the corresponding position of the figure?

(b) Given a drawing of a parallelogram, with a diagonal drawn, or a line through midpoints of opposite sides, explain with reasons why this is a line of symmetry, or why it is not.

4. Three-dimensional visualization task: Can you take a two-dimensional region and rotate it about an axis to generate a solid of revolution by prediction?
WHAT DO FUTURE MATHEMATICS TEACHERS EVALUATING AN IMPLICATION WHEN FACING THE CASE OF PREMISE FALSENESS?

Marc Rogalski, Janine Rogalski
AGAT Lille1-CNRS & IMJ Paris6-CNRS

Laboratoire Cognition & Activités Finalisées Université Paris8-CNRS

We propose a poster linked to a Short Oral communication by J. Rogalski and M. Rogalski, organised around the main results of a study about how future mathematical teachers deal with different types of implications, when confronted to the falseness of the premise. Such situations not only appear in advanced mathematical thinking but also when teachers are confronted to students’ reasoning: their control is part of the competence of a mathematics teacher in secondary and high school. It will present:

• 1. **examples of the variety of items:** factual non computable implications with a false premise; assessment of a formal rule (two versions of the “classical” selection task of Wason); implication with a false premise in a social contract (“if somebody solves the problem, I will give sweets to everybody”) computable mathematical implications: hypothesis always clearly false (such as: “if 1=2 then 2=3”); hypothesis unknown: the implication may be proved without looking at the value of the premise (which will be proved to be always false); the case of the falseness of the hypothesis has to be considered in a twofold quantified implication (such as: “for every x and for every m, if \( x^2 - 2mx + 2m + 3 \leq 0 \) then \( |x| \leq (m-1)^2 - 4 \));

• 2. **examples of typical students answers** oriented toward “logic” (expected correct answer), “relevance” of the implication, or “falseness” due to the false premise;

• 3. **results** of a test proposed to 71 future mathematics teachers, aiming at: a) testing the generality of results of a previous study with 107 other teacher-students (Rogalski & Rogalski, 2001); b) evaluating the effect of changes in wordings (introducing the canonical form “if ... then...” in some critical items); c) identifying factors involved in the management of the falseness of the premise in mathematical implications (proposition vs predicate, premise always false vs falseness for some values).

• 4. **discussion of the global results:** the rationality of future mathematics teachers in their use of implication appears not to be resilient to atypical situations, interactions with a somehow difficult mathematical content, or unusual students’ arguments. Consequences for their use of logic as an indispensable tool in teaching mathematics (Hanna & Jahnke, 1993) will be discussed.

THE STRUCTURE OF MATHEMATICAL ABILITIES

Valery A. Gusev, Ildar S. Safuanov,
Moscow Pedagogical State University, Pedagogical Institute of Naberezhnye Chelny

We present a systematization of all components of mathematical abilities based on previous research in the area. Consider one of possible classifications of components of mathematical abilities of pupils.

Block 1. Components of mathematical abilities, influencing the development of general abilities of pupil.

1.1. Components of mathematical abilities describing inherent qualities of the person and singularities of mental activity.

1.1.1. Qualities of the person: strong-willed activity and capacity of working hard; persistence in reaching the purpose; good memory; arbitrary control of attention; introversion; intellectual inquisitiveness.

1.1.2. Qualities of mental activity; skill of abstract thinking; economy of thought; exactness, conciseness, clearness of verbal expression of a thought; quickness; ability of analyzing.

1.2. Components of mathematical abilities helping to raise the effectiveness of any educational activity of pupils.

1.2.1. Possession of basic means of educational activity: habit of working regularly; skill of schematizing; ability of independent extracting knowledge; skill of making conclusions.

1.2.2. Possession of means of research and creative educational activity; the art of consistent and correctly partitioned logical reasoning; skill of raising new problems; skill of comparing conclusions.

Block 2. Components of mathematical abilities, ensuring effective mathematical activity.

2.1. Components describing mathematical activity of the pupils.

2.2. Components describing “mathematical style” of thinking: flexibility of mental process; a reversibility of mental process during mathematical reasoning; economy of thought, strictness of a thought and its expression; clearness, simplicity and beauty of solutions.

2.3 Components describing qualities of the person of pupils as mathematicians: Inclination to discovering the logical and mathematical sense in all phenomena of the reality; a habit to rigorous logical argumentation; speed of mastering of an educational material; geometric imagination or “geometric intuition”; possession of sufficient patience in mathematical problem solving; mathematical memory.
From the beginning of 2002, shops have displayed prices in euros. Eleven EU countries have adopted the Euro. It has become a reality within our society, at the market, at the bank and even at school. A fact we cannot avoid.

We take for granted the measures adults take to deal with the new currency such as new pocket calculators, little mathematical tricks, government information, etc. But how do first and second year children acquire the necessary skills to cope with the Euro? How can a child who can barely count up to 1000, add and subtract deal with such abstract concepts like the correlation between money, value and price?

Our project has been carried out by first and second graders (7 and 8 year olds). They had to discover for themselves and get to grips with the new currency as the rest of society. Our goal has been to introduce the Euro in our school bringing to the students the reality from outside. The students built a “Euro Shop”. They brought in real product packages and worked out prices. At first, we did not have any prices.

The students were free to invent, create and imagine. The starting price for a single milk carton was over 1000 euros. Within a couple of weeks the prices had come down drastically. The teachers were observing without interfering. Everyday interest and the role play brought new values for the money and the products. The milk carton went from 1000 euros to 500 euros, to 10 euros and finally to 50 cents. No direct teaching was involved.

Our project development showed us how the very young ones learn by themselves how to deal with unknown and new quantities (for example decimal numbers). The quantities where related to blocks of units, tens and hundreds. The decimals where treated as another part of the value. Our big standard was: 1 EURO = 100 CENTS. They did not need anything else. No explanations.

Our presentation shows some results from our students and shares the excitement of a very new Europe-wide-project. At the same time, we wanted to prove once more that mathematical thinking can be turned into a simple game, an everyday situation or a challenging test.
NEW WAYS OF DEVELOPING MATHEMATICAL ABILITIES
Mihaela Singer, Institute for Educational Sciences, Romania

From informational islands to structured knowledge

According to the traditional philosophy of learning, which is still very strong everywhere in the world, information represent the essential in mathematics teaching, the mathematical thinking being just a mechanical consequence of their assimilation. The results of this philosophy are expressed in the present-day fact: the average student’s failure to learn mathematics. This average student possesses, at best, just “informational islands”. Researches carried out on secondary-school students reveal major flaws exactly on the level of mathematical thinking; but these flaws have their roots precisely at the beginning of the informational stairway, that is as early as the first grade. The teaching that is focused on developing mental capacities implies an extremely structured knowledge organization.

From problem solving to learning the generators

It is equally important to teach the child how to solve a problem and how to communicate the problem’s solution, i.e. how to present a series of items of reasoning or operations accepted by consensus as explaining the way to get to the result. This consensus represents the accumulation of an historical experience, so it is a cultural acquisition. Therefore, how numerous must the problems be in order to ensure learning? How should these problems be dosed in a textbook so that understanding might occur without an exaggerated effort? To make learning more effective, it is necessary to have an inventory of generative situations and to offer children as many opportunities as possible in order to have them interfere with various learning specific environments. Generator, in this context, means that on its basis, by combination, substitution, by enlarging-narrowing the domain, by varying the actions, changing the topic, etc., a great variety of problems can be created. Generators learning as opposed to problem solving has the advantage that it structures the understanding of the mathematical phenomena hidden behind particular statements. If, together with the ability to solve problems, the student gets the ability to understand and use the generators of a class of problems, then the child’s cognitive acquisition is definitely superior and it refers to the arising of an over-learning phenomenon.

From “drill and practice” to “practice and structure”

Understanding word problems is closely connected with analyzing and transforming the problems. The child is stimulated to create word problems using various starting points. The technique is practiced loudly, silently, in written form, maintaining the interest in exercising as many capacities as possible and stressing the passage from one type of activity to another. There is also a systematic training of becoming aware of errors. The teacher “hides” some errors in exercises or problems, in series of numbers, in comparisons, etc. These errors are analyzed with the purpose to eliminate the pupils’ typical errors, as well as to improve the analysis ability. Estimations and approximations are also systematically taken into consideration. The objective is focused on understanding the significance of numbers size and on checking the computing validity. Finally, two tasks are left to be solved: raising the internalized structure to the level of formal representations and transforming the internalized structure into a dynamic one.
The aim of this poster is to present a new methodological tool for analyzing the Who and Mathematics (WM) -instrument developed by Forgasz (2001) and Leder (2001) and to get an integrated view about mathematics as a gendered domain. Our methodological contribution is based on diagrammatic model inspired by Donald Wolfe (1959), who investigated family authority structure. The data used for this methodological development was gathered from two Finnish schools. The total number of 7th grade students was 508.

The gendered domain is divided into two dimensions. The x-axis represents the gender-free values (GF). The GF -score is determined by the number of items which are answered „no difference between boys and girls“. The possible maximum score on this dimension is 30. It would indicate that mathematics is completely gender neutral domain to the student. The y-axis represents the male - female -dimension (MF), with female dominant in the top and male dominant at the bottom. The MF-score is based on the sum of the numerical codes across the 30 items in the instrument and it ranges from 30 to 150.

Figure shows the diagrammatic model of the theoretical distribution on genderness on these dimensions. The dotted line divides the genderness into four types. Domain A can be seen as neutral domain. Domain B represents female and domain C male domain. Domain D can be seen as a indifferent domain – some aspects of mathematics are seen more female or more male. With help of this model we can consider, how genderness is divided in our sample on the whole. We can make diagrams on various groups. We believe, this model gives a promising tool to compare international samples, too.

REMEDYING SECONDARY SCHOOL STUDENTS' ILLUSION OF LINEARITY: A DEVELOPMENTAL RESEARCH

Wim Van Dooren¹,², Dirk De Bock²,³, An Hessels², Dirk Janssens² and Lieven Verschaffel²

¹Research Assistant of the Fund for Scientific Research – Flanders (F.W.O.)
²University of Leuven and ³EHSAL, Brussels; Belgium

A series of ascertaining studies by De Bock, Van Dooren, Verschaffel and Janssens (2001) has shown a strong and irresistible tendency among secondary school pupils to overgeneralise the linear (or proportional) model when working on applied geometrical problems about the lengths and the area/volume of similar geometrical shapes. These studies have shown that even with considerable support (such as self-made and ready-made drawings or metacognitive stimuli calling students’ attention to the problematic character of the word problems), only very few students appeared to make the shift to the correct non-proportional reasoning. Moreover, a lot of information was obtained on the actual process of problem solving: although some students seem to really ‘believe’ that quantities are always linked proportionally, their improper use of linearity often results from superficial and intuitive reasoning, influenced by specific mathematical conceptions, habits and beliefs leading to a deficient modelling process. Altogether, these studies yielded valuable building blocks for the final stage of our research program, namely the design, implementation and evaluation of a powerful learning environment aimed at overcoming the illusion of linearity by developing in students a deep conceptual understanding of proportional reasoning including the disposition to distinguish between situations that can and cannot be modelled linearly.

This poster illustrates the major design principles of the learning environment by means of a sample of the instructional materials that were constructed in this developmental research. The learning environment is interspersed with various realistic problem situations, both linear and non-linear ones, which typically challenge students’ mathematical (mis)conceptions, socio-mathematical norms and habits leading to stereotyped modelling. The relevant mathematical concepts and insights are explored and clarified from a variety of perspectives (using verbal, numerical, graphical, algebraic, and pictorial representations) serving as different lenses through which students can interpret these problems and their solutions. Finally, the learning environment relies on a combination of instructional techniques that have proven to be successful in enhancing students’ deep understanding and higher-order thinking skills, such as coaching, scaffolding, articulation and reflection.

During the development of a Mathematics’ lesson, specially in those which geometry is the main topic, pupils bring interest in some subjects. When this situation happens, teachers take decisions about how to explain some contents. These decisions grow up during the class and need solutions, which have been generated at the same place. When this appears, the textbook shows as an instructional resources, which suggests to the teacher different ways of class engineering. What pupils learn about geometry is conditioned by the contents of the lesson which appear in the textbook because itself brings us the most important geometrical acknowledgement to be studied during the school class. Although, teachers and pupils find a lot of different activities in the textbooks. Due to this, we propose an “Analysis Form of Textbooks”. This form is based on four dimensions or categories showed in this tetrahedral:

These categories bring information about:

The way by which the author of the textbook presents his production to the pupils (structural dimension); What is mathematics and which is its epistemological frame (epistemological dimension); The author’ thinking about mathematics and its didactics (didactical dimension); The mathematics’ concepts and its relations which a semiotic frame (semiotic dimension).

HIGH SCHOOL STUDENTS' IDENTIFICATION OF EQUAL SLOPE AND Y-INTERCEPT IN DIFFERENT STRAIGHT LINES

CLAUDIA ACUÑA
cacuna@mail.cinvestav.mx

CENTRO DE INVESTIGACIÓN Y DE ESTUDIOS AVANZADOS
IPN-MÉXICO

Abstract
In this study I use a semiotic perspective to analyze with three student samples from different schools identification tasks of equal slope and y-intercept in different straight lines. Some of the students strategies take into account a visual conception that lies upon Duval’s vision concept (Duval, 1999). When using these strategies, the students set aside the previously known slope and y-intercept definitions and the graphical aspect of the line, and limit themselves to the use of the coordinate axes as a visual reference, serving as an anchorage for the visual orientation for the identification of the line.

Resumen
En el presente estudio utilizo una perspectiva semiótica para analizar el trabajo de identificación de la ordenada al origen y la pendiente de tres muestras de estudiantes provenientes de diferentes escuelas. Algunas de las estrategias usadas por los estudiantes tomaron en cuenta una concepción visual que se ajusta al concepto de visión de Duval (1999). Al utilizar tales estrategias, los estudiantes hacen a un lado sus conocimientos previos sobre las definiciones de ordenada al origen y pendiente de una recta y su aspecto gráfico, y se limitan al uso de los ejes de coordenadas como referencia que sirve como anclaje de la orientación visual para la identificación de la recta.

Introduction
I want to mention two remarkable misconceptions about the understanding of the straight line. The first one was mentioned by Janvier (1978), quoted by Leinhart, et al, (1990). According to Leinhart et al, Janvier says that between the findings about the construction and interpretation of a straight line are those about slope/height confusion: "students have been found to confound these two graphical features on both interpretation and construction tasks" (op. cit. 1990, p. 37). "No consensus exists regarding the cause for such errors ... A common interpretation is that students are
confusing two graphical features: highest value versus slope” (op. cit., p. 39).

The second one is mentioned by Schoenfeld, Smith and Arcavi (1993). In their fine-grain analysis, they found in an interviewed subject that she had separate ideas about slope and y-intercept notions. This was evident when she had to develop construction and interpretation tasks. In their study they say that she knows that \( m = \frac{y_2 - y_1}{x_2 - x_1} \), but this knowledge is nominal and although it is used to compute the line slope, this computation has no graphical entailments, and although she knows that \( b \) is the y-intercept, her understanding is nominal too and it is not tied to the underlying structure. The authors think that this is caused by the absence of what they call the Cartesian Connection, that is, “a point is on the graph of the line \( L \) if and only if its coordinate satisfy the equation of \( L \)” (Moschkovich, Schoenfeld and Arcavi, 1993, p. 73).

In regard to the above “misconceptions”, I rather prefer the term “alternative students’ conceptions”. These conceptions appear when students interpret or read the graph. For Mavarech and Kramarsky (1997, p. 229) interpret or read the graph means the “students’ ability to read a graph (or a portion thereof) and make sense or gain meaning (of) it ”.

In the first “misconception” it is necessary to compare the slope and height graph; and in the second one, in order to make the Cartesian Connection, the student needs to translate between two different representations, one algebraic and other graphic.

In my research I used a questionnaire with items that require the only visual strategies. Unlike the results mentioned above, my work lies upon the visual aspects of the straight line, and the elements that take place in the treatment are the semiotic signs, their meanings, and their relations.

But, what is a graph? And what do we have to see in it so as to read it? From Bertin’s (1968) perspective the visual perception (in graphs) consists of the perception of three factors: the variation of shadows and the two dimensions on the plane, regardless of the time variable.

In a similar way, Duval (1995, p. 142) claims that “a figure is an organization of sharp contrast of the brightness. It emerges from a background through the presence of ‘traces’ or ‘spots’, governed by Gestalt laws and perceptual clues”.

The visual information in the graph, must be an important part of the graph comprehension. Some researchers, like Friel, Curcio and Bright (2001, p. 132), claim that “by graph comprehension we mean graph readers’ abilities to derive meaning from graphs created by others or by
themselves”, but they do not explicitly consider, in their graph structure comprehension, the importance of the meaning of sign. They missed the consideration of the semiotic meaning of the graph.

From Duval’s point of view, the function of a graphical representation lies upon two figures: the ground-figure (axes, grid and orientation) and the form-figure (the graph). This relation is completely defined by this representation forming gestalt rule (Duval 1996, 2001).

From his interpretation I take the idea of representational units (Duval, 1999), as well as the gestalt relation, and I consider two of the three units: the slope and y-intercept. I am not considering the third unit, the angle with the x-axis, because it is not included in the high school math curriculum.

In my early observations of this kind of tasks that require visual interpretation, I have found that the students use some specific visual strategies. In this research, they used two different strategies to identify whether the slope and the y-interception of straight lines are the same or not, without taking into account the geometric or algebraic definition. These strategies are:

S1. The student can make a visual movement, in general translation or rotation, from one line to another. They can make a parallel translation in the case of the straight line position, they move the approximate measure of the angle related shape slope or of the position of the y-intercept respect to the horizontal axis.

S2. The student can take into account some real or imaginary tokens, or apparent relation, to help the orientation of the graphic elements, for example the quadrants that the path of the straight line observed and that make sense to the line position.

I observed that both strategies are neutral, this means that you can use them either with right or wrong results, in this way it is useful to mention Duval’s idea (op.cit, p. 12) about vision and visualization concepts: vision refers to a visual perception, it gives direct access to the physical object; it consists of a simultaneous apprehension of several objects or a whole field. Visualization is based on the production of a semiotic representation. A semiotic representation shows relations between two representational units.

In my work I found that students used the mentioned visual strategies, regardless the algebraic or proportional definitions, to do some identification tasks. They used a vision oriented conception. This conception has a strong reference on the interpretation of the axes like an anchorage (Mesquita and Padilla, 1990).

Methodology
In this work I used a questionnaire answered by high school students in the 3thd. semester (17 years old). I worked with three samples of students (A,41; B,23 y C,35) in three different schools located in two industrial cities. The intention was that the samples were different only in their location because I wanted to see if this factor affected the answers.

Previous to my study, the students had some knowledge about straight line, namely, its point by point graph construction from a known equation, a slope definition coming from algebraic and proportional issues. They had some skill in calculating straight line slopes and y-intercepts. They knew that between two points only on straight line can pass and they calculated slope and y-interception from visual information on a graph.

In my questionnaire I asked for the construction of different straight lines with different slopes and y-intercepts. I requested some explanation about possible changes in the construction in order to make two different lines equal. The students also needed to identify equal straight lines among different lines. In general, the students did well. Most of them showed that they can easily recognize the visual shape of slope and y-intercept.

But, in some items, I found two kinds of answers that caught my attention. In this paper I will report one of them. This result seem to show that under specific situations the student quit the definition and limits herself to consider exclusively the shape. This kind of answer were detected in two groups of exercises in which the students have to identify slope and y-intercept among several options; before they answered the questionnaire, I gave to the students a definition of slope and y-interception because I did not want this to become an obstacle in their performance. The referred items are supported on visual information only, and the indications were posed in natural language.

In this qualitative research I expect to give an approximate answer to the following questions: Can the student make a consistent visual identification of same line with the slope and y-interception among different straight lines?, to what kind of signs do the students pay attention to find the difference?

**Question Analysis and Results**

My observation is based in the following two groups of questions. The student have to choose among different graphs using visual criterions posed in natural language. In the table we have written the frequency of incidence of right answers and the some of most frequent wrong answers, in order to compare the results.

The first group of exercises (belonging to Item 9 of the questionnaire) follows:
9. For each graph on the left, mark with an X the graph on the right that has the same slope. The slope is the slant that the straight line has with the horizontal axis.

Frequencies of right answers of the samples A, B and C for item 9.

In Item 9(a) it seems that the term “same slope” is associated to “same angle” between the straight line and the x-axis, but in doing the identification they consider an non-oriented angle. In this case they followed strategy S2 and the tokens used are, in one hand, the x-axis and the “opening” that it forms with the line, both tokens are part of the global aspect of the graph. And in the other, there is the point (0,0) that appears as y-intercept on both lines.

In this case, their use of S2 is oriented by the vision that refers to a visual perception, and it gives access to the physical object and give us the simultaneous apprehension of several objects or a whole field (Duval, 1999). Students focus their attention on the x-axis and the point (0,0), and these tokens are considered like an anchorage (Mesquita and Padilla 1990). Their solution does not have a semiotic treatment, that is, a treatment in which the semiotic representations show their relations between representational units, the gestalt relation is missing.

The other group of exercises (belonging to Item 10) are:

10. For each graph on the left, mark with an X the graph on the right that have equal y-intercept. The y-intercept is the point where the line crosses the y-axis (see diagram on the next page).

In this exercise the students’ identification is more or less successfully in 10(a) and 10(c) (A, 85% and 68%; B, 78% and 73%; C 80% and 77%
respectively) nevertheless, the situation in 10(b) is quite different, this is shown in the frequencies graph that follows (see next page). The wrong answers are supported by a consideration of the global shape of the graph, oriented by the vision, instead of a visualization. It seems that a oblique line has nothing to do with a horizontal one.

Frequencies of both groups of exercises

**Discussion**

The present research lies only on the visual treatment of a straight line graph, for this reason the students’ conceptions, evident from wrong answers, are different from those that have a functional treatment like in Janvier (1978) and Schoenfeld et al (1993); the visual application of the conceptions are different too.

The students’ difficulties can appear even in the visual situations when we ask the students to make graphs without explaining nor working the gestalt relations, that is, the relation between form-figure and ground-
figure, or how we can plot graphs considering the spatial relation ruled by the axes, the grid and the orientation.

In my opinion this students' conceptions where the strategies S1 and S2 take place, were hidden because the visual treatment was not sufficiently considered in the school curricula.

The identification tasks about y-intercept and slope are quite far to be simple applications of a definition, the results suggest that the students can make almost always a consistent visual identification but the wrong answers in items 9(a) and 10(b) suggest that in tasks with a strong situational component, this visual identification fails, so there is evidence that students are not entirely consistent in making visual identifications in the case of y-intercept and slope.

The answers permit us to know some students' conceptions about y-intercept and slope. In fact, our students pay attention to the marks on the axes, and the axes themselves are used as important visual tokens, but in some critical situations this mechanism do not work adequately because the election is arbitrary. In these cases, the axes function like a strong anchorage in the general shape of the graph.

Finally, the students used their own "gestalt" relation that took place on the visual identification despite the previous training or definitions about slope or y-intercept, and they make their own interpretations in cases in which there was not an intentional intervention of the teacher, this interpretations are supported by their own ideas.

A developmental scale for assessing probabilistic thinking and the tendency to use a representativeness heuristic

Thekla Afantiti Lamprianou and Julian Williams
University of Manchester

We report a study of children’s probability conceptions and misconceptions due to the representativeness heuristic. Rasch measurement methodology was used to develop a 13-item open response instrument with a sample (N=116) of 12-15 year olds. A hierarchy of responses at two levels is confirmed for this sample, and a third level is hypothesised. Each level is characterised by the ability to overcome typical ‘representativeness’ effects, namely ‘recency’, 'random-similarity' (at level 1), 'base-rate frequency' and 'sample size' (at level 2-3). Our interpretations were validated and anomalies identified through clinical interviews with children making the errors (n= 8), suggesting another measure, which we named the ‘representativeness tendency’ from 11 multiple-choice errors.

Introduction

This study builds on previous work on children’s understandings, intuitions, use of heuristics and misconceptions in their probabilistic thinking (Fischbein, 1975, 1997; Kapadia & Borovcnik, 1991; Shaughnessy, 1992) and especially the significance of the representativeness heuristic (Green, 1982; Kahneman, Slovic & Tversky, 1982; Amir & Williams, 1999; Amir et al, 1999). The misconceptions based on the representativeness heuristic are some of the most common errors in probability: children tend to estimate the likelihood of an event by taking into account how well it represents its parent population and how it appears to have been generated.

In this study we aim to contribute to teaching by developing an assessment tool which can help teachers diagnose inappropriate use of the representativeness heuristic in responses to questions relevant to the probability curriculum. Williams and Ryan (2000) argue that research knowledge about students’ misconceptions and learning generally needs to be located within the curriculum and associated with relevant teaching strategies if it is to be made useful for teachers. This involves a significant transformation and development of research knowledge into pedagogical content knowledge (Shulman, 1987), which requires its own study. The development of the assessment instrument involved tuning of, or development of diagnostic items from the research literature: thus the instrument provides a ‘boundary object’ between the research practice and innovative practice of assessment for teaching and learning.

Thirteen items were used to construct the instrument (the instrument can be seen in full on the web at http://www.education.man.ac.uk/lta/tal). The items identify four effects of the representativeness heuristic; the recency effect, the random-similarity
effect, the base-rate frequency effect and the sample size effect. Most of the items have been adopted with slight modifications of those used in previous research by Green (1982), Kahneman, Slovic & Tversky (1982), Konold et al (1993), Batanero, Serrano & Garfield (1996), Fischbein & Schnarch (1997) and Amir, Linchevski & Shefet (1999). Other items were developed based on findings of previous research.

Items called recency1, 2 and 3 tested for the negative recency effect and the gambler’s fallacy. According to this effect, a long sequence of one outcome must be followed by the other outcome in order to equilibrate the proportions. Items called random-similarity 4, 5, 6 and 8 tested for the effect which expects a sample to appear similar in proportion to the parent population and apparently randomly-generated. These items were developed from Kanheman, Slovic & Tversky (1982), Fischbein & Schnarch (1997), Green (1982) and Shaughnessy (1992), respectively.

Items called base-rate 10, 11 and 12 were written to examine the effect of prior probability or the base-rate frequency of the outcomes in contexts appropriate to this age group. According to this effect, prior probabilities are effectively ignored when misleading irrelevant but stereotypical information is introduced. As Kahneman, Slovic and Tversky (1982, p.5) mentioned, “when no specific evidence is given, prior probabilities are properly utilised; when worthless evidence is given, prior probabilities are ignored”. Finally, items called sample size 7, 9, 13 tested for the tendency to neglect sample size in estimating probability: the first from Fischbein & Schnarch (1997), the second from Shaughnessy (1992), the last ours. These items examined the belief that the probability of a certain proportion in a sample is independent of the sample size, contradicting the central limit theorem, i.e. the probability of getting a certain empirical result tends to approach the theoretical prediction as the sample gets larger.

Method

In order to be able to administer more items to the same sample of pupils two separate test-forms with common linking items were constructed. Test A, designed to be easier, consisted of eight items - items 1 to 6, 9, 10 - and Test B, intended to be more difficult, consisted of ten items - items 3, 4, 6 to 13. Five of the items were included in both tests. Test A was administered to pupils in Year 7 and Test B was administered to pupils in Year 8 and 9.

The tests were administered to 116 pupils from two schools in the North West of the United Kingdom. Before administering the tests to the pupils, the teachers of the six classes were asked to read and comment on the suitability of the tests for their classes. They found the wording of the items acceptable for the pupils’ age, but they commented on the degree of difficulty of question 13 (sample size 13).
For the analysis of the results of the tests, a Rasch common calibration was used. Since all items had both a multiple-choice and an open-ended question, a common item Partial Credit analysis (Wright and Matsers, 1982) was run. One mark was given for the correct multiple-choice answer and another one for the correct explanation of the open-ended question for each of the 13 items. The result is a single scale consisting of a 'difficulty' estimate for each scored point and an ‘ability’ estimate for each child consistent with the Rasch measurement assumptions. Item 13 fell outside a model infit statistic value of 1.3 (see Wright & Stone, 1979) reflecting the difficulty of this item for the sample. The term ‘ability’ is defined by the performance of the pupil in this particular test, which we consider to imply an ability to avoid inappropriate representativeness effects, and so a particular ability with probabilities: it is NOT a measure of general ability, or even of mathematical ability. We will use the term ability italicised in this way throughout this paper.

In addition to the test analyses, we drew on structured clinical interviews with 8 children about the test items to gain insight into the cause of the effects described above, to confirm the literature, validate the items and identify anomalies.

Results

According to the table below, the test and sample can be interpreted as falling into a hierarchy of three levels. At level 1, (-3.0 to -0.5 logits) children can succeed on questions that tested for the recency effect and easy questions that examined the base-rate frequency and the random-similarity effect. At level 2 (-0.5 to 2 logits) children attain higher performance and they can explain their answers to the easier questions that tested for the random-similarity effect, they can manage harder base-rate and random-similarity questions and they are beginning to answer some sample size questions correctly. Very few children manage to attain level 3 by answering the hardest questions on sample size or explaining their answers to the harder questions that tested for the random-similarity effect. In order to establish level 3, it is suggested that a more able sample would be required.

By averaging the ability estimates of those children who made an error, we are able to plot errors on the same logit scale in the table. Pupils who gave responses indicating the recency misconceptions had a rather low ability. Answers indicating misconceptions based on the random-similarity effect were given by a broader range of ability pupils (averages ranged from -1.95 to -1.25 logits). On the other hand, the mean ability of the pupils who gave responses based on the sample size and base-rate effect was near the average ability of the sample, reflecting the fact that these errors were made by so many children (36%, 49%, 73%, 78% and 86% !!).
This encouraged us to consider building a ‘representativeness tendency’ measure from those errors which we can authentically attribute to this heuristic, as a diagnostic measure of tendency to inappropriately apply this heuristic. The main purpose of the pupil interviews was validation of the test, in particular our interpretation that the errors in the test are symptomatic of the representativeness effects discussed in the literature. In this section we illustrate with the interviews of children the random-similarity effect, which was examined by random-similarity 4, 5, 6 and 8. For example, random-similarity 4 is illustrated below:

**Random-Similarity 4:** A fair coin is tossed five times. Which of the following sequence of outcomes is the most likely result of five flips of the fair coin? (H: Heads, T: Tails)
(a) HHHTT (b) THHTH (c) THTTT (d) HTHTH (e) All four sequences are equally likely. (Explain why).

**Child10:** … I’ll probably pick (b), because it’s a mixture of answers.
Teacher: (b), because it’s a mixture of answers and -
Child10: Because it is more realistic, because it’s been a good ... em mixed. ... 
Teacher: OK. But we have the same here in answer (d). There are three Heads and two Tails. Why did you choose that answer?
Child10: Because it’s a bit more...em... because that’s a Head, Tails, Head, Tails, Head, Tails and I think... I don’t think it will be ... to get that most times ...

When this child was asked to solve a similar problem (random-similarity 5), his choice of frequency was representative to its parent population (it consisted of equal number of boys and girls) and it appeared to be a random mixture of boys and girls:

Random-Similarity 5: In a family of six children which sequence of births is the most likely? (B: Boy, G: Girl) (a) BBBGGG (b) BGBGBG (c) GBBGBG (d) GBGGBG (e) All four sequences are equally likely. (Explain why)

Child10: I’ll probably think (c).
Teacher: Why?
Child10: Because you would more likely to em... pick that one because it’s more mixture, but sometimes with different people they have all boys or just all girls. But some people have a mixture.

However, some items proved problematic. Random-similarity 6 and 8 (the multiple-choice answers were classes of sequences, i.e. 6 Heads and 6 Tails) were developed from an item from Green, in which, as Amir, Linchevski & Shefet found, the majority of the pupils chose a different incorrect answer to the expected random-similarity. This was based on the conceptual error which reflected children’s failure to discriminate between sequences and classes of sequences (combinations), between ordered sets and unordered sets in probability. An example from the interviews:

Teacher: ... So. Why did you answer (e) “All have the same chance”?
Child61: Because they are all likely. You can’t guess what ... which one will be it. But they all have the same chance, because it’s half. ... 

Teacher: OK. ... (Child62 writes WWWGGG) ... Is there any other sequence for three white and three grey?
Child62: No.

We therefore came to the conclusion this misconception was distracting from the random-similarity effect, which was only given by 6% of children in random-similarity 6. Indeed this fell to 0% for random-similarity 8, which suffered similarly. Worse still, children chose the correct option but for the wrong reason, arguing from a representativeness perspective, that ‘6 Heads and 6 Tails’ would be most likely, because:
C33: Because, em, there's two sides on the coin and you get, em... even chances of getting six heads and six tails, because if you divide by two... added to two sides of the coin there's six on each, like heads and tails.

This also explains why so few children could give a correct explanation for their answers to these items. We suggest these items may need therefore to be deleted, redesigned or developed and re-scored.

*Base-rate 10* might also be discarded when using the test diagnostically for this age group. Almost all pupils answered this question correctly. In addition, all eight interviewees gave the correct answer and justified their responses correctly. From the answers that children gave, it seemed that the irrelevant information did not distract any of the children and they did not ignore the prior probability. This item seemed as if it had no diagnostic value. Analysis of *base-rate 11 and 12*, however, suggested that the more the distracting description is related to a stereotype, the stronger the *base-rate* effect is.

### Construction of a representativeness measure

Since the purpose of the diagnostic instrument was to assess whether the representativeness heuristic influenced children's thinking when solving probability problems, a second Rasch model analysis was run. One mark was given only for the multiple-choice answer that indicated the effect of the representativeness heuristic but no marks were given for any other responses. The result was a single scale of items (none of the mark points fell outside a model infit value of 1.3), indicating that the *sample size* effect and the *base-rate* effect were very frequent among the pupils. The random-similarity and the recency effect influenced a small number of pupils of this sample (see graph below). *Random-similarity 8* and *base-rate 10* were removed from the Rasch analysis because all pupils gave different responses to the expected representativeness effects.

The result is a measure of 'representativeness tendency' for each person, and this naturally correlates negatively with their *ability* as measured previously (rho=-0.64). However, the outliers are interesting: these represent three children who either found ways of scoring relatively well despite their tendency to use the representativeness heuristic, and vice versa. These might be the focus of further case study.

Children higher up the scale are more likely to make representative-effect related errors, and items higher up the scale are less commonly occurring, i.e. only made by those with a strong 'representativeness tendency'. Note that these fall into the two levels of questions identified previously in the table, with *recency* and *random-similarity* effects generally occurring at level 1 and *base-rate frequency* and *sample size* effects at level 2.
Conclusions and discussion

We have managed to develop two scales measuring children’s responses to the instrument which is revealing about their probabilistic knowledge, especially as regards their inappropriate use of a representativeness heuristic in responding to test questions which are relevant to their curriculum. We have further identified some previously unknown interpretations of children’s responses.

While most of the particular items in the scale are not new, the development, validation and calibration of the measures around this heuristic for 12-15 year old children is. We expect these to be useful research tools, but also to impact on teaching practice and teacher education, as discussed in Williams & Ryan (2001).

Having collected responses of some teachers to the instrument, we are doubtful that teachers are aware of these common misconceptions or of the significance of the representativeness heuristic, and we suggest that many teachers might benefit from using such an instrument in their assessment and teaching. The knowledge that teachers would collect from these scales, might enrich teachers’ mental models of their learners and help them improve their classroom practice. We will be studying this aspect in the next stage of the work.

PURPOSE AND UTILITY IN PEDAGOGIC TASK DESIGN

Janet Ainley & Dave Pratt

Mathematics Education Research Centre, University of Warwick, UK

In England and Wales, the introduction of a National Numeracy Framework for the teaching of mathematics from ages 4 to 13 has placed a very strong emphasis on teachers’ planning of objectives. By looking retrospectively at the design of computer-based tasks that have underpinned our research for many years, we recognise a theme of purposeful activity, leading to a planned appreciation of utilities for certain mathematical concepts. We discuss how the identification of objectives needs to go hand-in-hand with careful consideration of the planning of tasks, and propose two constructs to guide that planning.

BACKGROUND

The National Numeracy Framework (NNF) (DfEE, 1999a) was introduced to England and Wales in 1999. By defining how teachers should plan, assess and teach mathematics, this initiative extends the previously established National Curriculum for Mathematics (DfEE, 1999b), which merely set out to define a syllabus of content. The NNF is organised around sets of yearly objectives based on the content of the National Curriculum. The NNF also emphasises short-term planning based around tasks and activities:

- short-term plans: weekly or fortnightly notes on tasks, activities, exercises, key questions and teaching points for 5 to 10 lessons, including how pupils will be grouped, which of them you will work with, and how you will use any support. (p 41)

For clarity, within this theoretical paper, we use the term “task” for what is set by the teacher, and reserve the term “activity” for what subsequently takes place in the classroom setting. The planning emphasis in the NNF makes it opportune to reflect on the complexity of connecting objectives to the design of tasks. We believe that, though this reflection has stemmed from a phase in the development of curricula in England and Wales, in fact the arguments and principles elaborated below will have relevance to mathematics educators and teachers across international boundaries. We begin by problematising the procedure of setting objectives in mathematics lessons, and later we look retrospectively at the design of tasks that have played a significant part in our own research in order to propose two constructs that can guide the connecting of objectives to the design of tasks.

THE PLANNING PARADOX

We begin with a statement of what we call the planning paradox.
If teachers plan from objectives, the tasks they set are likely to be unrewarding for the children and mathematically impoverished. But if teachers plan from tasks, the children’s activity is likely to be unfocussed and learning difficult to assess.

To elaborate a little, we offer two contrasting examples. The teacher begins the lesson by saying, “Today, we are going to work on adding two-digit numbers together”. The lesson proceeds with some explanation and then practice. The task has been determined by the objective in a narrow and constrained way. Such a teacher has fallen foul of the first part of the planning paradox. Now consider a teacher who, as the focus of the mathematics lesson, asks the children to design their ideal bedroom. The children may become highly engaged in a meaningful activity, but the teacher may find it difficult to monitor any mathematical thinking.

**TASKS INSIDE AND OUTSIDE THE CLASSROOM**

In recent years, mathematics educators have taken a great interest in situated cognition research (for example, Lave, 1988, and Nunes et al, 1993). Such studies argue that everyday tasks (“street mathematics”) lend an authenticity to activity that provides not only purpose but also meaning. A possible implication is that we should attempt to offer such authenticity to children in classrooms. Whilst we would agree with Schliemann (1995) that “for meaningful mathematical learning to take place in the classroom, reflection upon mathematical relations must be embedded in meaningful socially relevant situations”, we see the provision of “authentic” tasks as inherently problematic.

Teachers often provide children with tasks that may superficially offer authenticity. For example, a teacher of young children may set up a play shop in the corner of the classroom to encourage some mathematical learning. However, the structuring resources provided by this situation will be very different from those offered when the child is really shopping with a parent. For example, in the play-shop task, emphasis may be placed on number, and so the prices of items on sale are simplified to an extent that even young children will recognise as unrealistic. Even with an element of role-play, the social interactions of the play-shop will not provide the structure and constraints experienced in a real shopping trip.

Situated cognition research has typically studied the activities of master and apprentice. In such situations, the master and the apprentice have a common goal, which in the short-term is typically to make some product (so the tailor and his apprentice may aim to make a waistcoat), and in the longer-term is to make a profit. We question whether teachers and children can have common goals. The teacher’s agenda must be to focus on their pupils’ learning (and the children know this), whereas the children’s agenda will be to complete the task, hopefully to the satisfaction of the teacher. This leads us to question what kinds of products teachers and children might make together. We now consider approaches that do place
product creation at the forefront of children’s activity, though in ways which differ significantly from the tailoring workshop.

Our focus over many years has been on the use of technology in the learning of mathematics, and so it is natural for us to look towards the literature in that field for inspiration.

The constructionist movement (Harel & Papert, 1991a) has proposed that tasks in which children make products, generally through programming computers, are particularly conducive to learning. Thus, in one sense the constructionists replace the “waistcoat” with a product that is programmed by the child into the computer. In our experience (for example, as reported in Pratt & Ainley, 1997, and Ainley et al. 2000), such programming tasks can generate activity that has some of the characteristics of everyday activity studied in the research of situated cognitionists. For example, teachers often become engaged in working with the child to make the virtual product, reminiscent of the tailor and apprentice collaborating to make the waistcoat. The task, rather than the externally set objectives, takes on the role of being the arbiter of what counts as progress. Thirdly, any mathematical learning that takes place is contextualised within the activity of making the product, which provides meaning for the mathematics, but perhaps limits its apparent range of applicability.

Harel and Papert (1991b) also recognise the connection between constructionism and situated cognition, and at the same time signal some differences in emphasis.

We see several trends in contemporary educational discussion such as ‘situated learning’, and ‘apprenticeship learning’... as being convergent with our approach, but different in other respects... our emphasis (is) on developing new kinds of activities in which children can exercise their doing/learning/thinking...(and) on project activity which is self-directed by the student... (p42)

We believe that the constructionist approach recognises that the classroom is not the market place, and does not attempt to place emphasis on authenticity, but, by placing emphasis on the creation of products, it positions consideration of meaningfulness and motivation high on the agenda for the design of tasks that are likely to promote mathematical learning. Our aim is to draw out from these ideas constructs that inform the teachers’ problem of connecting objectives to task design (the planning paradox).

CONNECTING OBJECTIVES AND TASK DESIGN

Schliemann (1995) concludes a discussion of the problems of bringing everyday mathematics into the classroom with the statement that ‘we need school situations that are as challenging and relevant for school children as getting the correct amount of change is for the street seller and his customers’. In considering both constructionist approaches, and ‘authentic’ settings for learning mathematics, we identify a common feature, which may provide this challenge and relevance, as the purposeful nature of the learners’ activity. We see this feature of purpose for the
learner, within the classroom environment, as one key construct informing pedagogic task design. It is important to note that purpose, as we use the term here, is not necessarily linked to ‘real world’ uses of mathematics. Indeed, there is considerable evidence of the problematic nature of pedagogic materials which contextualise mathematics in supposedly real-world settings, but fail to provide purpose (see for example Ainley, 2001, Cooper and Dunne, 2000). We define a purposeful task as one which has a meaningful outcome for the learner, in terms of an actual or virtual product, or the solution of an engaging problem.

Thus the purpose of a task, as perceived by the learner, may be quite distinct from any objectives identified by the teacher. In a classroom situation, this maybe true in a trivial sense: learners may construct the purpose of any task in ways other than those intended by the teacher. However, we are saying something more than this: within our framework for task design, purpose is a distinct element that needs to be considered separately from, but in parallel with, objectives.

However, a focus on purpose in isolation may produce tasks which are rich and motivating, but fall foul of the second part of our planning paradox, by lacking mathematical focus. We therefore introduce into our framework a second construct of utility. Within pedagogic tasks that are designed to have purpose for learners, we have found that it is possible to plan for opportunities for learners to appreciate the utility of mathematical concepts and techniques. Whilst engaged in a purposeful task, learners may learn to use a particular mathematical idea in ways that allow them to understand not simply how to carry out a technique, but how and why that idea is useful, by applying it in that purposeful context. This parallels closely the way in which mathematical ideas are learnt in out-of-school settings.

A TASK DESIGNED WITH PURPOSE AND UTILITY

An example may help to clarify the related constructs of purpose and utility. A task which we have used (and written about) on a number of occasions, is that of designing a paper spinner, or ‘helicopter’ (see Ainley et al, 2000). In this task the purpose for the learners is clear: to make a spinner that will stay in the air for as long as possible. In investigating aspects of the design, for example by changing the length of the wings, children record results of test flights on a spreadsheet, (for example, the wing length and time of flight). Their activity offers opportunities to use a number of mathematical ideas, including measurement of length and time, decimal notation, graphing. From these we now describe two examples of utility.

Initially it is difficult for children to see patterns in the numerical data on the spreadsheet, partly because the data is not usually collected in a systematic way, and partly because of experimental inaccuracy. Using a scatter graph to display the results at intervals during the experiment makes it easier to see emerging patterns in the time of flight as the wing length varies. Information from the scatter graph is used to make conjectures about the effects of changing the wing length, and which
spinners will prove most efficient, and also to identify further areas for experimental investigation. Using a scatter graph in this purposeful way offers opportunities to learn about the conventions of this particular graph, but also to understand that graphing is an analytical tool, which can inform the process of doing an experiment: that is, the children are given clear opportunities to construct a utility of graphing.

Discussion of the experimental inaccuracies in the activity leads us to introduce the idea of taking the mean value of several experiments with each wing length to produce a ‘better’ graph. This can be done quickly and easily using the AVERAGE function of the spreadsheet. Children are able to use their everyday knowledge of the meaning of ‘average’ to understand enough about this process to appreciate a utility of average (which does indeed produce a clearer graph), even though they do not know the detail of how the mean was calculated.

These two instances of introducing the utility of mathematical ideas both involve situations in which the use of technology means that mathematical ideas (graphing, average) can be used without children having learned the skills and techniques that underpin them (constructing a graph, calculating the mean). This is not co-incidental, and we return to further discussion of this point later in the paper. What we wish to emphasise here is that the opportunity to understand the utility of these ideas arises because of the purposeful nature of the task set, and of the learners’ activity in response to these tasks. Without the underlying purpose of producing an efficient spinner, graphing experimental results and using average values could only have been introduced as isolated techniques. Their usefulness might be described through imagined applications, but could not be experienced in ways that allowed learners to construct rich meanings for the mathematical ideas.

RESOLVING THE PLANNING PARADOX

The two constructs of purpose and utility offer a framework for task design that may resolve the planning paradox. Designing tasks that are purposeful for learners, ensures that the activity will be rich and motivating. Such purposeful tasks provide opportunities to learn about the utility of particular ideas, which will give the focus that may otherwise be absent.

It is widely recognised that constructing meaning for a mathematical idea involves many related elements. The distinction is often made between those elements relating to procedures or techniques, and those concerned with conceptual or relational understanding. We propose here a third cluster of elements: those relating to the utility of an idea. A rich understanding of a mathematical idea involves procedural and conceptual elements, but also understanding why that idea is useful, how it can be used and what it can be used for. We conjecture that understanding mathematical ideas without an understanding of their utility leads to significantly impoverished learning. Unlike ‘street’ mathematics, ideas in school mathematics are frequently learnt in contexts where they are divorced from aspects of utility. Within the
classroom, opportunities to understand utility can only be provided through purposeful tasks.

However, the design of tasks that offer both purpose and utility is challenging. It requires the teacher to imagine the trajectory of a learner's activity, taking both a mathematical and a learner-centred perspective. In order to tease out aspects of the design of such tasks, we will discuss our own struggle to create a task with purpose and utility in a particular environment (for an extended discussion of this task see Pratt and Ainley, 1997).

As part of a long-term project, a group of children in our research school had been given access to dynamic geometry software (the original version of Cabri), and had explored its use as a drawing package with little intervention from their teacher. The children had explored many of the features of the software, and produced impressive drawings, but had actually made no use of construction. Their (self-selected) tasks were purposeful, with clear end products (drawings of a football pitch, a clown, and motorcycle and rider), but we felt that the children were not learning any mathematics.

We set out to design tasks that would be equally purposeful for the children, but also introduce the idea of geometric construction in a way that allowed children to understand its utility. This proved problematic. It was easy to design tasks that involved construction (such as creating a square which couldn't be 'messed up') but such tasks had no purpose for the children – except to satisfy the teacher. We knew that the children found creating drawings purposeful, but for such tasks placing points by eye, rather than constructing them, was perfectly satisfactory.

Eventually, we came upon the idea of harnessing the children's interest in drawing by setting them the task of producing a 'drawing kit' for younger children to use. This entailed them writing macros to produce a range of basic shapes (triangles, squares, diamonds etc.) from which young children could create their own pictures. For this task, there was a real purpose behind constructing a square, which could be reproduced many times and manipulated without being messed up by the younger children. As the children worked on making their drawing kits, the utility of construction for producing 'perfect' robust shapes became clear.

The design of the drawing kit task embodies some elements which we offer here as heuristics for creating purposeful tasks.

i) It has an explicit end product that the children cared about (a feature in common with the 'spinner' task described earlier).

ii) It involves making something for other children to use. In this case, the fact that the children for whom the product is intended were younger added an implicit further dimension of teaching other children.
iii) It was well focussed, but still contained opportunities for children to make meaningful decisions: although most of the drawing kits produced contain a similar set of basic shapes, many groups added their own designs, such as wheels or roofs.

To these, we add two other heuristics, which we know to be effective.

iv) Purposeful tasks are often based on an intriguing question. The spinners task may be seen as an example: how does wing length affect the spinner? Questions like this, which are solved through optimisation, seem to be particularly rich.

v) Tasks which involve children arguing from a particular point of view can engage children purposefully in contexts which may be unfamiliar (see for example McClain and Cobb, 2001, Ben-Zvi and Arcavi, 2001).

A SHIFT IN EMPHASIS: INVERTING A PEDAGOGIC TRADITION

The two examples given above of tasks designed using the constructs of purpose and utility exemplify the role of technology in supporting a shift in pedagogic emphasis, which we see as lying at the heart of opportunity for powerful mathematical learning offered by this approach. Mathematical ideas (such as average, graphing or geometrical construction) are rich and complex, composed of different elements, which here we categorise very roughly as procedures (techniques and algorithms, specific rules of formulae), relationships (links within mathematics, internal structure and consistency), and utilities (why, how and when the idea may be useful). As a learner constructs meaning for a new mathematical idea, mental connections will be made with existing knowledge, but the pedagogic emphasis placed on the different elements will affect the ways in which those links are made.

It is generally acknowledged that pedagogic approaches that focus mainly, or exclusively, on procedures will result in impoverished learning. However, even approaches that emphasise relationships tend to give little attention to utilities. The pedagogic tradition, embodied in textbooks around the world, is to begin with procedures and relationships, and to address utilities as the final stage in the pedagogic sequence (if at all). We suggest that this results in mathematical knowledge becoming isolated as weak connections are made to the learner’s existing knowledge of the contexts in which it may be usefully applied.

In learning mathematics in out-of-school contexts, we believe that immediate connections between the learner’s existing knowledge and the utilities of the new idea are established in ways which enrich mathematical learning. In school mathematics, the initial links are generally made to procedures and relationships. Pedagogic design based on the framework of purpose and utility, with the support of technology, inverts the pedagogic tradition of school mathematics by placing the emphasis primarily on the utilities of a new mathematical idea. Thus the learner is able to construct meanings that are shaped by strong connections to the application of that idea.
This inversion is made possible largely (though not exclusively) by the power of technology to offer opportunities for using a mathematical idea before you learn about its procedures and relationships. Technology affords the possibility of pursuing purposeful tasks by working with mathematical tools, instantiated on the screen, whilst simultaneously coming to appreciate the utility of those tools, in ways which lead to powerful mathematical learning. Ongoing research is developing and refining this framework for the design of pedagogic tasks in various areas of the mathematics curriculum.

REFERENCES

In this paper we focus on students' understanding of the core concept of function, which is mathematically simple yet carries within it a rich complexity of mathematical ideas. We investigate the linguistic complexity that reveals itself through the mathematically simple notion of a constant function and the representational complexity involved in different representations. Results reveal a spectrum of performance in which a few students may be able to grasp the function concept as a rich highly connected cognitive unit, but others are overwhelmed by a complexity that is highly complicated with many separate aspects weakly connected together.

INTRODUCTION
To a mathematician, the notion of function is a model of simplicity. What could be simpler than the idea that "we have two sets and each element in the first is linked to precisely one element in the second"? The definition is not only mathematically simple, for the mathematician it provides access to a huge complexity of mathematical ideas. Some students are able to build this subtle combination of simplicity and complexity. For others, however, the situation is quite different. As they respond to being introduced to the notion of function, they bring their implicit understandings of language and all their previous experiences to bear on the task. The result for them is a highly complicated array of personal meanings that both help and hinder their interpretation of the mathematical concept.

LITERATURE REVIEW
The complexity of the function concept has been a focus of attention for almost a generation. Vinner (1983) drew attention to the distinction between the concept definition that mathematicians use to define a mathematical concept and the concept image which people generate in their mind. He also showed that most students use their own personal concept definition for the notion of function, giving highly idiosyncratic meanings to the term. Subsequently, two distinct lines of enquiry have occurred in the literature, on the one hand the nature of function as process and mental object (Dubinsky, 1991; Breidenbach et al, 1992; Sfard, 1992); and the multiple representations of a function (Confrey, 1994; Kaput, 1992; Keller & Hirsch, 1998; Leinhardt et al., 1990). Others have since combined these two aspects into a broader perception of 'horizontal growth' (between representations) and 'vertical growth' (in compression from process to concept) (Beineke et al., 1992; Schoenfeld et al, 1993).
THEORETICAL FRAMEWORK

Our study focuses on the nature of the concept definition and its interpretation in a variety of representations as presented in the Turkish mathematical curriculum. We are particularly interested in the subtleties of meaning attributed to the (personal) concept definition, and the meanings inherent in the various representations.

Thompson (1994), questioned the meanings given to representations seemingly shared by the mathematics education community:

...the idea of multiple representations, as currently construed, has not been carefully thought out, and the primary construct needing explication is the very idea of a representation... the core concept of “function” is not represented by any of what are commonly called the multiple representations of function, but instead our making connections among representational activities produces a subjective sense of invariance. (Thompson, 1994, p. 39)

In practice, the simple core concept (given essentially by the definition) proves cognitively elusive and students are introduced to examples in various forms:

- a verbal representation of a function in formal or colloquial (everyday) language,
- a set diagram (representing a function by two sets and arrows between them),
- a function box (representing an input-output relationship),
- a set of ordered pairs (considered set-theoretically),
- a table of values (often computed using a formula or computer procedure),
- a graph (drawn by computer or by hand),
- a formula.

Each of these has its own peculiarities that contribute to the complication of the student’s concept image. To describe the manner in which the human mind copes with these images, the literature has developed a language of prototypes (typical instances) and exemplars (more specific cases), the latter often being seen as clusters of examples. (See Makin & Ross (1999) for a detailed discussion). Our analysis suggests that different representations are presented and interpreted in subtly different ways. For instance, set diagrams are often introduced as prototypes to represent general ideas, whilst graphs and formulae are met successively in clusters (linear functions, quadratics, trigonometric, exponential, and so on). This presents a dilemma for the curriculum developer:

The learner cannot construct the abstract concept of function without experiencing examples of the function concept in action, and they cannot study examples of the function concept in action without developing prototype examples having built-in limitations that do not apply to the abstract concept. (Bakar & Tall, 1992, p. 13)

BACKGROUND OF OUR STUDY

The purpose of this paper is to explore the nature of this subtle mathematical blend of simplicity and complexity and to focus on problems that it presents to many students, with particular reference to a specific curriculum for the function concept. The Turkish curriculum, in which our study is situated, begins with the following:
Formal Definition

Let $A$ and $B$ two sets other than empty set, and $f$ is a relation defined from $A$ to $B$. If

i) $\forall x \in A$, $\exists y \in B$ s.t. $(x, y) \in f$,

ii) $(x, y_1) \in f$ and $(x, y_2) \in f \Rightarrow y_1 = y_2$.

Then the relation $f$ from $A$ to $B$ is called a function and denoted by $f: A \rightarrow B$ or $A \rightarrow \rightarrow B$. $A$ is called the domain and $B$ is called the range.

This mathematically simple notion is followed by a four part colloquial definition to help the student focus on the essential properties of a function. These explain properties (i) and (ii) and add (iii) different elements in $A$ can be related to the same element in $B$, (iv) some elements in $B$ may not be related to an element of $A$.

The students are then given experience of functions in different representations as

set diagrams, ordered pairs, graphs and formulae,

(but not as function boxes or tables). Our research is to investigate and analyse the use of formal definition and the concept images that arise (in the sense of Tall & Vinner, 1981), with particular interest in the role of language and the prototypes and exemplars that arise in the students written and spoken responses.

METHODOLOGY

One hundred students from four different upper-secondary schools in Turkey were given a questionnaire which asked whether various graphs, equations, correspondences between two set diagrams, sets of ordered pairs are functions or not. Based on an analysis of the responses, eight students were chosen to represent a spectrum of performance for individual interviews. The interviews were semi-structured with certain questions asked of all students with a flexible continuation to take account of individual responses. In this paper, we focus on two specific areas in the interviews: responses to the mathematically simple case of a constant function and responses to a range of questions relating to graphs (with marked domains), set diagrams, ordered pairs, and formulae.

DATA ANALYSIS

The constant function

Mathematically, the simplest function is a constant function that assigns to every element of the domain a single element in the range. Cognitively, however, this example is far from simple. It is a singular case violating strong links in the concept image (such as the idea that $f(x)$ 'depends on' or 'varies with' $x$).

The following questions were asked to eight students from grade 9-10-11 (aged 15-16-17) in four different upper-secondary schools in Turkey:

I will show you some expressions. Can you tell me whether they are functions or not?
They were then, in succession, shown cards with the following written statements:

\[ y = 4, \]
\[ y = 4 \text{ (for all values of } x) , \]
\[ y = 4 \text{ (for } x \geq 2). \]

The subtle differences in these three expressions greatly affect the student responses so that there is a wide range of responses. Six of these are as follows:

<table>
<thead>
<tr>
<th></th>
<th>( y = 4 )</th>
<th>( y = 4 \text{ (for all values of } x) )</th>
<th>( y = 4 \text{ (for } x \geq 2) )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Eren</td>
<td><em>Yes:</em> This is ( f(x) = y ) ... it can be a constant or a variable, this goes to a constant, thus it is a function.</td>
<td><em>Yes:</em> It is a function which is not dependent on ( x ).</td>
<td><em>No:</em> not a function, there isn’t anything for values less than 2 ... [When the domain was mentioned, he changed his response to <em>yes.</em>]</td>
</tr>
<tr>
<td>Can</td>
<td><em>Yes:</em> It always goes to 4 in the range.</td>
<td><em>No:</em> There are elements left in the range ... [see below]</td>
<td><em>Yes:</em> It goes [is assigned] for less than two. [see below]</td>
</tr>
<tr>
<td>Aysun</td>
<td><em>Yes:</em> It is a constant function ... without ( x ) ... dependent on ( y ) ... ( y = ax+b ) ... without ( x ) it is constant.</td>
<td><em>No:</em> There isn’t any value for ( x ) ... I can’t see ( x ) here ... there isn’t any ( x ) on the other side of ( y ).</td>
<td><em>Yes:</em> I have to see two sets, this is a function. In the domain, elements greater than 2 are assigned to 4.</td>
</tr>
<tr>
<td>Murat</td>
<td><em>No:</em> not a function ... I can’t say the reason ... I don’t know.</td>
<td><em>Yes:</em> function ... because it says “for all values of ( x )”</td>
<td><em>Yes:</em> function, since 4 is greater than 2.</td>
</tr>
<tr>
<td>Irem</td>
<td><em>No:</em> there should be an equation, but there isn’t ... there should be an unknown.</td>
<td><em>Yes:</em> this may be a function ... because it says for all values of ( x ), thus there is ( y ) being a correspondent of ( x ).</td>
<td><em>Yes:</em> it can be function, then there was an equation, thus a function.</td>
</tr>
<tr>
<td>Deniz</td>
<td><em>No:</em> there should be ( f ) in the front.</td>
<td><em>Yes/Not Sure:</em> we used to put ( y ) instead of ( x ) ... but we find ( x ) then.</td>
<td><em>Yes/Not Sure:</em> function ... ( x ) greater than 2, then I am not sure.</td>
</tr>
</tbody>
</table>

Table 1: Student responses to the various formulations of a constant function

None of the students responded *yes* to all three examples, with the possible exception of Eren, who gave a simple definitional response to the first two examples, but was troubled by the third because some elements were not assigned. The interviewer drew his attention to the notion of domain and he immediately changed his response to declaring it to be a function using the colloquial definition. Student Can responded to the first part using the colloquial definition but drew a graph with only positive values of \( x \) in the second part, becoming confused. In the third he gestures to the values of \( x \) greater than two and says ‘values less than 2’, a possible slip of the tongue. Aysun correctly identifies the first example, but sees it as a special case of a linear function, is thrown off course by the absence of an ‘\( x \)’ in the formula in the second case, but correctly identifies the third using the colloquial definition. The other students (represented here by Deniz, Murat, Irem) respond in a variety of ways that reveal a range of complications. They respond to each separate example by noting certain aspects in isolation without at any stage referring to any form of function definition.
Different representations of functions

Students were given different representations of functions in isolation. They were given the following items and asked whether they were functions or not.

Set diagrams:

a) Set diagrams:
   - a) f
   - b) f
   - c) f
   - d) f

Set of ordered pairs: \( f: \{1,2,3,7,9\} \rightarrow \mathbb{R} \quad f = \{(1,3), (2,5), (3,2), (7,-1), (9,1)\} \)

Graphs:

[On the original, the thicker parts on the axis were marked red and denoted the domain.]

Formulas:

(a) \( f: \mathbb{R} \rightarrow \mathbb{R}, \quad f(x) = \sqrt{x} \)  
(b) \( f: \mathbb{R} \rightarrow \mathbb{R}, \quad f(x) = \frac{1}{x} \).

In the interviews, students were asked to explain why they consider these as functions or not. This gave the responses of eight students on four representations. These were then analysed first by considering each representation in turn, then by considering and comparing the performance of individual students.

Set diagrams were answered by seven students in terms of the colloquial definition. Four of these were successful and seemed to use the colloquial definition as their personal concept definition. For instance, Can said:

(a) is not a function because there is an element left in the domain ... (b) is function because for every element in the domain there is an element in the range ... (d) not a function because there are two values for a (in the domain). (Can)

Three others used the colloquial definition, but were unsuccessful. For instance, Sena was confused about the properties of a function, saying ‘one can go to two’.

Ordered pairs again evoked the colloquial definition, this time from six students. Three of them successfully checked the definitional properties using the colloquial definition as their personal concept definition:

Here there shouldn’t be anything left, 1,2,3,7,9 all of them are used and used once, thus I considered this as a function and all of the elements here are reals. (Eren)

Function, because every element in the domain goes to an element in the range. (Can)

All these in the domain are joined with different elements in the range. (Murat)
Graphs were more likely to provoke recall of examples rather than the definition:

Function...there used to be graphs like that in the tests. (Fatma)

If we join these (three pieces) then it looks like a function. (Irem)

The vertical line test was used by three students (Eren, Can, Aysun) who were able to focus on the role of the coloured domain for each graph. The other five students' responses were highly complicated and based on recalled exemplars, and selected details such as absence of numbers on the axes, as in the case of Sena.

Formulae also evoked examples rather than the definition. Only Aysun used the definition (in a colloquial form) to respond successfully to the question. Eren and Can were able to consider the domain of the formulas, but the other five student responses were complicated and did not use the core properties of function at all.

This first part of the analysis suggests that the responses to set diagrams and sets of ordered pairs act like prototypes that are less complicated than the responses to graphs and equations which are seen more as clusters of exemplars.

The second part of the analysis considered the performance of each individual student. Responses indicated that there is a spectrum of performance for students which we illustrate in terms of four categories which may overlap.

In the first category are two students (Eren, Can) who use their personal concept definitions to give a greater unity as they pass from one context to another, not only for set diagrams and ordered pairs, but also for graphs and equations.

In the second category is Aysun who used the colloquial definition of function for set diagrams and formulas and the vertical line test for graphs. She was unsuccessful with the function properties for ordered pairs.

In the third category are the two students (Fatma and Murat) who use their personal concept definitions for one of the two prototypes (set diagrams or ordered pairs). Their responses to the other representations were complicated combinations of exemplars and selected details without any reference to any definitional properties.

In the fourth category are the other three students who could not focus on the core concept for any of the representations. They produced complicated responses affected by the subtle differences in the particular representations without any reference to the definitional properties at all.

CONCLUSION AND REFLECTIONS

In this paper, we have considered how students deal with aspects of the linguistic and representational complexity of the function concept. Figure 1 illustrates our observations, with the positions of two starred items (function box and tables) inferred from other research (Crowley and Tall, 1999; McGowen & DeMarois & Tall, 2000). The data in this paper is drawn from a curriculum in Turkey, which begins by mentioning the formal definition, interprets it in a colloquial form, then
Figure 1: The complexity and complication of the function concept

Focuses on set diagrams, ordered pairs, graphs and formulas. The case of a constant function in several variant expressions reveals that the simplicity of the core function concepts eludes most students. The empirical data suggests that a small number (represented by Eren and Can) generally use the core function concept definition in a colloquial form to link ideas across a range of different representational forms into a rich cognitive unit. Errors that they make from time to time are usually amenable to reconsideration through discussion. Essentially, for them, the core concept has a simplicity that can be applied in a variety of contexts.

The other students do not yet have the sophistication to see this simplicity. Some of them focus on the core concept in the form of a colloquial definition for the prototypical forms of set diagrams and ordered pairs. However, graphs and formulas are—at best—seen more in terms of exemplars, relating to types of functions they have met or, in the case of the less successful students, in terms of almost arbitrary aspects of the examples that they happen to focus upon.

A FRAMEWORK FOR THE STUDY OF INTUITIVE ANSWERS TO RATIO-COMPARISON (PROBABILITY) TASKS.

Silvia Alatorre

National Pedagogical University, Mexico City

ABSTRACT. This paper describes a framework for the study of strategies used in ratio-comparison problems, which was constructed for the analysis of adults' responses to double urn probability tasks. This framework involves two systems, one for the interpretation and classification of answers (strategies), and one for the planning of the numbers involved in ratio-comparison questions (situations). It was applied in an experiment with university students. Some results are reported, which refer to the relative occurrence of strategies, the difficulty levels of different situations and a classification of the subjects according to their performance.

The purpose of this article is to describe a framework for the classification of answers given in ratio-comparison tasks and for the categorization of the numbers involved in questions for such tasks. It was constructed in the frame of a research aiming at understanding how Mexican university students solve the “quantification” problems designed by Piaget and Inhelder (1951) in the context of a double urn probability task. In this research it became clear: a) that many of these adults cannot correctly solve what Piaget and Inhelder claimed to be solvable by the age of 15, and b) that the Piagetian categories were ineffective for the explanation of their behaviours.

Although the research was based upon the classical definition of probability, its main purpose was not to see whether the participant subjects use it or not, but to understand how they deal intuitively with the tasks. Piaget and Inhelder’s (1951) work concerning children’s conceptions of chance is at the foundations of the study. Fischbein’s (1975) definition of intuition is used: it is a form of immediate knowledge which can appear to a person as obvious; it responds to a biological need for action and for certainty, from where it gets its characteristic reliability, stability and coercing nature. Tversky’s et al (1982) concept of heuristics is also considered, as is their notion that people use a limited amount of heuristic principles to simplify the complex tasks of estimating probabilities and predicting values, but which lead frequently to serious and systematic errors. In the construction of the framework several references were considered, among which Noelting’s (1980) classical orange juice experiment, and Falk et al’s (1980) and Maury’s (1986) researches on probability learning.

The adult subjects who participated in this study were shown two sets of cards, A and B, that were black or white on the obverse and red patterned on the reverse. When the subject had clearly seen all the cards, they were turned upside down and each set was shuffled separately. He or she was then asked: “Suppose there was a big prize if you took out a black card, but you only have one chance of choosing one card from one of the two sets. From which set would you choose a card: A, B or is it the same?” (No
actual prizes were to be given, however). The subject had to make a decision and to justify it. When this was done, the number of black and white cards in each set was changed and the same question was posed. After some such experiments with actual cards, the subject was just shown drawings representing the sets as they were before the cards where turned upside down and shuffled, such as the one in figure 1.

Figure 1: Array (1,3)(2,5)

A framework was constructed, which consists of two ways of envisaging these problems. One of them focuses on the answers given by the subjects; this generates a system of strategies. The other one focuses on the particular quantities involved in the questions; this generates a system of situations. Although different in nature, both systems have a correspondence with each other. The two sections of this article are dedicated to the presentation of the framework constructed and to the description of some results obtained from its experimental application.

THE FRAMEWORK

Each question is defined as an array, which is a pair of sample spaces S1 and S2; each of them is in turn characterized by a pair of favourable (f: black cards) and unfavourable (u: white cards) cases. An array is thus an expression of the form \((f_1,u_1)(f_2,u_2)\). Also defined for each array are the total cases \((n = f + u)\), the differences \((d = f - u)\) [1] and the probabilities \((p = \frac{f}{n})\) [2]. For instance, the question in figure 1 has \(f_1=1, u_1=3, n_1=4, d_1=-2, p_1=\frac{1}{4}\); \(f_2=2, u_2=5, n_2=7, d_2=-3, p_2=\frac{2}{7}\). These definitions are used in the constructed framework, which will be described here: the systems for strategies and situations, as well as the correspondence between them.

Strategies

Strategies are understood here as solution mechanisms used to solve problems, that have a certain structure or logic and that can be reproduced for other problems of the same type. They are structured heuristics in the sense of Tversky et al (1974) [3]. Strategies are classified as simple or composed; simple strategies are in turn grouped in centrations and relations [4].

Centrations. The subject concentrates on only one class of elements of the array: the total, the favourable or the unfavourable cases. In each instance, the subject can decide to choose the side where there are more elements of the class (positive centration), or where there are less elements (negative centration), or he or she can answer “it is the same” if in both sides there is the same amount of the considered class of elements (equality centration). There are nine different centrations, grouped in three families:

\{CN\}. Centrations on total cases: Choosing the side where the total amount of cards is smaller (\{CN−\}) or larger (\{CN+\}), or saying “it is the same” because in both sides this amount is the same (\{CN=\}).
Centrations on favourable cases: Choosing the side where the amount of black cards is smaller (\{CF-\}) or larger (\{CF+\}), or saying “it is the same” because in both sides this amount is the same (\{CF=\}).

Centrations on unfavourable cases: Choosing the side where the amount of white cards is smaller (\{CU-\}) or larger (\{CU+\}), or saying “it is the same” because in both sides this amount is the same (\{CN=\}).

Relations. The subject considers simultaneously two classes of elements, and after establishing two relationships between them, he or she compares the results. These relationships can be based on order comparisons, or they can have an additive or a proportional nature [5]. There are ten different relations, grouped in three families:

Order relations: Choosing the side where the black cards prevail over the white ones, whereas in the other side either the white cards prevail (\{ROwl\}: win-lose) or there are as many black cards as white ones (\{ROwd\}: win-draw). Or choosing the side where there are as many black cards as white ones, whereas in the other one either the white cards prevail (\{ROdl\}: draw-lose) or the black ones prevail (\{ROd\}: draw). Or saying “it is the same” because in both sides the black [white] cards prevail (\{RO=\}: win-win [lose-lose]).

Difference relations: Choosing the side where the difference of black minus white cards is the largest (\{RD+\}) or the smallest (\{RD-\}), or saying “it is the same” because the difference is the same in both sides (\{RD=\}).

Proportionality relations: Choosing the side where the quotient \(\frac{b}{w}\) or the quotient \(\frac{w}{b}\) is the largest (\{RP+\}), or saying “it is the same” because the quotient is the same in both sides (\{RP=\}).

Composed strategies. Two or more simple strategies can be linked in a logical juxtaposition; each of them may be dominant or dominated. If \(X\) and \(Y\) are two strategies, there are four possible compositions between them:

Conjunction: Both \(X\) and \(Y\) lead to the same decision (S1, S2 or “same”) and they support each other. Both \(X\) and \(Y\) are dominant.

Exclusion: \(X\) leads to the election of one side or to the decision “it is the same”, and \(Y\) leads to the election of the other side, but \(X\) prevails. \(X\) is dominant and \(Y\) is dominated.

Compensation: \(X\) leads to the election of one side, and \(Y\) leads to the decision “it is the same”, but \(X\) prevails. \(X\) is dominant and \(Y\) is dominated.

Counterweight: \(X\) and \(Y\) lead to the election of different sides and they cancel each other, causing the decision to be “it is the same”. \(X\) and \(Y\) are dominated.

There are also multiple compositions: compositions of strategies, one (or both) of which is in turn a composed strategy.

Examples. Table 1 shows the most common strategies that would be applicable in figure 1, the decisions they lead to, justifications that could have been prototypically
given by subjects, and the mathematical description of simple strategies.

Table 1: Simple strategies and some compositions applicable in the array of figure 1

Situations

A situation is a set of arrays such that the different simple strategies lead to the same decisions in all the arrays. Each situation is characterized by two subsystems, which define a crossed pattern; the two subsystems are combinations and locations.

Combinations. A combination is the succession of results obtained when an order relationship is established between the following pairs of an array: the total cases n, the favourable cases f, the unfavourable cases u, the differences d, and the quotients p. For instance, the array \((f_1,u_1)(f_2,u_2) = (1,3)(2,5)\) of figure 1 has \(n_1<n_2\), \(f_1<f_2\), \(u_1<u_2\), \(d_1>d_2\) and \(p_1<p_2\), which gives the combination \(<<><<\) ). Seventeen such combinations exist [6], which are the following: K0 (== === =): identity array; K1 (<<<<<<), K2 (<<<<<>: arrays without discrimination (most strategies lead to the same side: S2 in K1 and S1 in K2); K3 (<<<<<<<<<), K4 (<<<<<<<<<), K5 (<<<<<<<<<): equalities of total, unfavourable or favourable cases; K6 (<<<<<<<<<), K7 (<<<<<<<<<): \{RD\} and \{RP\} lead to the same side; K8 <<<<<<<<, K9 <<<<<<<<: \{RD\} and \{RP\} lead to different sides; K10 (<<<<<<), K11 (<<<<<<): equality of differences; K12 (=<<<<<<), K13 (<<<<<<), K14 (<<<<<<), K15 (<<<<<<) and K16 (<<<<<<): equality of probabilities, with probabilities respectively equal to \(p=0\), \(p=1\), \(p<1/2\), \(p>1/2\) and \(p=1/2\). (In K6 through K16, centrations lead to the election of different sides). Thus, the array of figure 1 is K8 [7].

Locations. A location is a non-ordered pair of the following alternatives for both probabilities of the array: c: certainty (\(p=1\)); w: win (\(1>p>1/2\)); d: draw (\(p=1/2\)); l: lose (\(1/2>p>0\)); and i: impossibility (\(p=0\)). There are also seventeen possible locations [6]: c=c (1=p_h=p_k), cw (1=p_h>p_k>, cd (1=p_h>p_k=1/2), cl (1=p_h>1/2>p_k>0),

2 - 36 478 PME26 2002
ci (1>p_h>p_k=0); w=w (1>p_h=p_k>½), \(ww\) (1>p_h>p_k>½), \(wd\) (1>p_h>p_k=½), \(wl\) (1>p_h>½>p_k=0), \(wi\) (1>p_h>½>p_k=0); \(d=d\) (p_h=½=p_k), \(dl\) (½=p_h>p_k>0), \(di\) (½=p_h>p_k=0); \(l=l\) (½=p_h=p_k>0), \(ll\) (½=p_h>p_k>0), \(li\) (½>p_h>p_k=0); and \(i=i\) (p_h=p_k=0). Location \(c=c\) is called “double certainty”, \(dl\) is “draw-lose”, \(ww\) is “win-win”, etc. For instance, the array (1,3)(2,5) of figure 1 is \(ll\) (“lose-lose”) [8].

Not all locations exist in all combinations; there are 86 intersections of both subsystems of categories, and thus 86 different possible situations [6, 9].

**Correspondence between the systems of strategies and situations**

One of the most important features of these systems lies in the correspondence between them, which makes it possible to know, for each problem posed, which strategies may be occurring and which lead to each of the three different decisions (S1, S2 or same). The combinations account for the possible decisions induced by all simple strategies except the \{RO\} family, and the locations account for the ones induced by the \{RO\} family. For instance, the applicable strategies, the decisions and the justifications depicted in table 1 could be the same for all K8-ll arrays.

The correspondence also permits a classification of all strategies according to their correctness in each situation. A correct strategy is one that coincides algebraically with the formal probability, and an incorrect strategy is a behavioural pattern associated with an inadequate intuition, one that may eventually lead to a decision different from that prescribed by the formal probability. Three groups can be defined:

- **Correct strategies**: always correct when applicable. Relations {RP+} (applicable in K1–K11), {RP=} (K0, and K12–K16); {ROowl} (locations wi, ci, cl, wl), {ROdl} (di, dl), and {ROwd} (wd, cd). Ten composed strategies such as {CF+ & CU–} (K1–K3) and {CF+ * CN=} (K3). Compositions with correct dominant and incorrect dominated strategies, such as {RP= N–}, are also considered correct.

- **Eventually correct strategies**: correct only in certain situations. Centrations {CF+}, {CF=} (only correct in i locations), {CU–} and {CU=} (only correct in c locations). Four composed strategies such as {CU– * CF=} (only correct in K5, but also incorrectly applicable in K12, which only exists in i=i).

- **Incorrect strategies**: always incorrect when applicable. Families {CN} and {RD}. Strategies {CF–}, {CU+}, {ROd} and {RO=}. Also, most composed strategies.

All the correct strategies other than \{RP+\} or \{RP=\} may be thought of as Vergnaud’s (1981) théorèmes en acte: the subject using them may be perceiving and using properties of the relationships between elements of the array without necessarily being able to make them explicit or to justify them. A particular case are the correct composed strategies, such as \{CF+ * CN=\} in K3, because when a subject uses \{CF+\} in K3 the question could arise that he or she might be considering \{CN=\} but is not stating it, because it is too obvious. In such cases \{CF+\} is considered a potentially incomplete expression of a correct justification (abbreviated PIECJ).
AN APPLICATION OF THE FRAMEWORK; SOME RESULTS

In order to prove its effectiveness, the framework was applied in six experiments in Mexico City involving 64 university students who had not previously taken probability courses [10]. A test was designed in each experiment [11]; each test had between 20 and 40 items of the exposed form, all with \( n_1 \) and \( n_2 \leq 10 \), and covering a variety of situations. Some of the tests were applied in paper and pencil form, and some in taped interviews. A total of 1630 answers was obtained, of which 1144 (70%) were interpreted, 405 (25%) had a decision (S1, S2 or same) but were non-interpretable (mainly because of poor or none justification), and 81 (5%) had to be cancelled [12].

The evaluation of the experimental results is carried out from three viewpoints: strategies, situations, and subjects. Firstly, the frequency of each strategy or group of strategies is calculated. Secondly, the amount of correct responses in each situation permits to define levels of difficulty for situations. Thirdly, each subject can be classified according to his or her performance in each of those levels.

**Occurrence of strategies.** In the analysis of the 1144 interpreted answers, each strategy's occurrence was calculated as a quotient of the times it was observed over the times it could possibly be observed (for instance, \{ROwd\} could have been observed only in items with locations \( wd \) or \( cd \), which were 200). Table 2 shows the relative occurrence of the most common strategies in simple or composed forms.

</table>

**Table 2:** Possibilities \( (N) \) and relative occurrence (%) as simple \( (S) \) or composed \( (C) \) forms (including dominant and dominated) of the most common strategies [13]

Among these results, the following may be highlighted. The high occurrence of \{CF\} among these young adults contradicts many authors' assertion that the centration in favourable cases disappears by the age of 11 (e.g. Falk et al, 1980). Also noticeable is the high occurrence of the incorrect \{RO=\}, greater than the additive \{RD\}. The proportionality reasoning was easier when the ratios were equal: \{RP=\} was more frequent than \{RP+\} (to these, a 3% of arithmetically incorrect attempts at \{RP\} may be added).

**Overall correctness distribution.** Of the 1144 interpreted answers, 37% had incorrect justifications (12% with and 25% without a correct decision), 53% had correct justifications and 10% were PIECJ. Among the correct justifications, 38% came from
the simple proportionality strategies, 16% from simple correct order relations, 44% from théorème en acte strategies (simple or composed) and 2% from other correct compositions. It is noticeable that théorème en acte strategies, to which the PIECJ could be added, amount for approximately one half of the answers.

Evaluation of situations. The distribution of correct justifications varies among situations. All 1549 non-cancelled answers were used to analyse the correctness distribution of each situation, and six difficulty levels were defined according to the percentage of correct justifications [14]: I: Situations with impossibilities (including K12 and K13) (93%); II: Situations with certainties and identity situations (77%); III: Situations around p=½: locations w1, d1 and w2 (59%); IV: Proportionality situations: combinations K14 to K16 (35%); V: Combinations K1 to K5 in l or w locations (35%); VI: Combinations K6 to K11 in l or w locations (13%) [15].

Evaluation of subjects. These levels also permit the classification of subjects, with the following criterion: A subject is assigned level L if he or she can correctly solve and justify at least 50% of the items of level L and all levels prior to it, but cannot reach 50% in the subsequent levels. Of the 64 subjects, 23% were in level I, 28% in level II, 14% in level III, 16% in level IV, 11% in level V, and 8% in level VI.

Thus, half of the adult subjects who participated in these experiments could only correctly solve and justify the items corresponding situations with impossibilities and certainties; the “one variable” problems (level V), which according to Piaget and Inhelder (1951, Ch VI-4) can be solved by the age of 8, could only be solved by 19%, and the “two variables” problems (level VI), supposedly solvable by the age of 15 (ibid, Ch VI-6), could only be solved by 8%. A question that remains to be answered is whether university students of this kind encounter also difficulties in solving other ratio-comparison tasks, or if the difficulties were enhanced by the probabilistic nature of the task, as happens with younger subjects (Cañizares et al, 1997).

NOTES
1. The term difference is used in this paper as f-u and not as |f-u|, thus possibly having positive or negative values.
2. For the sake of non-repetition, n1 ≤ n2 and if n1=n2 then f1≤f2. Thus, in figure 1, side A is S1 and side B is S2.
3. Other unstructured heuristics were also found in the experimentations with adults, but they were rare and were not considered in the construction of the system of strategies. Some examples: attraction ("It is more fun to choose A") and graphic presentation ("The way in which they are put begins with a black card..."). Usually, subjects who used them did so only at the beginning of the experiment, and then settled into the strategies considered in the system.
4. Centrations and relations have also been respectively called “single variable” and “two variables” strategies (Cañizares et al, 1997). Positive centrations correspond to the “more A-more B” intuitive rule identified by Stavy et al (2000) and equality centrations to the “same A-same B” intuitive rule.
5. All relations are described and exemplified in this paper in their “within” forms. However, all of them can also happen in a “between” form (See Noelting, 1980).
6. The proof of these assertions requires simple (albeit long) algebra; they can be consulted in Alatorre (1994).
7. Some other examples: KO: (3,5)(3,5); K1: (1,5)(4,3); K2: (2,3)(1,5); K3: (4,3)(5,2); K4: (2,4)(3,4); K5: (3,1)(3,2); K6: (1,2)(4,3); K7: (2,1)(3,4); K8: (1,2)(4,6); K10: (1,2)(3,2); K12: (0,1)(0,2); K14: (1,2)(2,4); K16: (2,2)(3,3).
8. Some other examples: c=c: (2,0)(3,0); cw: (2,1)(3,0); cl: (1,0)(2,3); ci: (1,0)(0,2); w=w: (2,1)(6,3); ww: (2,1)(4,3);
9. Some examples: combinations K1, K2 and K3 have arrays in all locations except c=c, w=w, d=d, l=l and i=i. K12 – K16 only exist in one of these = locations (which only exist in them and in K0). K8 and K10 only have l and i.

11. In each experiment, some items were repeated identically in different parts of the test, and some were used as controls for A and B sides of the same array (see note 2). There was a general inconsistency, such as observed by Koch (1987), although not more in the latter than in the former.

12. Of the cancellations, 51 were due to a misunderstanding of the task, 18 to the use of heuristics such as described in note 3, and 12 to other reasons.

13. Not included in table 2 are {CN+}, {CF – }, {CU+} and {RD+}, because they had very low occurrences (S+C<2%).

14. These percentages were calculated in each group of situations as the mean of the percentages of only correct justifications and correct plus PIECJ plus non-justified-correct-decision answers.

15. These results generally coincide with those of authors like Falk et al (1980), Maury (1986) and Noelting (1980), although the comparison is difficult because of the differences in subjects' age, settings and framework (for instance, all of Noelting's K3, K5 and K7 items were in w, dl or wd locations). Also, it has been shown that there is a strong influence of context in the results obtained in ratio-comparison tasks (Karplus et al, 1983).

REFERENCES

This paper presents some findings on students and authority in the mathematics classroom. It is shown that students create a web of authorities that extends not only to their teachers but also to their fellow students. While it is not asserted that relationships based on authority should be abolished, it is shown that such relationships can interfere with the formation of intellectual partnerships necessary, for example, in collaborative learning. It is also suggested that the dominance of authority relationships may hinder the development of reflective thinking about mathematical ideas. A brief description is also given of the Learners Perspective Study, in which these observations were made.

Much research in recent years has been dedicated to the social context of mathematics education (e.g. Clarke, 2001; Cobb & Bauersfeld, 1995; Edwards & Mercer, 1987). Indeed, it has become almost a truism that understanding the social context of learning is essential to understanding mathematical learning itself. Thus, there is good reason to study students’ relationship to authority: who becomes authority figures for students, what their authority means to students, and how does the relationship to authority affect learning. These are the big questions towards which this paper hopes to make some small steps.

THE RESEARCH SETTING AND METHODOLOGY: THE LEARNERS’ PERSPECTIVE STUDY

The considerations on students and authority presented in this paper emerged from a more extensive, and still ongoing, study of the students’ point of view, called the Learners’ Perspective Study (Clarke, 1998, 2000). The goal of that study is to explore a number of questions concerning the ways students conceive mathematics classroom practice and mathematics learning. Since the answers to such questions are likely to have a cultural dimension, the project adopts an international approach, with research teams working simultaneously in Australia, Germany, U.S.A, Hong Kong, Japan, Israel, Sweden, and South Africa. The authors of the present paper are the principal investigators for the Israeli team.

The Learners’ Perspective Study arose out of the Third International Mathematics and Science Study (TIMSS). TIMSS not only established national profiles of student achievement, but also sought to identify national norms for teaching practice that might account for “poor” or “high” achievement scores by videotaping and analyzing a statistically representative sample of eighth-grade mathematics classes in Japan, Germany and the USA (Fernandez, C. et al., 1997). Although this component of the TIMSS study was impressive and unprecedented in international comparative studies,
the validity of the “effective scripts” discerned in the TIMSS videos was widely debated and not universally accepted (e.g. Keitel & Kilpatrick, 1999; Stigler & Hiebert, 1997, 1998, 1999). One of the major objections was that the TIMSS Video Study focused exclusively on the teacher and ignored the important role students have in the learning process. The present project, accordingly, overcomes this objection and expands on the work done in the TIMSS study by focusing on student actions within the context of whole-class mathematics practice and by adopting a methodology whereby student reconstructions and reflections are considered in a substantial number of videotaped mathematics lessons.

Two specific cases formed the basis for this paper. The first was a sequence of 15 lessons on systems of linear equations taught by a dedicated and experienced teacher, whom we shall call Danit. Danit teaches in a comprehensive high school. Her 8th grade class is heterogeneous and comprises 38 students, mostly native born Israelis, but also new immigrants from the former Soviet Union and one new immigrant from Ethiopia. The second case was a sequence of 4 lessons on geometry taught by a teacher, whom we shall call Sasha. Sasha is a new immigrant from the former Soviet Union with several years experience teaching in Israeli schools and much experience teaching in Russian schools. His 8th class is a high-level class and comprises 30 students.

As specified in Clark (2000), all the classroom sessions were videotaped using an integrated system of three video cameras, one viewing the class as a whole, one on the teacher, and one on a “focus group” of two or three students. Following each lesson, the students in the focus group were interviewed, and their notebooks, containing the notes for that particular lesson, were photocopied. Moreover, once a week the teachers themselves were interviewed. Although we had a basic set of questions for both the student interviews and the teacher interview, we allowed the interview protocol to remain flexible so that we could freely pursue particular classroom events; in this respect, our interview methodology was along the lines of Ginsburg (1997). An important aspect of the interviews was that during the interviews the students could view and react to the videotape of the lesson for which they were the focus group. Needless to say, the interviews themselves were also videotaped.

Among the research questions for the study originally set out in Clarke (2000) was the question of whether teacher and learner practices are conflicting or mutually sustaining. This led us to ask the students about the circumstances in which they request help from their teacher, and, from there, whether they request help from other people as well. These questions, among others, gave rise to a new set of questions for us concerning students and authority, namely, Who is an authority for students? What is the extent of the authority of various people? How pervasive is the influence of authority in students’ mathematical lives? What effect does students’ relationship with authority have on their mathematical practice? Our preliminary findings regarding these questions are the subject of this paper.
Students' Sources of Assistance

When students were asked to whom they turn for help when they run into difficulties, they provided always the following sources of help: their teacher, their friends, their parents, or their siblings. Of these, the students' teacher and friends were the dominant sources of help spoken about in the interviews. When asked to whom they turn first, some students said the teacher and some their friends. The reason given for turning to friends first was almost always that the "teacher is too busy and can't get to everyone." Often, however, it seemed to us from our observations of the class that students turned to their friends first simply because their friends were near, for usually they were students sitting at the same desk.

Teachers, friends, parents and siblings form a web of sources of assistance; when one source is unavailable or unable to help, one turns to another. For example, if Yarden in Sasha's class cannot get help from Sasha, for one reason or another, she turns to one of her friends:

Interviewer: Whom do you turn to for help with homework?

Paulina [the second girl in the focus group]: There's a "dialogue hour" with the teacher.

Interviewer: What if that's not possible?

Yarden: I call a friend.

Interviewer: And if your friend doesn't know?

Yarden: If my friend doesn't know, I ask someone else—or my father.

Can this web be characterized as a hierarchy? One sense in which it can has already been alluded to, namely, as a hierarchy according to physical proximity. Thus, in this hierarchy friends, since they sit at the same table, come first, then the teacher, then parents and siblings. However, more significantly, the web forms a hierarchy according to the degree of authority possessed by the sources. By "the degree of authority" we mean the degree to which a person's statements are to be taken unchallenged (this sense, in a way, is already built into the word "source"; indeed, the Greek word for "source," arche, also means "sovereignty," and in the plural, hai archai, "the authorities"). Conversely, turning to an authority means turning to a person for an answer or for instructions, not, by contrast, for a discussion. Moreover, we use the word "authority" rather than, say, "expertise" because the reason a person's statements are not to be challenged is, as we shall soon see, not always dependent on the degree of the person's knowledge, though it may be perceived that way. Now, in this hierarchy, there is no question, the teacher comes first.

The Teacher's Authority

The teacher's tremendous authority, in every sense of the word, was evident in all of the student interviews in both Danit's and Sasha's class. For example, at one point in
our interview with two students in Danit’s class, Moshe and Sharon, we asked whether a graphical method or algebraic method of finding the solution to a system of equations was more reliable. Here is the exchange:

Moshe: If I get a answer for one and a different answer for the other, then you’ve got to check. If I get the same answer, then I’ll believe it’s correct. But if there’s, maybe, still some doubt in my mind, I ask Danit.

Interviewer: What does Danit have that other people don’t?

Moshe: She’s a teacher, she can help; if you make a mistake, she corrects it!

Interviewer: And if she errs?

Moshe: She doesn’t err.

Sharon: She studies everything at home before she comes to class.

Moshe: Otherwise she couldn’t correct—she’s a teacher!

Interviewer: But she did make a mistake at the board [during the lesson, Danit had made a careless error at the board].

Sharon: She got mixed up because she substituted wrong.

Moshe: Those are nonsense things she gets mixed up about, but real things [gestures to show the weightiness of the things he has in mind]—if two exercises [systems] are supposed to get the same answer or not, it doesn’t seem to me she’d get mixed up about that.

In this exchange, one is impressed by the extent to which Moshe and Sharon are willing to see Danit as nearly infallible, and the extent to which they are willing to defend her authority, even when she is seen to make a mistake. The students view her, apparently, not only as one who knows more than they do, but also as a strong figure with powers they lack. When Moshe says, “She’s a teacher, she can help; if you make a mistake, she corrects it!” he sounds as if he is speaking of a healer, a miracle worker, rather than of his 8th grade math teacher. Similarly, when we asked Sivan and Shimrit, also Danit’s students, what exactly do they expect from the teacher when they ask her for help, Sivan said simply “That she will explain to us better,” to which Shimrit added immediately, “When she comes over to me, when she explains to me, suddenly I understand better...[emphasis added].” Consistent with this image of Danit, was the importance the students seemed to place on the mere fact of Danit’s coming over to help them when they worked on exercises. When we asked what the climax of the lesson was, Elah, in the same interview in which Sivan and Shimrit participated, answered, “When I was having trouble with the book and I called [Danit].” In a different interview, another girl in Danit’s class, Gal, answered the same question in precisely the same way. Conversely, on two different occasions we came across a student in Danit’s class who also appeared to be having trouble with the exercises, but who did not ask Danit for help. When we asked them why not, we received the same response both times: “The teacher doesn’t want to help
me." Such a statement presents a picture in which the attention the students receive from the teacher is dependent on the teacher’s whim. The teacher becomes, in this interpretation, a dictator, though, surely, for most students, a beneficent one who willingly helps them when they need help. Nevertheless, conceiving the teacher as a creature of whim is to conceive the teacher as a creature with terrific power.

**The Web of Authorities**

That the teacher should be given this degree of authority by the students is perhaps not very surprising. However, we were surprised to see how easily students are willing to see other people as authorities to a degree similar to that to which they see their teacher as an authority. For example, we were interested in seeing how students understood the significance of “showing their work,” whether this was only a requirement of students or of mathematics itself. So, we asked whether a salesman who explained to customers how much they should pay given such and such a discount had to show his/her work. To this, Boaz, again from Danit’s class, replied: “No, I can rely on him—I can rely on him—for sure lots of people come to him—there must be those who know percentages and things, and they rely on him, so I can rely on him too.” It is worth noting here that the Hebrew word Boaz uses for “rely” is somech, which is closely related to the word somchute meaning, literally, “authority.”

Students tend to see authorities at every turn. Their web of sources of assistance becomes, in this light, a true web of authorities. What is particularly striking, though, is that this extends also to the students’ friends. As mentioned above, friends in the class are a dominant source of help. But when the students turn to their friends they tend to turn to them only for answers. And, as we saw with Sasha’s student Yarden, when one friend does not know, she turns to another. In one interview in Danit’s class, we asked a student why he did not ask his friend for help at a certain point during the lesson. He replied, “I knew Uri wouldn’t know the answer...” Thus, when students are perceived by their fellow students as knowing the answer to some question they are treated for that instant as an authority, that is, the answer is accepted and not discussed. When students are not perceived as knowing the answer, they are usually not asked. In fact, in the classroom videos it can be seen quite often (though less so in the geometry classes) that students sit together, occasionally speak together, but do not really work together, even though they are not necessarily encouraged to work individually.

To understand the significance of this tendency of students to treat one another as authorities ad hoc, one needs first of all to see what alternative stands opposed to it. This need not be considered hypothetically, for in Sasha’s class we found an exception to the tendency. During his lesson, Sasha gave a geometry problem to the class; we watched as two girls, Yulia and Roni, solved the problem in a truly collaborative spirit. Roni showed her diagram to Yulia; Yulia commented and pointed to her own diagram; they discussed the problem together, and, finally, came to a solution. Yulia and Roni happened to be our focus group for that lesson, and throughout the interview we saw how different their behavior was from other
students we observed: they consulted with one another, raised possibilities on their own, revised opinions, and seemed to arrive at common conclusions. In other words, rather than treating one another as possible authorities, that is, only as possible sources of answers, Yulia and Roni treated one another as intelligent interlocutors who could work together to make progress on the question at hand. We should stress that this was, indeed, behavior different not only from that of students in Danit's class, but also from that of other students in Sasha's class. For instance, at one point in our interview with Yarden, we asked if she could draw a triangle having two acute exterior angles; she said she could, and she proceeded to draw a diagram, which, obviously, could not be correct. When we asked Paulina, the second girl in the focus group, whether Yarden's diagram was ok, she assented immediately and with no further remark.

**CONCLUSIONS—AUTHORITY AND STUDENTS' ABILITY TO REFLECT**

Speaking about argumentation, Simon (2000) claims that, because students treat teachers as authorities who can give a stamp of approval on the students' mathematical arguments, it does not follow that students lack the ability and willingness to engage in the validation process themselves. This is a reasonable claim, and, certainly, our interview with Moshe, quoted above, gives some confirmation of it. Simon compares the students' relationship to the teacher, in her/his capacity as an authority, to the situation of a mathematician who is working in a field not her/his own and who seeks the evaluation of an expert in that field (Simon, 2000, p.166). But the evidence presented above shows that the way the teacher is an authority for the student is much stronger than this. In this connection, we tend to agree with Lewis-Shaw when she writes “[The students’] perspective consists in relating to the world with less awareness of the nature and extent of their personal authority or control. Consequently, they strive for a sense of belonging, count on the teacher for some level of security and authority and regard him as the holder of knowledge and expertise” (Lewis-Shaw, 2001, p.182).

This strong authority relationship is bound to effect the way students engage in mathematical thinking. An indication of this is given in Helme and Clarke (2001). They report that when a teacher approached a small group of students working on a problem there was a different pattern of interaction in which the teacher's questions became the central focus. Moreover, “With the teacher asking virtually all the questions, there was little opportunity for students to initiate ideas or spontaneously express and resolve uncertainty” (Helme & Clarke, 2001, p.146). Such a situation cannot be conducive to reflective thought about mathematical ideas.

In Danit’s class, we observed an interesting instance that demonstrates, we believe, that the teacher’s authority can create conditions in which it becomes very easy for students to use concepts unreflectively. At a certain stage while discussing the system,
Danit asked what allows us to go from \(2x+3y=18\) to \(2\cdot3+3y=18\), that is, what allows us to substitute 3 in place of \(x\)? She prompted the class, saying, “It begins with ‘A’…” Finally, Uriel, whom we interviewed afterwards, said “axiom.” But which “axiom”? Danit gave the answer the “axiom of replacement.” We asked Uriel about what went on in that instance. Uriel told us how he remembered the word “axiom” when Danit said that the word began with “A”. We discussed the meaning of axiom, which he seemed to grasp in a very rudimentary way. However, when we asked Uriel if he had any idea why such an axiom might be needed, he had difficulty grasping what we were asking him. It became clear that Uriel recognized an axiom here mainly because Danit said there was one. In other words, the need for an axiom was accepted on Danit’s authority only. This was striking because more than once during the lesson Danit emphasized that things in mathematics were not true because she said so, or because the book said so, or because anyone else simply said so.

That the pattern of authority existing between teacher and student can also come to characterize the relationship between students, even in a small measure, clearly has important implications for collaborative learning. For as Johnson and Johnson say, “Simply placing students in groups and telling them to work together does not promote greater understanding of mathematical principles or the ability to communicate mathematical reasoning to others. Group efforts can go wrong in many ways” (Johnson & Johnson, 1989, p.237). Where students are accustomed to treat one another as authorities one student will simply listen and assent to the other, or, if not, will turn to a different authority, just as Yarden turns to another friend when the first “doesn’t know.” The point is, where students are accustomed to treat one another as authorities no true dialogue takes place between them, and where there is no true dialogue there can be no true collaborative learning. Thus, the establishment of an authority relationship between students becomes one of the most potent ways in which “Group efforts can go wrong”! The point would be merely an academic one if it were not that collaborative learning seems to be one of the more effective means of encouraging reflective thinking (e.g. Johnson & Johnson, 1989, p.236). In this way, by helping to develop a relationship between students not based on authority, but on intellectual partnership, we go far towards encouraging also the kind of thoughtful approach to learning mathematics that most of us strive for.

SCAFFOLDING PRACTICES THAT ENHANCE MATHEMATICS LEARNING

Julia Anghileri

University of Cambridge, UK

It is just over 25 years since Wood et al. (1976) introduced the idea of 'scaffolding' to represent the way children's learning can be supported. Despite problems, this metaphor has enduring attraction in the way it emphasises the intent to support a sound foundation with increasing independence for the learner as understanding becomes more secure. It has resonance with the widely accepted notion of construction and the constructivist paradigm for learning. The discussion that follows will characterise some classroom practices that can be identified as scaffolding, revisiting some of the original classifications, and identifying further scaffolding strategies with particular reference to mathematics learning.

BACKGROUND

The metaphor of scaffolding was introduced by Wood et al. (1976) to explore the nature of adult interactions in children’s learning, in particular, the support that an adult provides in helping a child to learn how to perform a task that cannot be mastered alone. Such interactions are also informed by Vygotsky's (1978) concept of the Zone of Proximal Development, and writing based on the relationship between these two ideas have been extensively developed (Rogoff and Wertsch, 1984).

The notion of scaffolding is used to reflect the way support is adjusted as the child learns and is ultimately removed when the learner can ‘stand alone’. Wood et al. identifying six key elements: recruitment - enlisting the learner’s interest and adherence to the task; reduction in degrees of freedom - simplifying the task so that feedback is regulated and can be used for correction; direction maintenance - keeping the learner in pursuit of a particular objective; marking critical features - accentuating some and interpreting discrepancies; frustration control - responses to the learners emotional state and demonstration; or modelling a solution to a task. In discussing the last of these, a hint is given to the complexities that may not be apparent in this classification. In demonstrating or ‘modelling’ a solution to a task, for example, “the tutor is ‘imitating’ in idealised form an attempted solution tried (or assumed to be tried) by the tutee in the expectation that the learner will the ‘imitate’ it back in a more appropriate form” (Wood et al. 1976:98).

Tharpe and Gallimore (1988) use the term ‘assisted learning’ in relating educational practices with Vygotsky’s notion of a Zone of Proximal Development. They identify six interdependent means of assisting performance: modelling - offering behaviour for imitation; contingency management - rewards and punishment arranged to follow on behaviour; feeding back - information resulting from experiences; instructing - calling for specific action; questioning - calling for linguistic response; cognitive structuring - providing explanations and belief structures that organise and justify. Of these they
claim cognitive structuring, which provides a ‘structure for thinking and acting’, is the
most comprehensive and most ‘intuitively obvious’. They note, however, ‘study after
study has documented the absence in classrooms of this fundamental tool: assistance
provided by more capable others that is responsive to goal-directed activities’ (Tharpe
et al.1988: 42).

The dependence on adult interaction is qualified by Rogoff and colleagues who use the
notion of ‘guided participation’ and regard children’s development as ‘occurring
through their active participation in culturally structured activity with the guidance,
support and challenge of companions who vary in skills and status’ (Rogoff et
al.1993:5). They noted two patterns of interactive behaviour: one in which the adult
structures children’s learning by organising children’s attention, motivation and
involvement and by providing lessons taken from the context of an ongoing activity;
the other in which children take primary responsibility for learning by managing their
own attention, motivation and participation with adults providing assistance that is
more responsive than directive.

SCAFFOLDING AND CLASSROOM PRACTICES

Research that attempts to characterise scaffolding practices in the classroom has
suggested that teaching situations are more complex than small group settings and
‘contingent responding requires a detailed understanding of the learner’s history, the
immediate task and the teaching strategies needed to move on’ (Hobsbaum et al.1996).
Despite this difficulty they support the notion of scaffolding and characterise key
elements identified in a Reading Recovery scheme:

- a measured amount of support without reducing the child’s initiative;
- careful selection of the task at just the right level of difficulty with right balance of
general ease but some challenge;
- child must be able to make sense of task using every available source of
information;
- strategies made explicit - drawing explicit attention to strategies and processes.

(Hobsbaum et al.1996: 22).

In their analysis of ‘talk cycles’ they found ‘the predominant teacher strategy, by a
long margin, for leading the move onto the next word cycle was telling’ (p26). Teachers
did, however, ‘structure the internal setting so that the child develops
increasingly more complex actions independently’.

In studying classroom teaching sequences in mathematics, science, and design and
technology, Bliss et al.(1996) looked for instances of scaffolding but report ‘a relative
absence of scaffolding in most lessons’. Some ‘actual scaffolds’ are identified as:
approval, encouragement, structuring work, and organising people. ‘Props scaffolds’
are also identified where the teacher provides a suggestion that will help pupils
throughout the task and ‘localised scaffolds’ providing specific help ‘where a teacher
finds it difficult to help the pupil with an overall idea or concept simply because it is too large and complex'. Two further scaffolds which Bliss et al. suggest were ‘really more like cueing’ were step-by-step or foothold scaffolds (often in a series of questions) and hints and slots scaffolds (narrowing questions until only one answer fits). They report few actual scaffolds and suggest reasons for absence of scaffolds in 4 categories: pseudo-interactions or bypassing (which accounted for the majority of classroom instances recorded); scaffolding precluded by directive teaching; scaffolding excluded by initiative being given to the pupils; conditions for scaffolding present but not noticed by the teacher (Bliss et al.1996:46).

Despite the negative connotations of the latter study, teachers are integral to the learning process and the following discussion will identify strategies that can be classed as scaffolding, with illustrations taken from research studies in mathematics. Some different aspects of the scaffolding process will be illustrated in relation to geometry in the early years of schooling and arithmetic in later elementary years.

IDENTIFIABLE SCAFFOLDING PROCESSES

Some scaffolding practices are found in every classroom while others may be lacking completely. The classroom environment, for example, is prepared by a teacher as a resource for learning with materials available for the students to see, touch and use in their work. Other forms of scaffolding that may be less evident include peer interactions which is minimised where students work from texts in class and at home. Explaining and questioning will be common in most teaching approaches but analysis of these practices shows complex variations in the balance of interactions intended to support pupils’ learning. In the following discussion, scaffolding strategies will be identified with further classification as reviewing and restructuring in a hierarchical inter-relationship.

Teaching strategies that focus on the provisions for the learning environment but do not directly relate to interactions between students and teacher are classed as Level 1 scaffolding. Also classified at this level will be emotive interactions that are general in their nature. Level 2 involves direct interactions between teachers and students specifically focused on the task in hand. Such strategies vary from direct instruction - showing and telling - to more collaborative meaning making. At Level 3 the fundamental aim is to establish connections between what students have within their experiences and new mathematics to be learned. Mathematical thinking is supported through conceptual discourse and the establishment of representations. At any stage, mathematical learning is enhanced by scaffolding at each of these levels, and the following hierarchy reflects not only the progressive (and often circular) supporting strategies that can be used, but also the way effective interactions may be bypassed in more direct teaching approaches.
LEVEL 1 SCAFFOLDING

Before interacting with the children, teachers will create an environment for learning with a choice of wall displays, puzzles, tasks, appropriate tools and classroom organisation (Tharpe et al. 1988). This form of scaffolding has not always been explicitly acknowledged in research (e.g. Bliss et al. 1996) but is a crucial element of any school practice. Opportunities for using building blocks in free play, for example, results in improved performance on geometry tasks with this performance further enhanced by interactions with a ‘more experienced other’ (Wood et al. 1976; Coltman et al. 2002). Self-correcting elements provide feedback that supports pupils, not only in finding a solution, but also in reflecting on the processes involved in such a solution and so becoming self-regulating in their actions (Tharpe et al. 1988).

The tasks that teachers select require organisational considerations, for example, appropriate sequencing and pacing, and groupings for peer collaboration. Light and Littleton (1999) report ‘compelling evidence for the benefits in terms of learning of peer collaboration’ and establish that peer collaboration need not involve ‘a more
experienced other'. Doise et al. (1984) showed that children of slightly different pre-
test level, working together in pairs or threes, tended to perform at a higher level when
working as a group than children working alone and this benefit carried over to post-
test performances. Large differences in terms of the children's pre-test levels were
associated with less progress than small differences in initial ability.

Also at Level 1, but less specific to mathematics learning is emotive feedback like
gaining individual's attention or offering praise. Bliss et al. included 'approval (and)
encouragement' in the majority of what they called 'actual scaffolds' along with
'structuring work' and 'organising people' (Bliss et al. 1996: 47).

LEVEL 2 SCAFFOLDING

Mathematics can be presented as a series of skills and processes that are known to the
teacher and transmitted to students through showing and telling. On the other hand,
students can be more involved in the development of mathematical knowledge through
interactions that progressively develop their own understandings.

Showing, Telling and Explaining

Showing and telling need little introduction as they have been traditional in classroom
teaching for generations and continue to dominate classroom practice (Hobsbaum et
al. 1996; Pimm, 1987). With this strategy teachers retained control and structure
conversations to take account of the 'next step' they have planned. Students can make
their own sense of instruction sometimes in very different ways from the teacher
(Bliss et al. 1996: 41). Closely related to the classroom practice of 'showing and
telling' is the notion of 'explaining' where the teacher amplifies a process or concept,
or elaborates why solutions are inaccurate or inappropriate. In contrast to this teaching
approach which is built upon teachers' explanations, social norms can be established
in the classroom where the students actively participate by explaining and justifying
their own thinking (Cobb et al., 1991). Askew et al. (1997) found that for effective
teaching it is crucial to encourage pupils to 'develop strategies and networks of ideas
by being challenged to think, through explaining, listening and problem solving'.

Scaffolding that goes beyond showing, telling and explaining

In contrast to telling students what to do and how to think about a problem, there are
practices which provide support for developing students' own understanding of
mathematics. REVIEWING relates to interactions that: encourage students to look,
touch and verbalise; use questions, cues and parallel modeling; interpret student
actions. RESTRUCTURING involves teachers making adaptations: by constraining or
limiting the tasks; by giving meaningful contexts; by sensitively rephrasing students'
talk and solutions; and by negotiating meanings.

Looking, touching, verbalising, and parallel modelling

In arithmetic teaching the encouragement to “tell me what you did” can help a student
to be self correcting or more efficient. ‘It seems that the act of attempting to express
their thoughts aloud in words has helped pupils to clarify and organise the thoughts
themselves' (Pimm 1987:23). Handling materials and verbalising observations can
provide a different orientation and lead to better understanding of mathematical tasks
(Coltman et al. 2002). When such reflective interactions are not sufficient there can be
a temptation to 'tell' a solution. However, an alternative strategy, evident in studies of
gEometric block tasks, can be 'parallel modeling' where an equivalent task is
demonstrated that helps develop transferable skills in the student (Coltman et al.2002).

Questioning

Pimm (1987) discusses a framework of questioning which 'locks the teacher into
'center stage', acting as controller as well as heavily influencing the types and range of
spoken pupil contributions in class. Tharpe et al.(1988) note that 'it is easy to feel “in
sync” with the students when the yes/no answers flow smoothly.....(when) she (the
teacher) has inadvertently ‘fed’ them lines rather than assisting comprehension'. At the
other extreme, questions can be posed that encourage the children to construct their
own mathematical understanding and to determine independently whether they have
reached mathematically valid solutions. Chappell et al.(1999) propose that ‘when we
modify the questions that we ask ... our assessment of students’ thinking refines our
instructional practice and indicates to students that we value their ability to
communicate about mathematics’.

Interpreting students actions/ Making strategies explicit

Wood et al. (1976) note that ‘the learner must be able to recognise a solution to a
particular class of problems before he is himself able to produce the steps leading to it
without assistance’ (p90). This recognition of the relevance of actions can involve a
teacher interpreting students actions and making strategies explicit. Hobsbaum et al.
include ‘drawing explicit attention to strategies and processes (which) provides a
model of behavioral regulation for the learner, which may become internalised, a

Constraining, limiting and simplifying

In Wood et al.’s original paper one element scaffolding was identified as: ‘reduction in
degrees of freedom - simplifying the task so that feedback is regulated to a level which
could be used for correction’. An example is given in reducing from three blocks in a
repeating sequence to two blocks (Coltman et al. 2002) or simplifying the numbers in a
calculation can make a task accessible before building towards the more complex task.

Identifying meaningful contexts

Meaningful contexts can help students find solutions to tasks where they cannot solve
related abstract problems. Young children can more successfully solve tasks given in
context and then transfer their learning back to abstract tasks (Coltman et al. 2002). In
arithmetic, the shift from an abstract calculation, for example, ‘6 ÷ 12 = ’, to a
contextual setting: “Six pizzas are to be shared among 12 people. How much does
each person get?”, can take a problem from inaccessibility to the construction of a meaningful solution (Anghileri 2000).

**Re-phrasing students talk and negotiating meanings**

As a teacher pays close attention to the utterances of pupils, many ‘spoken formulations and revisions will often be required before an acceptable and stable expression can be agreed upon by all participants’ (Pimm 87:23). The teacher’s role is to highlight processes involved in solutions, sometimes re-describing students efforts and making clear the mathematical aspects that are most valued. Considerable sensitivity may be needed to ‘unpick’ the essence of students’ talk, rephrasing where necessary to make ideas clearer without losing the intended meaning, and negotiating new meanings to establish mathematically valid understandings (Anghileri 1995).

**LEVEL 3 SCAFFOLDING**

**Making connections**

Through both REVIEWING and RESTRUCTURING students can be supported in making connections with their previous experiences. Askew et al.(1997) use the term ‘connectionist’ to characterise highly effective teachers who believe that pupils develop strategies and networks of ideas with teacher interventions to connect existing understandings with mathematics to be learned. Lack of connections can hamper progress. In arithmetic, for example, discontinuity between informal approaches and taught procedures can result in little progress while teaching approaches that develop progressive connections lead to better improvements (Anghileri 2000).

**Developing representational tools**

Much of mathematical learning relates to the interpretation and use of systems of images, words and symbols. Such representations, in addition to providing a means of communication, can also be developed as tools for structuring knowledge and to index the systems in which they arise. Cuoco et al. present a wide range of perspectives about the nature and purposes of representation with distinctions made between external representations (marks on paper, geometric sketches, equations etc.) and internal representations (images we create in our minds for mathematical objects and processes) (Cuoco et al. 2001:x). With teacher guidance, a symbolic record can facilitate discussions, and representations including pictures, diagrams chart and tables can be used not only for recording but as tools for thinking.

**Generating conceptual discourse**

Teachers play a vital role in shaping classroom discourse through signals they send about the knowledge and ways of thinking that are valued. Cobb et al. (1991) identify classroom discourse as critical in supporting the students’ development and focus on 2 characteristics that relate specifically to math learning: the norms and standards for what counts as acceptable math explanation (conceptual not computational) and the content of the whole class discussion. With a conceptual orientation students are likely
to engage in longer, more meaningful discussions and meanings come to be shared as each individual engages in the communal act of making mathematical meanings.

SUMMARY
This brief review of scaffolding processes is an attempt to identify a hierarchy of classroom interactions that can enhance mathematics learning by diverging from the narrow approach that has been typical in the past.

PROVING OR REFUTING ARITHMETIC CLAIMS: 
THE CASE OF ELEMENTARY SCHOOL TEACHERS

Ruth Barkai, Pessia Tsamir, Dina Tirosh and Tommy Dreyfus
Kibbutzim Teacher College   Tel Aviv University

Abstract: We examined elementary school teachers’ justifications to number-theoretical “for all” propositions and existence propositions, some of which are true while others are false. We also assessed whether teachers regarded their justifications as mathematical proofs. About half of the teachers produced formal algebraic proofs. A smaller number of teachers produced non-formal proofs appropriate for presentation in elementary school classes. However, a substantial number of teachers applied inadequate methods to validate or refute the propositions. Finally, many teachers were uncertain about the status of the justifications they gave.

The processes of examining the validity of conjectures, proving correct ones as well as refuting wrong ones are at the core of any student’s mathematical development. It is therefore essential that teachers are intimately familiar with and confident in producing and reacting to arguments that purport to prove or refute mathematical statements that are discussed in their classrooms. Prior research (Jones, 1997; Martin and Harel, 1989; Movshovitz-Hadar and Hadas, 1988; Simon and Blume, 1996) has shown that not all is well in this respect.

This paper reports on a study aimed at examining elementary school teachers’ justifications to number-theoretical propositions, some of which are true while others are false. We also examined teachers’ views of the status of their justifications, that is, whether they regarded them as mathematical proofs. In this paper we shall focus on describing the various justifications that the teachers provided to “for all” propositions and to existence propositions.

METHOD

Participants

A class of 27 in-service elementary school teachers (25 women, 2 men) participated in the study. All were in their first year of a three-year professional development program at an Israeli university, a course that mainly focused on introducing the mathematics topics that are part of the elementary school mathematics curriculum from an advanced mathematical viewpoint. The participating teachers were engaged in teaching mathematics, as well as other subjects, in the upper grades of elementary school (grades 3-6). Their teaching experience varied considerably: Eight were in their first five years of teaching, eight taught between six and fifteen years and twelve taught more than 15 years.

Tools and Procedure

A questionnaire, including the following six, number-theoretical propositions, was administered to the teachers during a 90 minute session:
"For all" propositions
1. The sum of any five consecutive integers is divisible by five.
2. The sum of any four consecutive integers is divisible by four.
3. The sum of any three consecutive integers is divisible by six.

Existence propositions
4. There exist five consecutive integers whose sum is divisible by five.
5. There exist four consecutive integers whose sum is divisible by four.
6. There exist three consecutive integers whose sum is divisible by six.

Propositions 1 and 4 are both true, because the sum of any sequence of five consecutive integers is divisible by five. Propositions 2 and 5 are both false, because no sum of four consecutive numbers is divisible by four. Proposition 3 ("for all") is false and Proposition 6 is true, because the sum of some sequences of three consecutive numbers is divisible by six while the sum of others is not. Half of the teachers responded first to the "for all" tasks while the other half responded first to the existence tasks.

The teachers were asked to consider each proposition and (1) decide whether it is true or false and justify their claim; (2) determine whether, in their opinion, the lecturers would consider their justifications as mathematical proofs. It was assumed that the lecturers were perceived by the participants as representatives of the mathematical community. Therefore, this was a measure of the extent to which the teachers viewed their own justifications as mathematical proofs.

RESULTS
The results of both the "for all" and the "existence" tasks are summarized in the following Figure. The figure presents, for each proposition, the number of teachers who responded to it, the percentage of correct judgments (left, white bar) and the percentage of correct justifications (right, shaded bar).
Furthermore, the figure presents the percentage of teachers who expected their judgments to be acceptable by the lectures (line inside left bar) and the percentage of teachers who had given a correct justification and expected it to be acceptable by the lecturers (line inside right bar). It should be noted that justifications were classified as incorrect only if they contained mathematical errors or if they were inadequate in terms of the methodology that was used to prove or refute a proposition (e.g., using supportive examples to prove a “for all” proposition or using a counterexample for refuting an existence proposition).

“For all” Propositions

Proposition 1: The sum of any five consecutive integers is divisible by five.

All participants correctly stated that this proposition is true. However, only 41% accompanied their correct claim by correct justifications (see Figure). Almost all these justifications were algebraic proofs (33%) and they were commonly regarded as proofs by those who provided them (30%). A typical proof was:

Shelly: \( x+x+1+x+2+x+3+x+4 = 5x+10 \). Any number substituted for \( x \) is multiplied by 5, 5x is divisible by 5, 10 is a multiple of 5, so 5x+10 is always divisible by 5.

Two teachers, Odette and Anna, provided non-algebraic proofs. Odette attempted (and succeeded) to “cover all possibilities”:

Odette: I first tried all the possible examples of 5 consecutive numbers within the first ten numbers: 1+2+3+4+5=15, 2+3+4+5+6=20, 3+4+5+6+7=25, 4+5+6+7+8=30, 5+6+7+8+9=35, 6+7+8+9+10=40, 7+8+9+10+11=45, 8+9+10+11+12=50, 9+10+11+12+13=55, 10+11+12+13+14=60.

All other sums of five consecutive numbers are created by adding one of these sequences to certain multiples of 10 (for instance, 44+45+46+47+48 is composed of 5 times 40 and the sequence: 4+5+6+7+8=30 that we had before. The number 40 is composed of 10 times a number and since 10 is divisible by 5, 40 is also divisible by 5). The same holds for three digit numbers (since 100 is divisible by 5), for four digit numbers, etc. So each such sum is divisible by 5.

Odette regarded her justification as a mere example, insufficient for proving the proposition. She wrote: “I still need to find a rule, beyond my examples”.

Anna examined the general structure of any sequence of five consecutive numbers and gave the following, generic proof (Balacheff, 1987):

Anna: When we add five consecutive numbers, for instance, 1,2,3,4,5, we can look at these numbers in the following way: We have the number in the middle (3), then, the sum of the two numbers that stand next to it from both sides (2 on one side and 4 on the other) is 3-1 plus 3+1. The -1 cancels the +1 and we get 2*3. Similarly, 5 is 3+2 and 1 is 3-2 so we have, again, twice the number in the middle. All in all, the sum is 5 times the number in the middle, and 5 times any number is divisible by 5.

Unlike Odette, Anna was sure that her justification is a mathematical proof.
Most incorrect justifications consisted of providing one or more supporting examples (52%). These justifications were perceived as proofs by 33% of the teachers. Two teachers provided an improper algebraic justification. They reached the expression 5x+10, but then “solved” it in the following manner:

**Sofie:** \(x+x+1+x+2+x+3+x+4=5x+10\). \(5x=-10, x=-2\). The answer is \((-2, -1, 0, 1, 2)\). I got an answer; therefore the sum is divisible by 5.

While one of these two teachers viewed her justification as a mathematical proof, the other expressed reservations, stating that she was unsure whether one example \((-2, -1, 0, 1, 2)\) is sufficient to prove a proposition.

**Proposition 2:** The sum of any four consecutive integers is divisible by four.

The figure shows that in this case, all teachers correctly stated that the proposition is false and all those who justified this assertion provided correct justifications to their claim (three teachers stated that the proposition is false but provided no justification). Most justifications consisted of one or more counterexamples (72%). Some correctly commented that a single counterexample is sufficient for refuting a claim while others doubted the status of such examples. Indeed, half of those who provided counterexamples regarded them as proofs (36%).

Sixteen percent of the teachers provided algebraic proofs and regarded them as proofs. A typical proof was:

**Ramit:** \(x+x+1+x+2+x+3+x+4=4x+6\), \(4x\) is divisible by 4 but 6 is not divisible by 4. Therefore the sum \(4x+6\) is not divisible by 4.

**Proposition 3:** The sum of any three consecutive integers is divisible by six.

Here, unlike the previous cases, not all the teachers correctly judged the proposition as false (see Figure). While most teachers (69%) correctly stated that the proposition is false, 23% incorrectly claimed that it is true and 8% were unsure about its status.

All those who correctly argued that the proposition is false accompanied this judgment with correct justifications. Most correct justifications (42%) consisted of counterexamples. Maria, for instance, explained:

**Maria:** \(2+3+4=9, 4+5=6=15, 7+8+9=24, 8+9+10=27, 10+11+12=33, 14+15+16=45, 16+17+18=51, 27+28+29=51\). I found many examples for which the sum is not divisible by 6. Therefore, the statement is incorrect.

Unlike Maria, Lily provided only one counterexample and noted that one such example is sufficient for refuting a proposition of this kind:

**Lily:** This is a general proposition. We need one counterexample to prove that it is false: \(0+1+2=3\) and 3 is not divisible by 6.

Of the 50% who stated that the proposition is false and provided one or more counterexamples, most (38%) expected the lecturers to accept them as mathematical proofs. Those who did not (11%), were either unsure that examples are sufficient to
refute a given proposition or stated that examples are not mathematical proofs and further explained that they do not know the proof and therefore all they could do was provide some examples.

The remaining teachers who correctly stated that the proposition is false provided algebraic justifications (19% of the teachers) and all but one of them regarded these justifications as proofs. The most prevalent algebraic justification was:

Lima: \( x \) is the first number in the sequence \( x + x + 1 + x + 2 = 3x + 3 \). The sum of this sequence is divisible by 3. We have to show that the sum is also divisible by 2. If \( x \) is even then \( 3x \) is even but if we add 3 we get an odd number, so \( 3x + 3 \) is not divisible by 6. If \( x \) is odd then \( 3x \) is odd and \( 3x + 3 \) is even and then it is divisible by 6. The proposition does not hold for all sequences. Therefore, it is false.

Miki gave another argument that used algebraic notation:

Miki: \( 1 + 2 + 3 = 6, \) \( 6 \) is divisible by 6; \( 0 + 1 + 2 = 3, \) \( 3 \) is NOT divisible by 6; \( 4 + 5 + 6 = 15, \) 15 is NOT divisible by 6; \( 7 + 8 + 9 = 24, \) 24 is divisible by 6.

The sum of all sequences of three consecutive numbers \( x - 1, x, x + 1 \) is divisible by 3, because, \( x - 1 + x + x + 1 = 3x \) (-1 and +1 cancel each other and we get 3 times \( x \)).

But \( 3x \) is divisible by 6 only if the middle number, \( x \), is even.

All teachers who incorrectly claimed that the proposition is true provided supportive examples. Only one of them expected his justification to be accepted as a mathematical proof. Those who were unsure about the status of the proposition provided both supportive and counterexamples. They did not expect that their justifications would be accepted as mathematical proofs.

Existence Propositions

Proposition 4: There exist five consecutive integers whose sum is divisible by five.

All participants correctly stated that this proposition is true and all but one participant accompanied their correct claim by correct justifications (see Figure). The most prevalent justification consisted of one or more adequate examples (50%), yet, only half of those who gave such examples regarded them as mathematical proofs.

Two teachers explicitly related to the type of this proposition, arguing that one supportive example is sufficient for proving it. Ora, for instance, wrote:

Ora: If the claim starts with "there exist" it is sufficient to provide one example to prove existence. In this case, \( 1 + 2 + 3 + 4 + 5 = 15 \), and \( 15 \) is divisible by 5.

Algebraic proofs were given by about a third of the teachers (38%). Odette and Anna, who provided non-algebraic proofs to the matching, general proposition (Proposition 1), repeated the same justifications for the existence proposition. This time, however, both viewed their justifications as mathematical proofs. We note that none of the teachers referred to the fact that Proposition 4 trivially follows from Proposition 1, even though 50% of them had worked on proposition 1 shortly before
working on Proposition 4. Vinner (1983) has observed similar behavior among senior high school students.

Proposition 5: There exist four consecutive integers whose sum is divisible by four.

Most teachers (77%) correctly stated that this proposition is false. Yet, 15% incorrectly claimed that it is true and 8% were unsure about its status. This was the only proposition to which less than a quarter of the teachers provided both correct answers and correct justifications. Most correct justifications (19%) were algebraic proofs that were presented by the same teachers to both this proposition and to the matching “for all” proposition (Proposition 2). While 12% of the teachers viewed their algebraic justifications as mathematical proofs, 7% were unsure that such justification refutes the proposition.

Sami provided an original, correct justification:

Sami: There are no four consecutive numbers whose sum is divisible by 4. I’ll prove it in the following way:
The sum of the first sequence of numbers: 0+1+2+3=6, is not divisible by 4.
The second sequence is formed by enlarging each number in the sequence by 1. Instead of 0, 1, 2, 3 we get 0+1=1, 1+1=2, 2+1=3, 3+1=4 so we get 1, 2, 3, 4. The sum this time is 10 because we added 1 to each of the four numbers in the previous sequence. Since 6 is not divisible by four, and we added four, the sum (6+4) is also not divisible by 4. The next sequence 2, 3, 4, 5, is created in a similar manner, and the sum is 14. Consequently, the sum of each sequence is larger by 4 than the previous sum. Since we start with a sum that is NOT divisible by 4, the jumps by four always bring us to new numbers that are not divisible by 4. In this way we can show that the sum of no such sequence is divisible by 4.

Most teachers who incorrectly claimed that the proposition is true explained that they tried several examples and none of them fulfilled the condition. Yet, they felt that if they continued their search they would eventually find a supportive example. The teachers who were unsure about the status of the proposition went through a similar process (namely, trying, with no success, to find supportive examples) but they remained uncertain whether such an example exists.

Proposition 6: There exist three consecutive numbers whose sum is divisible by six.

Most teachers (68%) correctly stated that this proposition is true, and all but one of them accompanied their correct claim by correct justifications (One teacher provided no justification). The most prevalent justification consisted of one or more supportive examples (40%) most of which (28%) were regarded as mathematical proofs. The remaining justifications were algebraic and, much like in the case of propositions 1 and 4, they were identical to the algebraic justifications that were presented by the same teachers to the matching, “for all” proposition (Proposition 3).

The teachers who incorrectly stated that the proposition is false (24%) provided as justification one or more examples of three consecutive numbers whose sum is not
divisible by 6. Most of them (20%) regarded these examples as counterexamples and expected the lecturers to accept their justifications as proofs. Amit, for instance, wrote “a counterexample is sufficient to refute any proposition, including this one”. It seems that Amit, and others, overgeneralized a scheme that holds for refuting “for all” propositions and used it for refuting existence propositions as well. Two teachers (8%) could not decide whether the proposition is true or false, because they found both supportive and counterexamples.

FINAL COMMENTS

1. There is a wide consensus in the mathematics education community that teachers should encourage students to make mathematical conjectures and investigate them (e.g., NCTM, 2000). A growing number of studies identify conjectures, generalizations, refutations, and even proving among elementary school students (e.g., Ball and Bass, 2000; Lampert, 1990; Maher and Marino, 1996; Zack, 1997). Students present conjectures of different types (e.g., “for all”, existence, true, false) and apply different ways to verify them. Teachers, the representatives of the mathematical community in class, have a crucial role in establishing the various sociomathematical norms in general and those related to justifications, argumentation and proofs in particular (Yackel and Cobb, 1996). To fulfill this role, it is crucial that teachers be knowledgeable about different types of propositions and ways of proving or refuting them. Our paper shows that a substantial number of elementary school teachers applied inadequate methods to validate and to refute various propositions. Two salient cases relate to the use of examples: Supportive examples were used by about half of the participants to prove “for all” theorems and about 20% of the participants refuted an existence proposition by counterexamples. These findings call for more attention to this aspect of elementary school teachers’ knowledge in professional development programs and in research.

2. Teaching mathematical reasoning and proof in elementary school is a very demanding job. When an elementary school teacher is confronted with a student’s conjecture, such as the ones given here, he/she should be able to both examine its validity and to find suitable, non-formal ways to communicate about this conjecture with his students. The propositions that were presented in this study could relatively easily be proved or refuted with algebraic tools. Thus, algebra is a powerful tool that could be used by teachers in elementary schools to determine the validity of number-theoretical propositions and other propositions that could be raised by students in class. However, our data show that only about half of the teachers used algebraic tools in their attempts either to prove or to refute at least one of the propositions. These teachers usually did so in an appropriate manner and most of them were confident that their justifications are mathematical proofs. Moreover, about 20% of the teachers were aware of a need for a more general proof for some propositions, but noted that they did not have the required knowledge. Thus, it seems essential that professional development programs attempt to enhance elementary
school teachers’ algebraic reasoning so that they would be able to use this knowledge to determine the validity of their students’ conjectures.

3. As stated previously, it is essential that elementary school teachers be able to present non-formal proofs in their classes. A number of such proofs were presented by some teachers in our study (e.g., Odette, Anna and Sami). It is important to find out how students and teachers conceived these justifications: Do they regard them as proofs? How do they explain their decisions? Do teachers who have better algebraic reasoning accept these justifications as proofs? These and other related issues are currently under investigation.

REFERENCES

Having a facility with numbers (whole numbers and decimals) is essential for life skills. It requires an understanding and coordination of several powerful mathematical concepts (e.g., place value, additive and multiplicative fields, the role of zero, seriation) and principles (e.g., "odometer", associative, commutative distribute) (Baturo, 2000). This paper reports on 329 Year 6 students' proficiency with seriation of tenths and hundredths when instruction in these two places was complete. They were asked to add 1 tenth and 1 hundredth to a variety of given numbers with the overall results of 53.6% and 54.6% respectively. These results were evaluated in terms of the students' responses to basic place value tasks. This paper analyses the mathematical structure of the tasks, discusses some common error patterns discerned, and draws inferences for teaching.

The decimal number system is superficially simple but is structurally very complex. It is derived from the notion of a unit (Steffe, 1986), the importance (and complexity) of which is often not considered because of its deceptively simple association with one object. The decimal number system consists of simple yet powerful patterns within the domain of whole numbers and decimal numbers, patterns which should encourage the development of succinct yet global mental models within and between each of these domains. Within the domain of whole numbers, students are exposed to processes such as counting, comparing, grouping, regrouping, and approximating, most of which can be transferred without adaptation to decimal numbers (see Baturo, 2000, for a mathematical analysis of these processes). However, comparing is a process that must be adapted for decimal and common fractions (see, e.g., Resnick et al., 1989; Stacey et al., 2001). Furthermore, a study of whole numbers should develop an awareness of the commutative, associative, and distributive laws which can then be transferred without adaptation to decimal numbers (and to common fractions, percents etc.).

Another global principle that occurs in the decimal number system is referred to as the "odometer" principle in this paper. It underlies the counting process and requires an understanding that a place is "full" when it has 9 units (which could be ones, tens, tenths, etc) and that recording the next number requires a new position to the left of the place under consideration. Embedded in this principle is the notion of place value which requires an understanding of the role of the base, the order of places, and that numbers increase in value as they "move" to the left (and, conversely, decrease in value as they "move" to the right).

What makes the decimal number system powerful is the notion of place value and the use of 10 symbols only (base) to represent any number no matter how large or small
This capability is possible because of the multiplicative relationships \((\times, \div)\) that relate adjacent (and nonadjacent places) places. However, Baturo (2000) found that top-performing students only have an understanding of the bi-directional multiplicative relations.

Research (Baturo, 1997, 2000; Bednar & Janvier, 1988; Fuson, 1990; Hiebert & Wearne, 1992; Jones et al., 1996; Ross, 1990) has produced a plethora of evidence that students (particularly from Years 1 to 4) have great difficulties in acquiring an understanding of place value. The general consensus seems to be that “children find place value difficult to learn and teachers find it difficult to teach” (Ross, 1990, p. 13). Baturo’s numeration model (2000) gives some indication of the complexity of place value in that she indicates that there are three hierarchical levels which take account of Halford’s (1993) complexity model in which unary relations (e.g., memory objects such as position, base, order) are less cognitively difficult than binary relations (e.g., equivalence such as \(1 \text{ ten} = 10 \text{ ones}\)) which, in turn, are less cognitively difficult than ternary relations (e.g., transitivity where \(10 \text{ ones} = 1 \text{ ten}, 10 \text{ tens} = 1 \text{ hundred}\) so \(100 \text{ ones} = 1 \text{ hundred}\)).

In Baturo’s model, Level 1 place value knowledge is baseline knowledge associated with position, base, and order, cognitions which are required for all numeration processes. Therefore, without these cognitions, students have no chance of processing decimal numbers with understanding. On the other hand, having Level 1 knowledge alone is not sufficient for a full understanding of all decimal-number numeration processes. Level 2 comprises unitising and equivalence, one or both of which are required for Level 3 knowledge which is associated with reunitising, additive structure and multiplicative structure. These cognitions appear to provide the superstructure for integrating the other levels and, for this reason, were defined as structural knowledge.

Several researchers have pointed to the difficulty students have with grouping/unitising (Level 2) which involves quantifying sets of objects by grouping by 10 (in a base-10 system) and treating the groups as units (Fuson, 1988) and using the structure of the notation to capture the information about the groupings (Hiebert & Wearne, 1992; Ross, 1990). For example, Bednarz and Janvier (1988) viewed grouping as the basis for recognising and constructing multidigit numbers. Inherent in the process of grouping to form larger units or partitioning to form smaller units (called “superunitising” and “subunitising” respectively by Baturo, 2000) is the notion of base which gives rise to the positional aspect of place value. From their study, Bednarz and Janvier noted that few children see the relevance of grouping tasks and the validity of doing and undoing groupings (partitioning) to solve multidigit number problems. Moreover, they found that some children form groupings, but only to count collections of objects (by tens in the decimal number system). That is, children do not appear to abstract the role of the base in grouping to form larger places.

In their study with Year 1 students, Jones et al. (1996) developed a framework for nurturing and assessing multidigit number sense. The framework incorporated four
components (counting, partitioning, grouping and estimating, and number relationships and ordering) which they saw as representing a sequence of understandings related to place value. They predicted and confirmed that counting was the pivotal component of their framework with grouping the key concept. Their study found that solution at the higher end of their framework was dependent on facility with (or understanding of) the lower components. Their framework is attuned to Steffe’s (1986) framework with respect to units, namely, that there are four different ways of thinking about a unit, namely, counting (or singleton) units, composite units (grouping), unit-of-units (regrouping) and measure unit, with each type apparently representing an increasing level of abstraction.

Counting is the repeated addition of an iterated unit (counting forwards) or the repeated subtraction of an iterated unit (counting backwards). These notions hold true for counting whole numbers, decimal numbers, common fractions, etc. Counting from a place value perspective requires understanding of the odometer principle (i.e., grouping to form a new place after 9 ones, tenths, hundredths, etc is reached). Therefore, to be able to count/seriate successfully, students require an understanding of place value, order across and within places, the ability to group, and an awareness of when to group and of the effects of grouping.

THE STUDY

The study reported in this paper is part of a doctoral dissertation in which Year 6 students’ understanding of the numeration processes (identifying numbers from a variety of representations, counting, comparing, ordering, approximating) relating to tenths and hundredths were assessed (Baturo, 1998). To this end, a diagnostic test was constructed to determine the robustness of Year 6 students’ understanding of the numeration processes. The test was trialed with a convenience sample of 8 students, modified and retrialed with 156 students from two large suburban schools (referred to as Trial 1 in this paper), modified and administered to 173 students a year later (Trial 3) at the Trial 2 schools. All item directions were read to the students (but not the actual subitems) and special instructions issued. For example, for Item 1 (see Figure 1), a sample number (2.3) was written on the board and the students were told that answers such as “two point three”, “two decimal three”, or “two dot three” would not be accepted. They were told that they had to write the name of the decimal part. At the time of the test (early Year 6 in both trials), the students had received two years of instruction in tenths and one year of instruction in hundredths.

Item analysis

This paper reports on the students’ performances on five of the diagnostic test items (see Figure 1). The first three were focused on assessing the baseline knowledge of position and order (i.e., Level 1 in Baturo’s model) whilst the last two items focused on seriating, with most subitems at Level 1 but some at Level 2 (requiring grouping and thus more difficult). All subitems ranged from prototypic to nonprototypic cases (see, e.g., Baturo & Cooper, 1997) in order to assess the robustness of the students’
knowledge. With respect to the items in this study, prototypic tasks are classified as those that are given so frequently in class that students can acquire syntactic rules for their solution (e.g., adding 1 to the rightmost digit when finding the number that comes next after a given number, a rule that can develop from an overuse of counting on with whole numbers). Thus, in this study, nonprototypic tasks were seen as those that would not normally be part of the students’ experiences and could not be solved by syntactic rules. Figure 1 describes the tasks and the difficulty level of each subitem in terms of Baturo’s (2000) numeration levels and expected prototypicality.

| Item 1: Write these numbers in words: (a) 4.7 [1P]; (b) 6.39 [1P]; (c) 0.8 [INP]; (d) 5.02 [1NP]. |
| Item 2: Write these numbers: (a) nine, and 5 tenths [1P]; (b) 6 tenths [1P]; (c) four, and thirteen hundredths [1P]; (d) sixty hundredths [1NP]; (f) seven and one hundredth [1NP]; (g) three hundredths [1NP]. |
| Item 3: Write the number that has: 2 tenths, 5 hundredths, 4 ones [1NP]. |
| Item 4: Write the number that is 1 tenth more than: (a) 9.4 [1P]; (b) 2.9 [2P]; (c) 4.06 [1NP]; (d) 1.94 [2NP]; (e) 5 [1NP]. |
| Item 5: Write the number that is 1 hundredth more than: (a) 2.76 [1P]; (b) 3.9 [1NP]; (c) 0.09 [2P]; (d) 6 [1P]; (e) 4.91 [1NP]. |

Note. 1 and 2 indicate Baturo’s (2000) numeration levels; P = prototypic; NP = nonprototypic.

**Figure 1.** Items [and difficulty level] designed to assess Year 6 students’ understanding of place value and seriation.

*Items 1, 2 and 3 assessed the students’ baseline knowledge of place value (Level 1). Items 1 and 2 focused on position and naming whilst Item 3 focused on the order of the places. In Item 1, the first two numbers were considered to be more straightforward than the last two which incorporated a zero. Of these latter two, the last number was expected to produce lowest performance because of the internal zero. It was also expected that naming hundredths would produce a lower performance than naming tenths. *Item 3* was included to determine whether students used the semantic understanding of the places or whether they relied on the syntactic “left to right” order in which the digits of a number are usually written.

With respect to the seriation tasks, *Item 4* required the students to record the number that was 1 tenth more than the given number and, as such, could be considered to be a place value item because the students had to identify the place to change first. The subitems included prototypic and nonprototypic cases. Prototypic cases included 9.4 where the digit to change first is in the rightmost place and does not involve grouping, and 2.9 where the digit to change first is in the rightmost place and does involve grouping. Nonprototypic cases included numbers where the digit to change first is not in the rightmost place either because it is an internal place (4.07, which requires no grouping; 1.94, which requires grouping) or because the given number was a whole number (5).

*Item 5* was similar to Item 4 except that students were required to add 1 hundredth to the given numbers. With respect to the prototypic examples (2.76, 0.09, 4.91),
although they are structurally similar in that hundredths are provided and therefore 1 can be added to the rightmost place, they were deliberately selected to identify syntactic learners. For example, does a student see a “9” and automatically elicit the regrouping process (probably because of having been exposed to prototypic examples)? The nonprototypic examples (3.9, 6) were expected to produce 4/4.0/4.00 and 7 or 6.1 respectively.

The seriation items reported on in this paper were based on Jones et al.’s (1996) lowest component (counting) in their place value framework whilst the subitems required an application of Steffe’s (1986) simplest notions of unit, namely, counting/singleton units and composite units (grouping).

Results

Table 1 shows that the means per item were quite poor across both trials. With respect to Items 1, 2, and 3, the results indicate that the students did not have the prerequisite baseline place value knowledge (i.e., the names and order of the decimal-fraction places) that will enable them to process decimal numbers with understanding. Thus, not having baseline knowledge of the place names, it is then not surprising that the students were unable to add 1 tenth and 1 hundredth to the given numbers (Items 4 and 5 respectively). Table 1 also shows that, for the place value items, students generally performed much better on Item 2 than on Item 1, both of which were assessing knowledge of place names/position. (See Discussion.)

In Trials 1 and 2, the tenth item with zero, 0.8, generated much lower performances than the tenth item with no zero (4.7). With respect to Item 2, Table 2 shows that, generally, performance decreased markedly over the last three subitems, each of
which was classified as nonprototypic because they included a zero, particularly the last two which required an internal zero.

With respect to Items 4 and 5, Table 3 shows that the students performed best on the prototypic examples, namely, adding 1 tenth to 9.4 and 1 hundredth to 2.76 (where 1 could be added to the rightmost digit). Although Item 4b (2.9) and Item 5d were also prototypic in this regard, they had the extra distraction of "9" which either didn't evoke the odometer principle in Item 4b or erroneously evoked the principle in Item 5d.

The students' responses were analysed for error patterns and very few consistent errors were made by the same students across the range of subitems within an item, indicating that these students' responses were contingent on the "look" of the number. Generally, individual error patterns were discerned in Item 1. For example, if a student wrote "four point (or decimal/dot) seven" for Item 1a, s/he invariably wrote the remaining three numbers using the same syntax. However, across the 337 students, some errors occurred frequently. For example in Item 1, the prototypic examples (4.7, 6.39) produced an error rate of 22.8% and 46.8% respectively. The errors could be classified as "syntactic reading" (e.g., four point seven) or misidentification of places (e.g., 4 tenths or 4 tenths and 7 hundredths). Syntactic reading accounted for 14.9% of the errors whilst misidentification accounted for 11.2% of the errors. For Items 4 and 5, students’ errors on all subitems could be categorised as syntactic responses to overpractised tasks. That is, students either added 1 to the rightmost place or added 1 to the ones place irrespective of the number given. For example, when adding 1 tenth to 4.06 (4c), the most common responses were 4.07 (30.4%) and 5.06 (6.1%).

Furthermore, each subitem across the five tasks generated at least 20 different types of errors. The disparity between the number of error types within each item and the percentage of most common errors revealed the idiosyncratic nature of the responses as the students strived to make sense of the tasks. For example, in Item 2c, students gave 23 different erroneous responses but the most common error (4.013) occurred in only 2.7% of the 17.1% of these responses.

CONCLUSIONS

The results on all of these elementary place value and seriation tasks are of concern considering the length of school time devoted to developing students' understanding of decimal numbers. Almost 40% of these students could not read or write decimal
numbers to hundredths, and approximately 50% could not add 1 tenth or 1 hundredth
to a variety of decimal numbers. Without adequate foundational knowledge, students
cannot develop the facility for numbers (i.e., number sense) that is the focus of
current mathematics syllabi (e.g., NCTM, 2000).

These students’ lack of ability to read and write decimal numbers can be explained by
the “short-cut” method of reading fractions (e.g., “four point seven” rather than “four
and seven tenths”) that predominates in Queensland schools. Hence, students are not
practised in reading decimal numbers so that the name of the fractional part is heard.
This practice is also prevalent in reading common fractions, for example, “two over
three” rather than “two thirds”. Baturo and Cooper (1999) suggested that this form of
syntactic reading in the early years of learning is detrimental to students’ ability to
process fractions with understanding. Moreover, the poor performances on such a
low-level task as Item 3 (61.4%) suggest that the students have come to rely too
heavily on the “left to right” syntactic rule when recording numbers (as indicated by
their responses to Item 1, namely, 61.5%).

The seriation items evoked low performances, even on the level 1 prototypic tasks
(4a–78.1%; 5a–62.9%) suggesting that adding 1 to a decimal place was, in fact, a
nonprototypic task for these students. The most common error responses, namely, to add
1 to the ones place indicate that, for these students, seriation tasks had been limited to
whole numbers. Table 3 revealed that when the difficulty level was increased, the
results decreased. For example, the generally poor results for the Level 2 grouping items
(4b, 4d, 5c) indicate that grouping is not a simple process for young students. The results
of both of these seriation tasks indicate the fragile nature of students’ understanding of
place value and seriation. Students cannot seriate without good place value knowledge
and are limited if they cannot employ the odometer principle because of lack of
understanding of grouping.

With respect to teaching numeration processes, Ross (1990) claimed that children learn
to represent numbers with concrete manipulatives (as practised in Queensland schools)
through following the teacher’s directions rather than from thinking about what they
have constructed. The results of this study suggest that teachers need to be more creative
in the types and levels of examples they provide to ensure that students have the
robustness and flexibility of knowledge that is required for number sense.

Abstract

In this article, the general principles and practices adopted as guidelines to a graduate course for secondary Mathematics teachers are discussed. We argue that once the curriculum is designed both to complement the teachers' subject content knowledge and to provide activities promoting links between their conceptual knowledge and their actual practices, it can have a strong positive influence in teachers' subsequent practices. Two teachers who completed the course were subsequently followed during a two year period. They were interviewed and their practices were observed. We analyse their reflections on the main differences in their practices before and after attending the course.

Introduction

The need to create opportunities for regular in-service training courses for secondary Mathematics teachers in our geographical area led the team in charge of the undergraduate teacher-training course in our University (the oldest established in Brazil) to create a two year graduate course. The basic principles underlying the present versions of the graduate and the undergraduate courses is that the sum of solid mathematical formation with basic pedagogical and didactical knowledge is essential in training teachers, but it cannot be considered enough. Both courses should also include activities especially planned to allow the trainees to reflect upon the importance for their classroom practices of establishing connections between their own learning experiences in Mathematics at an advanced level and their practice as secondary Mathematics teachers.

Specific disciplines aiming at establishing these connections have been included in our undergraduate teacher-training curriculum few years ago. The experience on writing materials and developing one of these disciplines (Algebra and Arithmetic) is reported in Belfort, Guimarães and Barbastefano (2001a). This kind of experience has also reflected on the development of the curriculum for the graduate course.

We discuss in this article the general principles and practices adopted when designing the curriculum for the graduate course, and their consequences for the teachers’ subsequent practices. The main aims of the course are to complement the subject content knowledge preparation of the teachers and to associate this
knowledge with a series of activities specially prepared to "close the gap" between the Mathematics they are learning and the Mathematics they teach as secondary teachers.

In order to obtain data on how these experiences changed the practices of the teachers involved in the program, two teachers who completed the course were followed during a two year period. During this time interval, we had plenty of opportunities to observe their practices and to interview them. We discuss here their reflections on the differences in their practices before and after attending the course.

**Background**

There were many reasons leading us to conclude that it was necessary to include experiences specially designed to highlight the connections between the mathematical disciplines developed for the trainees in the program and the subject matter to be taught at secondary schools. There are indicators from research that a solid subject content knowledge may be essential for a successful teacher (for examples, see Ball and Feiman-Nemser, 1988; Grossman et al., 1989; Ball, 1991; Leinhardt et al., 1991). Nevertheless, Ball and McDiarmid had already taken one step further: they began to investigate the special qualities prospective teachers' actual subject content knowledge might lack in order to foster good classroom practices. Ball (1988) stated that "...[secondary teacher candidates' additional studies] do not seem to afford them substantial advantage in explaining and connecting underlying concepts, principles, and meanings" (pg. 24), while McDiarmid (1992) argued that "elementary and secondary teachers frequently lack connected, conceptual understandings of the subject matters they are expected to teach" (pg. 1).

Ma (1999) discusses the importance of the "profound understanding of fundamental mathematics (PUFM)" demonstrated by some elementary teachers. She defines this concept as "an understanding of the terrain of fundamental mathematics that is deep, broad, and thorough" (pg. 120). As a consequence of PUFM, some elementary teachers "do not invent connections between and among mathematical ideas, but reveal and represent them in terms of mathematics teaching and learning" (pg. 122). According to her, the work of these teachers displays the following characteristics: connectedness, multiple perspectives, awareness of the basic ideas, and longitudinal coherence.

Our practice in teaching subject matter in undergraduate and graduate courses directed at secondary Mathematics teachers suggests that the difficulties our trainees face with subject content are of a similar nature (Belfort, Guimarães & Barbastefano, 2001a, 2001b). If we add our experiences to other researchers' descriptions, we can

*The notion of 'gaps' between different learning stages can be found in Hart (1987), where she discusses the use of concrete materials in elementary education.*
at least conjecture that this may be a widespread problem.

If we attempt to transpose Ma’s ideas to the situation of the study of Mathematics at secondary level, we are faced with the twofold connection of this concepts: to the previous knowledge of elementary Mathematics the students would have and, in the other hand, to the mathematical structures studied in their undergraduate course. Issues such as Cognitive Units (Barnard & Tall, 2001) and Flexibility (Gray & Tall, 1991) also have to be taken into consideration, as explanations for and justifications of some of the mathematical procedures studied at secondary school may be provided only if one resorts to knowledge of structures and properties studied in advanced Mathematics (a simple example: several of the divisibility criteria often taught in the initial years of secondary school depend for their justification on the properties of the integer numbers as an integrity domain, and of the general properties of congruence in this set).

So it seems that, if the teaching of secondary Mathematics is to display characteristics of connectedness, multiple perspectives, awareness of the basic ideas and longitudinal coherence, the teacher would have not only to know Mathematics at an advanced level, but also to be able to reflect on its connections with the contents of secondary school. Such were the premises guiding the design of the curriculum for the graduate course.

**Curriculum Guidelines**

Several teachers enrolled in the graduate course were previously involved in a summer in-service course by our Institute. So, when designing the curriculum, we considered not only the research-based reflections mentioned above but also the difficulties these teachers seemed to face when dealing with secondary mathematics. Our experiences with these teachers had confirmed the lack of connected and conceptual understandings of the subject matters commented by McDiarmid (1992). These teachers also demonstrated different levels of mathematical reasoning (for example: inductive reasoning, incomplete and/or misleading arguments were found among their justifications to mathematical secondary results).

The curriculum included disciplines to allow the teachers to reflect upon results coming from Mathematics Education research and pedagogical matters. A discipline aimed at fostering the use of technology for teaching Mathematics was also included. But the majority of the disciplines offered these teachers opportunities to review, from an advanced standpoint, the contents they have to teach (algebra, geometry, number structures, calculus and statistics). Based on the principles discussed above, the development of all disciplines included activities designed to allow teachers to make connections between their learning experiences and their practices. We can summarise the general guidelines for developing the courses as:
• we offer the teachers several opportunities to work with (and reflect upon) the basic properties of the mathematical objects;
• we punctuate the courses with commentaries on mathematical reasoning and justification: what it means to show that a result is false (use of counter-examples) and different methods of proof;
• formal proofs are often accompanied by a previous discussion of the need for it and of the strategy in searching for it;
• we encourage the teachers in establishing connections between the topic under study and examples of actual practice in the secondary school classroom;
• every mathematical concept is correctly defined, and possible difficulties in its construction by secondary students are often discussed;
• we furnish ample opportunity for the critical analysis of texts and questions found in Brazilian textbooks;
• we present several examples of wrong and/or incomplete problem solutions to be analysed; and
• we often ask the teachers to present more than one solution to a problem, as a way to encourage flexible and consistent mathematical reasoning.

We expected the course to have a strong positive influence in teachers’ future practices. In order to verify this hypothesis, it was necessary to follow some of them in the subsequent years. In fact, it was not a difficult task to select a sample for the case studies. A partnership was established with many of the teachers engaged in the graduate course. They keep coming back to discuss their practices, to ask for comments on their work, to use the library or simply to have a chat.

**Teachers’ Reflections on their Practices**

We selected two teachers, with very different backgrounds, to be followed during a two year period after finishing the course. Their practices were observed and they were interviewed several times. The main aims of the interviews were to ask these teachers the reasons behind their teaching decisions and to verify how these differed from the ones they used to make before attending the course. Observation was used as a mean to verify the conformity between discourse and practice.

Ada is a very experienced and enthusiastic secondary school teacher, working in schools in Rio de Janeiro for the last 20 years. She had a secondary level training as a primary teacher and an undergraduate teacher training course for secondary Mathematics in a private college in Rio de Janeiro. Even though she had been enrolled in several in-service courses before joining our course, she had to work hard...
to overcome several difficulties with subject content matters during the graduate course.

Ricardo is also an experienced teacher, working in secondary schools in smallish town near Rio de Janeiro for 12 years. Ricardo did his teacher training course in a private college at his home town. He also had been enrolled in several in-service courses, and joined the one we offered in the summer of 1997. The year after that, he enrolled for the graduate course. He commuted to and from his home town every week for the duration of the course.

There were several changes in their careers in the last two years, and both declared them to be related to the course. Ada still works at a state school in Rio, as she has been doing for almost 20 years. She works in adult education during the evening period in this school. She got a new job in a highly respected experimental school in Rio, and became Head of the Mathematics Department there. She is also in charge of introducing the use of computers in Mathematics lessons. Apart from that, she is working as a trainer in in-service courses for primary teachers, and she was recently invited to lecture didactics of mathematics for prospective primary teachers at a private college in Rio. Ricardo also has changed jobs in his home town. He is now working in one of the most prestigious private schools in the city and became the Pedagogical Head of this institution. He is in charge of preparing secondary students for the universities’ entry exams and he is also training the school’s primary teachers at Mathematics.

Both teachers report several changes in their practices. For instance, Ricardo has changed the school adopted Mathematics textbook. He says:

"The old textbook had many exercises to train the kids, but did not teach them mathematical concepts... and most teachers usually only teach what is in the book. I know that because I used to do it myself (laughs). I used the textbook as my only source of study. I usually prepared all the exercises beforehand and, whenever I could not do one of the exercises, I took it out of the list I proposed to the kids. I never discussed solutions of the exercises with other teachers. I guess I felt too insecure to do that... anyway... we had a meeting to discuss the textbook. It was not easy to convince the other teachers to change the book... probably because they were used to the old one, and they did not feel secure adopting the new one. It took me a while to convince them that we would be working as a team, and that we would be discussing concepts and exercises. I guess they finally believed me because I was already bothering them during the breaks to help me with difficult exercises (laughs)."

Ricardo’s school accepts students for the last three years in secondary school. Ricardo says that the group of students joining the school this year came from different backgrounds, and most of them demonstrated gaps in their previous
mathematical preparation. He has implanted a “Saturday morning of work”. He is very enthusiastic about this experiment:

“All pupils in the group are volunteers ... well, sort of! (laughs). In fact, I asked them to solve selected exercises during an interview. It was easy to convince them that it would be a good idea to take time to review some of the concepts they were expected to know at this level. I have been planning these activities carefully, using different sources of materials, because I want the kids to enjoy each lesson and to come back for more the following week. Lots of games and competitions - they work in small groups most of the time. Whenever they finish an activity, they tell the others what they did. It is very noisy, but it is amazing to see this kids discussing their different solutions. This is also the moment of the lesson in which I reinforce the main results and generalise the mathematical concepts. The experience is still at its very beginning, but I believe that these kids would do well in their regular Maths lessons ... and they keep telling the others that the “Saturday lessons” are great fun.”

Ada not only changed the textbook she adopted but also she radically changed the way she uses the book. She usually gives the students a series of activities she prepared herself before she asks them to read and to do the exercises in the book.

“This is a much better textbook than the one I used to adopt. Nevertheless, the pupils do not enjoy using it all the time ... also, I believe that different experiences are necessary to promote mathematical learning. So, I usually get them started with a group activity. I use different sources to prepare these tasks, so they would have a great variety of experiences. This strategy also keeps them interested and it gives me the chance to complement the viewpoint presented in the book ... it is very helpful for the students.”

Ada declares that the course was a turning point in her career. She says:

“I had been enrolled in several in-service courses before, and I was almost giving up! It was a terrible experience to listen to the trainers statements: you should do this and you should construct that!... But I did not know how to do it and they most certainly did not teach me. I realise now that my mathematical knowledge was mostly instrumental, and I had little conceptual understanding. So how could I possible teach to promote it? ... I even had difficulties understanding the textbook I adopt now, and several activities proposed there were meaningless to me ... so, I avoided it - and every other one of the kind. After these in-service courses I kept doing instrumental teaching, relying on a bad textbook - and feeling very uncomfortable.”

Ada’s comments about her activities as a primary teacher trainer also show the importance she is now attributing to conceptual understanding:

“As a trainer in in-service courses I realised that most primary teachers could not justify their work... they know how to do it, but they don’t know why they
do it. I guess this is probably the way they were taught - and it is also the way they teach the kids! Mathematics has become a series of meaningless rules for them. On the other hand, it is interesting to observe their reactions to a series of activities aimed at constructing the concepts instead of instrumental Mathematics or Pedagogical discussions detached from content matters. Once they overcome their initial surprise, it seems that they start learning ... at least, they work hard and enjoy the experience! It is gratifying to see how quickly they adapt most of the activities of the course into activities for their pupils. Lots of good ideas discussed in the class! It feels like starting a machine: you turn on a button, and it goes on and on ... but then again, I believe it was the same process with me! (laughs)"

**Comments and Reflections**

Cooney (1988) described teaching as "an interactive process", in which conscious decision making is needed not only during the planning of the lessons but also "on the stage". Models to explain the role of the teacher usually consider the interaction between teacher’s knowledge and beliefs as the basis for their decisions (see, for instance, Fennema et al., 1989). The data from the case studies described above point to the strong influence of subject content knowledge in this process.

The case studies suggest that there were substantive changes in the ways these teachers work. Both are now in charge of special programs of study in their schools. Both have changed not only the adopted textbooks but also the ways they use this resource. They are designing complementary materials, which suggests they are much more confident about making decisions about their pupils’ learning experiences. As a consequence, the textbook is used as a helpful source of reading and activities, but it is no more determinant of the curriculum developed in their classrooms.

Their reflections on their work before attending the course are also notable. Because of the relationship developed during the course, they are very open to discuss their previous difficulties. Ricardo made clear that his previous difficulties were not related to class management or pedagogical issues, but were due to a lack of content knowledge. Similarly, Ada was almost giving up on in-service courses. Even though she was not able to make these reflections at the time, it seems that she felt uneasy about learning methodological issues she could not apply, mainly because they should be associated to a conceptual content knowledge she did not possess.

We can say that our main goal was to convince these teachers that subject content matter knowledge is at the very root of their jobs - and that it is also the most powerful of all tools they can apply as mathematics teachers. To use it effectively, it is necessary to develop a deep understanding of the mathematics they teach, making
it more flexible and establishing connections among different mathematical topics. We hope to have made them aware that this is a never-ending job.

Abstract - In this research, we investigated the cognitive domain of proportional reasoning mathematical knowledge of pre-and in-service elementary mathematics teachers – including its three components: the intuitive, the algorithmic and the formal. This investigation was carried out by assessment of change in participants’ procedures while they were presenting possible solutions to authentic problems and revealing their reasoning in dealing with ratio and proportion problems. The affective/behavioral domain was also investigated by measuring change in the attitudes toward teaching proportional reasoning following exposure to and experience of investigative proportional reasoning activities.

Theoretical Background

Recent research findings all over the world have indicated many gaps in the content knowledge of pre-and in-service teachers in mathematical subjects taught in the elementary school, including the topics of ratio and proportion. Frequently, existing knowledge is technical, schematic, unconnected and incoherent and, as a result, difficulties arise which are evidence of the pre-service teachers’ lack of understanding of mathematical concepts and feeling that they are incapable both, coping with the material and teaching it. This is usually based upon a negative attitude toward the specific material (Keret, 1999; Fischbein, Jehiam and Cohen, 1994; Tirosh and Graeber, 1990).

A review of the literature about proportional reasoning by Tourniaire and Pulos (1985) indicates a number of factors relating to the context and number structure of proportional reasoning problems that are responsible for much of the variability and difficulties in the performance of both students and teachers. The sources of the difficulties are mainly cognitive and they are consequences of the operational scheme’s second order status – meaning that to understand proportion one needs to make a comparison between two rates, each of which needs to be able to coordinate between two variables (Inhelder & Piaget, 1958).

Findings of many research studies indicate that appropriate practice, which includes realistic contextual problems that are interesting and challenging and which encourage students to construct their own conceptual and procedural knowledge, can help them build their proportional scheme (Harel and Confrey, 1994). The American Connected Mathematics Project (CMP) has developed learning material which incorporate these ideas for grades 6-8. The findings indicate that such students are capable of developing their own repertoire of sense-making tools to help them produce solutions and explanations (Ben-Chaim et al., 1996a). Findings of research studies with pre-service mathematics teachers indicate similar results (Keret, 1999).
The conclusion reached from these research studies is that, in order to improve the situation, we need to implement the research findings in teaching ratio and proportion topics in the elementary school and, in parallel, to deal with these topics differently in in-service teachers education. The in-service training should include three central components: the cognitive component which includes the mathematical content knowledge and the pedagogical-didactical knowledge; the affective component which includes attitudes, beliefs and feelings of being capable (that may prevent or encourage the readiness to teach the subject); and the component of teacher behavior which one can see in the teacher’s readiness to cope with constructing teaching units and planning the teaching of the subject. In this research, after exposing the pre-and in-service elementary mathematics teachers to investigative and authentic activities in ratio and proportion, we followed the way these teachers changed in regard to the above three components.

**Methodology**

**Sample**: 49 pre-service teachers from Israeli teachers colleges as part of their training to teach mathematics in elementary schools and 14 in-service mathematics teachers in elementary schools. The study was conducted during the academic year 2000/2001.

**Research Instruments**: 1. A proportional reasoning questionnaire that was administered twice: first at the outset of the course and second after gaining experience with investigative activities (19 activities in 10-12 teaching sessions). There were 3 versions of the questionnaires each consisted four parts:

**Five rate and density problems.** Problems 1&2 deal with unit price- where problem 1 needs numerical comparison and problem 2 has missing value. Problems 3&4 deal with proportional relations between distance, time and velocity – both using numerical comparison and the main difference between them is in their numerical structure. One problem includes only integers and the other includes fractions and decimals to present the factor of time. The fifth problem deals with information of population density, also of numerical comparison type, but with relatively larger numbers. In all numerical comparison problems, the ratios are not equal and in this case the problems are generally considered to be more difficult compared to those with equal ratios (Karplus et al., 1983a, b).

**Five ratio problems.** The first two problems deal with finding the ratios between the sizes of two groups of children. There is no need to solve the problems, but to specify as many different ways as possible to find the ratio between the sizes of the groups. The responses for these problems will be analyzed in a separate section. The third problem deals with comparison between two ratios. The fourth problem deals with the comparison made between different types of ratio representation. In the fifth problem there is a need to find the whole value by using a given ratio.

**Five scaling problems.** All five problems relate to finding a ratio and its application after enlarging or reducing the dimensions of pictures. Each problem refers to a different aspect; the first one deals with finding the scaling factor; the second one deals with comparing two ratios; the third one is of a missing value type; in the fourth
one there is a need to relate to a quadratic enlargement (areas); and the fifth problem relates to a situation with 2 consecutive enlargements.

Six exercises that include work with fractions. This part consists of six exercises with plain numbers/fractions/decimals similar to those included in the rate, ratio and scaling problems.

The questionnaires are based on versions administered to large populations in U.S.A. and that were translated into Hebrew (Ben-Chaim et al., 1998) with some correspondence of units, and local situations.

2. Attitude questionnaire. The attitude questionnaire includes 22 items and 3 open questions (more details are given in the results section).

3. Authentic investigative proportional reasoning activities. Nineteen activities were developed in order to assess the influence of exposing pre-service teachers to authentic investigative proportional reasoning activities. The development of the activities was based on research findings from around the world (Ben-Chaim et al., 1998; Keret, 1999). The activities were conducted in one of the pre-service mathematics education courses in each of the two participating teachers colleges.

4. Observations. These were aimed at the formative evaluation of the activities created and at a follow up of the learners’ procedures.

5. Personal Interviews. These aimed at in-depth and comprehensive examinations of the questionnaire’s findings. For this purpose, a representative sample of 14 participants was interviewed. The interviews served as a validation of the findings achieved from the observations and the questionnaires.

Results and Discussion

The layout of the research is one group pre-test – post-test. The questionnaires were administered before and after conducting the ratio and proportional reasoning activities. A special rating form was created to analyze and score the students’ responses. Three major response categories were identified and each of them was accordingly subdivided into subcategories (see Table 1).

As indicated before, six exercises in fractions were included to examine if the students had difficulties in comparing fractions and/or acting with naked numbers/fractions similar to those that appear within the verbal problems. In this part, there were no differences found between pre and post testing results. The students had no special difficulties in solving the fractions exercises.

The following report relates to the performance of the pre-service teachers on 15 problems, before and after exposing them to a process of solving authentic problems in ratio and proportion.

It should be noted that the assessment tasks are different from those that appear in standard tests. They stem from familiar situations such as: buying soft drinks, riding bicycles, population density, bussing to school and a visit to the photo shop.
Moreover, the problems and the situations are different from those presented within the investigative activities during the teaching sessions.

* All of the numbers in the table are percentages.

Table 1 presents the overall results of the pre-service teachers’ performance, before and after exposure to the authentic activities. It can be seen that, before exposure to the activities, 56% (Rate), 38% (Ratio) and 51% (Scaling) of the pre-service teachers correctly responded with correct support work. After the exposure to the activities, the performance of the students improved dramatically, to 86% (Rate), 81% (Ratio) and 70% (Scaling) of the pre-service teachers answering correctly with full support work. Furthermore before the experience with the proportional reasoning activities, 27% (Rate), 46% (Ratio) and 37% (Scaling) of the pre-service teachers did not attempt the problems or responded incorrectly using incorrect thinking. In contrast, the percentages after the exposure to the activities were only 2% (Rate), 2% (Ratio) and 11% (Scaling). The majority of the participants attempted to answer the problems with support work, both before and after the exposure to the activities. If we ignore the subcategories “only correct answer” and “only incorrect answer” and the category “Blank” then before the exposure: 78%, 61% and 80% of the participants and after the exposure: 99%, 97% and 96% of the participants provided support work for their answers. Hence, when examinees are asked to “show your work”, or “how do you know”, or “explain” they do add written support for their answers. Yet, the quality of writing is important. Analysis of the written support work clearly showed that after the exposure – during which the participants were guided to explain and discuss their reasoning and ideas, the arguments were more detailed, clearer and of a better quality.

The subcategory of “correct answer with incorrect support work” showed up before exposure to the activities 3% (Rate), 10% (Ratio) and 3% (Scaling). Thus, on a typical mathematics exam that does not ask for justification of answers, such
examinees would be marked correct and their misconceptions would be unrecognized and thus uncorrected. On the other hand, within the subcategory of “incorrect answer with partial understanding/thinking” there were 11% (Rate), 6% (Ratio) and 5% (Scaling) before the exposure, and 9% (Rate), 10% (Ratio) and 10% (Scaling) after the exposure. This subcategory of response often occurred when the problem called for calculations followed by reasoning, as is the case for most of the problems presented. The examinees can think correctly, but draw the calculations incorrectly, or they might get the correct number and information, but draw an incorrect conclusion about measurement units. It can be assumed for students in this subcategory that they are beginning to understand the content, but their understanding is still shaky. Certainly in this case, complementary teaching/learning is needed. All of the above is true and characteristic for each of the problems.

As indicated for the first two ratio problems, the participants were asked to specify different ways to present ratios and compare between them. The results show, that, before the exposure 32% (prob.1) and 50% (prob.2) of the pre-service teachers did not succeed in finding even one way to present ratios for problems 1 and 2 compared to only 3% (prob. 1) and 3% (prob. 2) after the exposure. Before the exposure, 68% (prob. 1) and 50% (prob. 2) of the examinees successfully solved problems 1 and 2 in at least one way; after the exposure there was a visible gain in success, while 97% of the participants correctly solved the problems using at least one way with the majority of them using more than two different ways.

Regarding scaling problems, the findings indicate that the pre-service mathematics teachers had difficulties especially in solving problem # 4 in which they were required to deal with quadratic enlargement – area enlargement. Before and after the exposure to the activities, the rate of success was 40%. Obviously, the quadratic enlargement here was not assimilated successfully. This is in agreement with findings of previous studies regarding pre-service teachers (Keret, 1998), as well as elementary school students (Ben-Chaim et al., 1996b). In contrast, the performance on the fifth scaling problem was much better one – 65.5% before the exposure and 80% after. In this problem, the examinees were asked to relate to double enlargement. This problem was presented in two versions: one version included a figure of segments (no numbers) and the problem was to assess the overall enlargement; the second version included a description of a machine that enlarges double and, then triples the size and the problem was to find the resulting enlargement. In both versions the rate of success was almost the same.

As indicated before, the attitudes toward the topic of ratio and proportion were also evaluated in order to detect changes that took place between pre and post exposure to the activities. The assessment was conducted by a Likert attitude questionnaire with a scale of 1-5. The questionnaire included items dealing with attitudes toward: mathematics teaching in general, confidence in the ability to deal with ratio and proportion, difficulties in teaching ratio and proportion, and the importance of teaching ratio and proportion.
Table 2 indicates that pre-service teachers’ attitudes toward teaching mathematics in general, before the exposure to activities, are quite positive - they like and enjoy teaching mathematics. Following the exposure, they were even more positive. The standard deviation measure of post testing indicated that all the participants enjoyed teaching mathematics. Another finding shows that the pre-service teachers are aware of the need for mathematics teacher to have much more content knowledge than the material taught in school. This finding is supported by the interviews, as one of the interviewees noted: “I would like to go deeper, there are additional subjects to learn, such as inverse ratio; in my opinion, teachers should know much more than pupils in order to teach”. A positive change occurred regarding the feeling of being capable of dealing with ratio and proportion. After the exposure the participants felt that they were more confident in their capability to teach the subject and felt capable of planning and creating relevant mathematics activities.

</table>

To those who were exposed to the activities, teaching ratio and proportion seemed to be more complicated than before the exposure. The interviews strengthened this finding, for example: “I thought that the topic of ratio and proportion was easy and that I knew how to teach it, but today after I have learned, I realize that it is very complicated and that I still lack of knowledge”; or another quotation: “It exposed me to a topic about which I did not know how much I don’t know and how unready I am to teach it”.

Another change that occurred following the exposure to ratio and proportion activities is connected to the need to include ratio and proportion as part of pre- and in-service teacher training. Before the exposure, not all the examinees thought it was very important to include a course related to ratio and proportion; however, after the exposure, almost all the participants thought that it was very important to include it. As one of the interviewees said: “It is very important to teach this topic of ratio and proportion in college since it is the A B C of mathematics. If you are not familiar with this topic, it is impossible to teach the other topics”. These findings indicate a significant improvement in the participants’ attitudes toward the overall components and aspects of ratio and proportion topics. The observations during teaching the
activities and the interviews conducted after the teaching, clearly indicated that the teaching style caused the participants to construct their understanding of the concepts of ratio and proportion through an enjoyable and efficient process; as one said: "Before, I learned the topic by formula and I could never remember which formula to use. This time the inquiry enabled me to develop it in my own way regarding the topics of ratio and proportion ...". Another one related to the authenticity of the activities: "The topic of the presented problems was new to me and topic that I did not like, but it brought it closer to me. I especially liked the recipes enlargement and reduction of a drawing, and the cutest of all was solving the detective’s puzzle – such activities raise curiosity and after you solve them, you suddenly know that you have advanced in learning ratios. It is wonderful". Another one related to teaching in the elementary school: "The activities are close to our world and it is possible to also fit them into the world of children and I am sure that they will also enjoy solving them".

**Conclusions**

The findings of this study indicate several crucial points:

1. Authentic activities are essential for teaching the topic of ratio and proportion in pre-and in-service elementary teacher education.

2. The type of activities developed and used in this study were found to be suitable, effective and contributory to pre-and in-service teachers for understanding the topics of ratio and proportion.

3. After exposure to the investigative ratio and proportion activities, the pre-and in-service teachers were more successful in solving the problems presented to them in the knowledge questionnaire. It is important to note that the problems and situations included in the questionnaires were different from those presented during the teaching cycle.

4. The majority of the students provided support work and explanations for their solutions before and after the teaching. Thus, when examinees are asked to add arguments and explanations most of them generally meet the requirement.

5. After exposure to the activities, the participants succeeded in finding more methods to solve the problems and their explanations for their methods were of a better quality.

6. The request to add support work is justified, since a correct answer with explanations, frequently identifies an examinee who has a lack of understanding and who would otherwise be considered to be successful. Furthermore, an incorrect answer accompanied by support work can reveal an examinee that already has partial or unstable understanding and just needs complementary tutoring.

7. The pre-and in-service teachers do not have difficulties in solving exercises with plain numbers/fractions and decimals.
8. Following learning ratio and proportion through the authentic activities, the pre- and in-service teachers improved their attitudes toward mathematics in general and all the components and aspects of ratio and proportion.

In summary, the concepts of ratio and proportion are basic concepts in mathematics. In addition they are important for other disciplines in which different phenomena are described as ratio and proportions. Conceptualization of the ratio and proportion concepts and the ability to implement them in problem solving arising from different disciplines can assist learners to construct their mathematical knowledge. More important however is that it will lead to the development of the ability to apply the proportion scheme – meaning proportional reasoning, something that is vital for developing analytical and mathematical thinking.

Selected Bibliography

This study involves a teaching experiment aimed to improve children's understanding of fractions. Fifty seven children (8-10 years old) were divided into three groups: Experimental and Control Groups: 3rd graders with no previous instruction in fractions; and Reference Group: 4th graders who were taught in a traditional way based on a mechanistic approach to fractions and focused on application of rules. Children in the Experimental Group were given a teaching experience based on problem solving situations and on activities that enabled them to think and discuss their thought processes when solving problems involving fractions. All participants were given a pre and a post-test. The Experimental Group showed a more expressive improvement than the other groups. The results are discussed in terms of the nature of instruction in fractions understanding.

Introduction

This study is based on conceptual field theory in which the fraction is considered one out many other concepts that takes part of multiplicative conceptual field, or simply multiplicative structures, such as multiplication, division, proportion, linear function, vectorial space. According Vergnaud (1983, 1988, 1997) multiplicative conceptual field is a set of situations that requires a diversity of concepts, actions and symbolic representations consistently linked to each other.

When dealing with fractions, for instance, children have to deal with many other concepts and with a large range of situations involving part-whole relations; equal or equivalent units; exhaustive division/sharing (that is, nothing remains); fair sharing; and equality or equivalence of shares. Also, they have to deal with the fractional language and its mathematical representation \(\frac{a}{b}\). Thus, fraction is not an easy concept to be understood and to be meaningfully mastered by children.

Children's difficulties with fractions are well known among researchers and educators (e.g.; Kerslake, 1986; Koyama, 1997; Nunes and Bryant, 1996; Watanabe, Reynolds & Lo, 1995). They have difficulties to understand fractions as mathematical ideas (a number or a quantity) and construct meanings of fractions. According to Streefland (1991) some of the sources behind the failure of fraction instruction reside in the complexity of this concept, and, also, in the traditional approach to fractions which is formal and mechanistic from the very start. Also, the teaching is often detached from reality, consists of rigid rule-oriented instruction, and the informal knowledge children have acquired is ignored entirely.
Thus, one may ask whether children would overcome their difficulties and develop an understanding of fractions if they were given an instructional experience that emphasises realistic and meaningful problem solving situations and that allowed children to show and discuss their informal knowledge (strategies used, informal representations of fractions).

**THE STUDY**

This study aimed to explore the role played by an instructional experience to improve children's understanding of fractions through a variety of problem solving situations. The idea was that third grade children who were taught about fractions for the first time would benefit more from this alternative teaching programme than fourth grade children who were taught in a traditional approach to fractions. Thus, a study was carried out in which a pre and a post-test were applied to children who were divided into three groups: Experimental Group (alternative instructional approach to fractions); Control Group (pre and post test only); and Reference Group (traditional approach to fractions).

**Participants and groups**

The participants were 57 low-class children aged 8 to 10 years old attending a public school in São Paulo, Brazil. These were divided into three groups:

Experimental Group (EG): 19 third graders (mean age: 8 years old) with no previous instruction in fractions were given a teaching experience based on a sequence of instructional activities that enabled them to think, discuss and communicate verbally their thought processes when solving problems involving fractions.

Control Group (CG): 20 third graders (mean age: 8 years old) with no previous instruction in fractions were given a pre and a post-test only.

Reference Group (RG): 18 fourth graders with previous formal instruction in fractions were taught about fractions in a traditional way based on a mechanistic approach to fractions, detached from realistic situations and focusing on rigid application of rules.

**Pre and the post-test**

The pre and post-test consisted of a series of 15 items involving fractions related to continuous and discontinuous quantities (Figure 1).
João has painted one of the four faces in a set. How can you represent the number of faces he had painted in relation to the total number of faces in the set?

Could you divide equally 4 bars of chocolate between 5 children? How much chocolate does each child get?

Make a circle around one third of the collection of hearts below. How can you represent the number of hearts you circled in relation to the total number of hearts in the collection?

Could you paint half of the figure below? How can you represent the number of parts painted in the figure below?

How can you represent the amount of parts painted in the figure below?
Some of these items involved part-whole relations and others involved sharing. In these items children had to solve the problem and then numerically represent its result in a form of a fraction (a/b). Both tests had the same level of difficulty and were mathematically equivalent. They were applied to all participants and solved by means of pencil and paper.

Overview to the teaching experiment

The teaching experiment offered to third grade children in the Experimental Group comprised ten 2-hours sessions, two sessions per week over five weeks. The sessions involved whole class activities focusing on a problem task and follow-up questions and discussion posed by the researcher who acted as a teacher according to a previously planned didactical sequence. Children also worked in pairs and in small groups. The role of the researcher was to provide assistance to the students, understand and clarify their thinking (insights and difficulties) and, at the end of each session, offered them a conclusion about the whole activity and its solution. In this instructional experience the approach to fractions was based on (a) realistic and meaningful problem solving situations; (b) student's own fragmentary and informal knowledge; (c) interactive situations: discussion and collaborative work; and (d) student's thinking about their own thought processes when solving problems and communicating verbally their strategies and ideas. Diagrams, manipulative and concrete materials were widely used in a large range of situations involving continuous and discontinuous quantities in which fractions were taught through partitioning and part-whole relations.

RESULTS

The results in the pre and in the post-test, in the three groups of children, were analysed according to the number of correct responses and according to the types of errors children made.

Correct responses

Table 1 presents the general scores in this study. It can be noted that no significant differences were found among the three groups in the pre-test. This result was confirmed by means of Mann-Whitney test (EG vs. CG: p = 0.6080; EG vs. RG: p = 0.7330; and CG vs. RG: p = 0.7502). However, there were marked difference between groups in the post-test (Man-Whitney - EG vs. CG: p = 0.0000; EG vs. RG: p = 0.0000; and CG vs. RG: p = 0.0000). This was due to children in the Experimental Group and in the Reference Group being more successful than children in the Control Group; and children in the Experimental Group performing better than those in the Reference Group.
Table 1: Number and percentage of correct responses.

<table>
<thead>

</tr>
<tr>
<td><strong>Post-test</strong></td>
<td>199 (69.8%)</td>
<td>37 (12.3%)</td>
<td>86 (31.8%)</td>
</tr>
</tbody>
</table>

The performance of each group in the pre and post-test was compared by Wilcoxon test. This revealed that there was no significant difference between pre and post-test for the children in CG (p = 0.5014). In contrast, EG and RG children performed significantly better in the post-test than in the pre-test (p = 0.001 and p = 0.003, respectively). This suggests that both groups of children improved their performance after instruction. However, it is important to know whether the progression children had was similar in both groups.

Looking at each child individually it was possible to identify that there were children who showed a progression from pre to post-test, while others showed a regression in their scores or did not showed any change in their performance (stability over tests). Table 2 and Table 3 presents the incidence of children in each group according to their progression, stability over tests and regression.

Table 2: Number and percentage of children in each group according to their improvement, stability and regression from pre to post-test.

</tr>
</tbody>
</table>

Children in the Experimental Group and in the Reference Group were able to benefit from the instruction given, independently of whether the instruction was a traditional way of teaching (RG) or an alternative one (EG). Regression in performance was only to be found among children in the Control Group. However, when we look at the improvement observed in more details, we can verify that the level of improvement was higher among children in the Experimental Group than among those in the Reference Group, as shown in Table 3.

It can be seen that children who took part in the teaching experiment had a greater improvement than those who were taught about fractions in a traditional way. This was particularly so in relation to the number of children who had Level 3 improvement (EG: 52.6% and RG: 0%).

Types of errors

Three main types of errors were identified in the pre and in the post test:

Type 1 – children interpret fractions as natural numbers when symbolic representing their answers. This error was more often when discontinuous quantities were involved.

Type 2 – children interpret fractions as natural numbers when solving the item, during the solution procedure. This error was more often when discontinuous quantities were involved.

Type 3 – children do not recognise the need of having equal shares when solving the items that required the division of the whole into parts. This error occurred when continuous quantities were involved.

Type 1 errors were related to the representation children used when writing down the results of the items; while Type 2 and Type 3 were related to the solution procedure adopted. On the other hand, Type 1 and Type 2 errors expressed their difficulty to discriminate fractions from natural numbers; while Type 3 expressed their difficulty to divide the parts into equal shares. These errors were reported in previous studies in the literature. Table 4 shows the frequency of these errors in the Experimental Group and in the Reference Group in the pre and in the post-test.

1 Children in the Control Group had the same high incidence of errors in the pre and post-test.
As a whole, the main difficulties children had in the pre-test decreased in the post-test. However, children in the Experimental Group showed a greater decrease of errors than those in the Reference Group. This was particularly so in relation to Type 1 and Type 3 errors. Thus, even though both groups seem to have overcome some of their initial difficulties, children who took part in the teaching experiment had a greater improvement than children who were taught in a traditional way. It is noteworthy to stress that children in the Experimental Group were younger and were attending a more elementary grade than children in the Reference Group.

CONCLUSIONS AND DISCUSSION

The results in this study revealed that the teaching experiment improved children's understanding about fractions. This intervention led third graders to have a better performance than (a) children of the same age and grade who did not receive any instruction on fraction; and (b) children who were older and attending a higher grade of schooling. It is interesting to mention that performance among groups was much the same in the pre-test. This means that children who were not instructed about fractions (third graders in the Experimental and in the Control Groups) showed a similar understanding of fractions as those who already had received instruction on fractions in a traditional way (fourth graders in the Reference Group). After instruction, children who took part in the teaching experiment increased the number of correct response and overcame the initial difficulties they had in the pre-test. Also the number of children who progressed from pre to post-test was greater among them.

The conclusion that can be drawn from the results was that even though both groups benefited from instruction, the alternative approach to fractions given to children in the Experimental Group was likely to be more successful than the traditional approach given to children in the Reference Group.

Another aspect that should be stressed was that a short period of teaching intervention (10 sessions) proved to be beneficial. The teaching appears to have achieved some success. However, one must be cautious about the fact that the teaching proposed here did not explore all the features and situations that are relevant for the understanding of fractions in a broader sense.

To conclude, it is crucial to find ways to reduce some of the difficulties children encounter when dealing with fractions. Also, it is important to encourage classroom discussion: talk to children about their errors, ideas and the strategies they use (independently of whether they are correct or not); and listen to children by encouraging them to communicate verbally their ways of thinking and their interpretation of fractions. Actually, teachers and researchers should, in collaboration, raise and test hypotheses about how to promote children's understanding of fractions.
Further intervention studies should be conducted with elementary school children. It would be of interest, for instance, to develop a teaching experience in which students would be given the opportunity to explore fractions in a wider context, in different situations, using different forms of representation and in connection with other mathematical concepts. Fractions should be introduced and explored through a large variety of situations (including 'part of a whole model' since it showed to be useful to establish some of the basic ideas about fractions) that allowed children to understand a fraction as a number, to relate it to division and to recognise the equivalence between fractions.

LINGUISTIC POINTERS IN YOUNG CHILDREN'S DESCRIPTIONS OF MENTAL CALCULATION

Chris Bills
Oxfordshire Mathematics Centre, Oxford, OX4 3DW

Children's descriptions of their mental calculations can reveal more to the teacher than merely the strategy that has been used. An analysis of nearly 2000 responses given in interview by 26 children aged between 6 and 9 years old has revealed that the language they use may point to individual differences in their modes of thought. Different use of pronouns, tense and causal connectives was associated with different levels of achievement. Descriptions of calculations which accompanied correct answers were more likely to be in the present tense, to be expressed in terms of what "you" do and were more likely to include explanatory words of deduction: "if", "then", "so" and "because".

INTRODUCTION

This paper focuses on the different styles of language that young children use when describing a mental calculation they have just performed. I have previously described this language as 'image-like' (Bills and Gray, 1999) because the words used were related to previous classroom activities. I have suggested that the language could indicate the influence of these activities on the children's thinking. Analysis of the descriptions of 45 mental calculation questions performed in six interviews has also revealed that higher achieving children tended to use a language of generalisation. Lower achievers simply described the particular calculation (Bills and Gray, 2001).

The data presented in this paper suggest that there are other linguistic characteristics of descriptions of mental calculations that are associated with levels of achievement. The speech style observed in the classrooms in this study used the present tense and the pronoun "you" to describe calculation procedures. Language of deduction (causal connectives: "if", "then", "so" and "because") was used in explanations by teachers and pupils. In my interviews with children they most frequently adopted this style when describing a calculation they had performed successfully.

All the children in this study had the same teaching yet differences in their learning was apparent in the differences in their language. I suggest that this is evidence that commonalities in language may simply reflect the speech style of the community yet differences in the use of language may be indicative of differences in mental constructions. The children in this study had been exposed to language of procedure and explanation and they all demonstrated that they could use it in non-calculation situations. The more frequent use of this language style in association with correct answers suggests that its use was not simply a linguistic trait but that it was used when children had a successful procedure. The conclusion is drawn that teachers may
learn something about learners' procedural knowledge from the language that they use. Language can act as a 'pointer' to different qualities of thinking.

LINGUISTIC POINTERS

Deictic terms: "this", "it", "you", (from the Greek 'deixis', meaning to point), serve to identify objects, people, times and places without reference to particular things. Rowland (1995) has thus suggested that the use of these words could be indicative of a generalisation. Rowland proposed as a 'deictic principle' that language is a code to express and 'point to' concepts, meanings and attitudes. So that not only deictic terms themselves but use of other words could be indicators of cognitive structures.

Rowland (2000) noted that the use of the pronoun "you" to refer to generalities, i.e. what usually happens, is common in non-mathematical situations where "you" is frequently used in place of the more formal "one". This is particularly true of children in their description of rules of games. Rowland has also suggested, however, that the use of "you" is an effective 'linguistic pointer' to a quality of thinking. For the pupil in Rowland's study the shift from "I" to "you" in a problem solving situation signified her move from working with particular numbers to expressing a generalisation.

The quality of the language used in explanations may also be an indication of the quality of understanding. Donaldson (1986) questioned whether young children's inability to give an explanation is due to poor understanding of the concept to be explained or to a lack of the linguistic ability to explain. She argued that adequate linguistic competence for explanation is demonstrated by appropriate use of the causal connectives "because" and "so". Her studies show that children do use "because" and "so" appropriately and by the age of eight years can use them in the deductive mode. She concluded that the linguistic ability of understanding causal connectives and the cognitive ability of understanding causality are interdependent.

In a study conducted by Vygotsky (1962) 80% of children in the sample, at both 7 and 9 years, were able to correctly complete sentence fragments ending in "because" when related to 'scientific concepts'. Only 60% of the 7 year-olds could do this with sentences related to 'spontaneous' everyday concepts. He attributed this to the fact that scientific concepts had been learned in collaboration with teachers. He assumed that the ability to use "because" appropriately in everyday concepts is improved by being able to do so in scientific concepts. Luria (1982) noted that children may understand the ordinary features of their familiar social experience but will need activities to provide experience of the unfamiliar scientific concepts encountered in more formal school settings. He suggested that at school children may initially use words or perform actions without knowing why. Thus children can use words and perform actions initially without having the same understandings as the teacher.

Piaget (1928) referred to Claparede's 'law of conscious realisation': the more automatically an idea is handled, the harder is the process of its conscious realisation. Piaget suggested that when asked how they had performed a calculation, after giving
an answer by some automatic process, children may invent something which would give rise to the same answer. In my study (Bills and Gray, 2001) it seemed that when the high achievers performed the calculation automatically (the answer was given very quickly) they simply stated a rule that would give the answer. The lower achievers tended to describe, in detail, the particular calculation they had performed. This adds supports to Piaget's suggestions that initially children can only reason about the particular (Piaget, 1928) and also that the child only imitates that which he can understand (Piaget & Inhelder, 1971). Higher achievers may have expressed themselves in terms of a generalisation because they understood the rule in this way whilst lower achievers only gave the steps in the particular procedure performed.

Rowland, Donaldson and Piaget suggest that language may indicate individual mental constructions whilst Vygotsky and Luria maintain that language is a social construction. The data presented in this paper suggest both perspectives are valid.

METHOD

Lesson observations and pupil interviews were first conducted with two classes from Year 3 (pupils aged 7 and 8 years) in a school for children aged 5 to 11 years in a large middle-income village near Birmingham U.K., from September 1998 to July 1999. The same pupils were also observed and interviewed in the following year. The 80 children in the whole year had been placed in one of three groups for mathematics lessons based on their previous attainments. Lessons with the high attainment and the middle attainment groups were observed and a sample of 14 pupils from the first and a sample of 12 pupils from the second was interviewed in December, March and July in each year. The samples were chosen to represent the spread of attainment levels in each group.

Over the six interviews 78 questions were used. They were classified into 10 calculation types and 6 non-calculation type. Each was presented verbally and followed by the question “What was in your head when you were thinking of that?”

PME26 2002
Each response to “What was in your head?” was analysed for its use of pronouns, tense and causal connectives.

Responses involving “I” and “you” were categorised in to three types which conform with the ‘particular’, ‘generic’ and ‘general’ classifications described in Bills and Gray (2001). The examples given here are responses to the question “What was in your head?” following the mental calculation “What is 48 add 23?”:

Category 1: responses related to the particular, expressions such as “I/you did this”
- Bobby: I added the 40 and the 20 to make 60 then I added the 8 and the 3.
- John: 48 add 20 comes 68 and then you add 3 on.

Category 2: responses related to examples, expressions such as “I/you do with these”
- Simon: say I was adding 30, I go 40, 50, 60
- Irene: you put the one down in the units column in your head and you carry one

Category 3: responses related to the general, expressions such as “I/you always do”
- Ellain: I count it all in my head, and I sometimes use my fingers
- Elspeth: you just take the ten of there and you put it back and you put it together

RESULTS

Linguistic characteristics of correct calculations

There were 1158 mental calculations performed in the interviews and 63% of these were correct. A comparison was made between the responses which accompanied correct mental calculations and the responses which accompanied incorrect calculations. Tables for the distribution of correct and incorrect responses involving different uses of pronoun, tense and causal connectives were compiled and chi-squared tests of significance conducted. Only tables for statistically significant results will be given here.

The following table suggests that pupils whose calculation was described exclusively using “you” were more likely to have been correct than those who used “I” exclusively or a mixture of the two. Notice that 97 responses used “you” only and
79% of these were correct. In comparison 520 responses used “I” exclusively and only 65% were correct. The differences in proportions of correct and incorrect responses was statistically significant (p<0.05):

<table>
<thead>
<tr>
<th>Percentage correct</th>
<th>“I” only</th>
<th>“I” and “you”</th>
<th>“you” only</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of responses</td>
<td>65%</td>
<td>66%</td>
<td>79%</td>
</tr>
<tr>
<td></td>
<td>520</td>
<td>166</td>
<td>97</td>
</tr>
</tbody>
</table>

Analysis of the categories of pronoun use is also informative. When “I” was used to describe specifically what the individual had done in that particular question the answer was less likely to have been correct than if “I” indicated what the individual did in general (p<0.005):

<table>

</tr>
</tbody>
</table>

By contrast the difference in the distributions for different categories of “you” was not statistically significant. These two results for categories of pronoun use suggest that the adoption of the common classroom speech style involving use of “you” may be less of an indicator of understanding than the use of the personal pronoun “I”. The use of “I” may point to ownership of the rule whilst “you” may simply follow the classroom convention.

The difference between the distribution of tenses in which children chose to phrase their explanations after they had given a correct answer and after an incorrect answer was also statistically significant. It appears that exclusive use of past tense was accompanied by a lower proportion of correct answers than present tense and mixed tense expressions (p<0.05):

<table>
<thead>
<tr>
<th>Percentage correct</th>
<th>past tense</th>
<th>present tense</th>
<th>mixed tenses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of responses</td>
<td>62%</td>
<td>71%</td>
<td>71%</td>
</tr>
<tr>
<td></td>
<td>391</td>
<td>244</td>
<td>259</td>
</tr>
</tbody>
</table>

There is again an indication that descriptions simply of what had been done were associated with less successful calculations than descriptions phrased in the rule giving, present tense, mode.

When any of the causal connectives were used it was more likely that the correct answer had been given than those responses where no causal connective had been used. This could indicate that use of language of explanations is more frequently associated with correct mental calculations and thus with greater procedural competence. The differences in the proportions correct were all statistically significant (p<0.005):
Linguistic characteristics of high and low achievers

The sample of 26 children achieved between 12 and 38 correct answers out of 45 mental calculation questions. The 13 pupils above the median were classified as ‘high achievers’ and the remainder as ‘low achievers’. Comparisons were made between the distributions of responses involving the linguistic indicators (pronouns, tense and causal connectives) for the two groups. The differences were all statistically significant (p<0.05)

<table>
<thead>
<tr>
<th>Percentage of responses involving the indicator</th>
<th>Higher achievers</th>
<th>Lower achievers</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>(n=578)</td>
<td>(n=580)</td>
</tr>
<tr>
<td>“I” only</td>
<td>42%</td>
<td>49%</td>
</tr>
<tr>
<td>“you” only</td>
<td>11%</td>
<td>6%</td>
</tr>
<tr>
<td>past tense</td>
<td>41%</td>
<td>34%</td>
</tr>
<tr>
<td>“because”</td>
<td>20%</td>
<td>13%</td>
</tr>
<tr>

<tr>
<td>“then”</td>
<td>45%</td>
<td>32%</td>
</tr>
<tr>
<td>any connective</td>
<td>66%</td>
<td>49%</td>
</tr>
</tbody>
</table>

The proportions of ‘category 3’ pronoun use were also compared. A higher proportion of the use of “I” was category 3 for the higher achievers than for the lower achievers. Similarly with use of “you”:

<table>
<thead>
<tr>
<th>Percentage of responses involving the indicator</th>
<th>Higher achievers</th>
<th>Lower achievers</th>
</tr>
</thead>
<tbody>
<tr>
<td>“I” category 3</td>
<td>32% (of 244 uses of “I”)</td>
<td>19% (of 284 uses of “I”)</td>
</tr>
<tr>
<td>“you” category 3</td>
<td>25% (of 157 uses of “you”)</td>
<td>17% (of 89 uses of “you”)</td>
</tr>
</tbody>
</table>

The differences were statistically significant (p<0.05). The responses to non-calculation items in the interviews were also analysed for use of the linguistic indicators. There were no statistically significant differences in the distributions for the two groups of children for any of these indicators in non-calculation contexts.
DISCUSSION

The fact that the two groups of children had the same linguistic characteristics in non-calculation questions suggests that the differences apparent in response to calculation questions were not simply a matter of linguistic ability. All the children were capable of using causal connectives in non-calculation context and the two groups did so in similar proportions. Their use of pronouns and tense was also similar in these non-calculation contexts. The differences between their response after calculations had been performed may thus be an indication that they had different ways of thinking about those calculations. The higher proportion of use of causal connectives to accompany correct calculations may indicate that the procedure was well understood.

The use of the pronoun “you” and present tense was common in the classrooms observed. All the children were exposed to phrases such as “you add the tens and you add the units”. Some used phrases like this when describing what was in their head after performing a mental calculation. Others talked only of the particular calculation and used phrases such as “I added 40 and 20 and I added 8 and 3”. Those who adopted the teachers’ mode of language were the most successful. This suggests that the children were not simply copying the language. They tended to use this mode of language when they were using a procedure which was successful. Notice that my question “What was in your head?” would seem to require a response from the individual in the past tense and in the first person. The fact that they chose to use the classroom speech style is an indication that they were following a familiar procedure.

Rowland has suggested that children’s use of “you” may be a pointer to their progress toward generalisation. In this study the use of “you” is an indication that a familiar procedure had been followed but rules that the individual used were also expressed in general terms using “I”. Expressions involving “I” to describe what the individual does rather than simply what they did were more likely to accompany correct answers. This mode of expression could thus be a powerful indication that the child has formed their own generalisation since it is not couched in the ubiquitous classroom style using “you”. The individual pupil may demonstrate their individual mental construction based on their experience of the classroom activities through their use of “I” in expressing general rules.

It is not surprising that children adopt the common classroom speech style but the results presented above seem to suggest that pupils are more likely to do so to accompany a successful calculation. The social constructivist perspective of Luria and Vygotsky could suggest that all children might simply adopt the classroom speech style. This study indicates that the pupils were most likely to do so when they were successful. There is an indication in this that the children’s different language use was a pointer to their different mental constructions. The pupils were capable of simply copying their teacher’s style of language but were less likely to do so when they had given an incorrect answer even though they were not told if their answer was right or wrong.
IMPLICATIONS FOR THE CLASSROOM

Use of “I” in the sense of ‘what the individual does in general’ was not common after mental calculations had been performed (8% of responses) but on nearly 80% of these occasions the answer was correct. Similarly exclusive use of “you” is unusual (11% of responses) and has the same high association with correct answers. The causal connectives are also strong indicators, particularly “because” and “if”, with low proportions of occurrence but high associations with accuracy.

These words thus act as linguistic ‘pointers’ to a quality of thinking which the teacher will wish to encourage. In the classroom children’s use of these linguistic pointers can alert the teacher to differences between individuals. They may also give indications of development in thinking. A single response can not, in itself, give an assessment of a pupils procedural competence but responses over a period of time can point to a changing quality of thinking. Identifying differences between pupils does nothing to improve the learning of pupils who are less successful in mathematics unless the information is used by teachers to help these pupils gain greater understanding. Identifying the pupils’ differences through the use of the linguistic pointers can be a first step.

Listening to the words that children use can be more informative than listening simply to the strategy that has been employed.

DESIGN PRINCIPLES FOR TASKS THAT SUPPORT ALGEBRAIC THINKING IN ELEMENTARY SCHOOL CLASSROOMS

Maria L. Blanton and James J. Kaput
University of Massachusetts Dartmouth

The purpose of this work is to describe design principles for mathematical tasks in elementary school that have been transformed from arithmetic tasks to those that exploit algebraic thinking. In particular, we discuss design elements of these 'algebrafied' tasks that can elicit students' activity of generalizing, where our particular mathematical focus is on generalizing from numerical patterns to describe functional relationships. We also consider ways in which arithmetic, particularly number and operation, are embedded in the creation and analysis of patterns. Classroom data in which third-grade students solve the Handshake Problem is used as a context for elaborating these ideas.

BACKGROUND FOR THE STUDY

Algebraic Reasoning as a Way of Thinking Mathematically

Traditionally, the focus of elementary mathematics has been deeply oriented to arithmetic and computation, with little attention given to the relationships and structure underlying simple arithmetic tasks. However, there is a growing recognition that algebraic reasoning can emerge from and simultaneously enhance elementary school mathematics (NCTM, 2000) and can consequently build habits of mind that will prepare students for the more complex mathematics of the new century (Romberg & Kaput, 1998). By algebraic reasoning, we refer to students' activity of generalizing about data and mathematical relationships, establishing those generalizations through public conjecture and argumentation, and expressing them in increasingly formal ways (Kaput 1999). Indeed, algebraic reasoning extends far beyond a traditional view of algebra as an act of syntactically-guided symbolic manipulations and can occur in various interrelated forms, including (a) the use of arithmetic as well as mathematical and non-mathematical situations as domains for expressing and formalizing generalizations; (b) generalizing numerical patterns to describe functional relationships (including covariation); and (c) generalizing about mathematical systems abstracted from computations (Kaput, 1998). Our interest in fostering the development of algebraic reasoning in elementary school mathematics prompted us to consider the kinds of tasks that might be used to exploit mathematical ideas that the discipline recognizes as "algebraic" and to examine characteristics of these tasks that signal this. We discuss our partial results here and report on them more widely in Blanton and Kaput (2001).
The GEAAR Professional Development Project

The work reported here is drawn from our multi-year, district-wide professional development program, Generalizing to Extend Arithmetic to Algebraic Reasoning (GEAAR), designed to develop elementary teachers’ ability to identify and strategically build on classroom opportunities for algebraic thinking. In particular, we engage in year-long professional development with teachers in a strategy directed toward classroom-grounded change along three dimensions: (1) building opportunities for algebraic thinking from teachers’ available instructional resources; (2) building teachers’ capacity to identify spontaneous opportunities for algebraic thinking in the classroom through a focus on student thinking; and (3) building teachers’ capacity to create a classroom culture that can support active student generalization and formalization within the context of purposeful conjecture and argumentation. As part of the project, teachers are asked to contribute “algebrified” tasks that they have developed or selected for use in their own classrooms. During one of our sessions with teachers (Kaput and Blanton, 1999), we and the teachers came to value the feature that generalizing a functional relationship could be achieved through an analysis of the form of non-executed sums describing a total for some prescribed quantity (e.g., the number of ‘right-side-up’ triangles in a large triangle subdivided into smaller triangles). As a result, we began to focus in our sessions with teachers on a genre of tasks with this characteristic and to explore how these tasks could further support algebraic thinking and simultaneously leverage students’ experiences with arithmetic, particularly number and operation.

We base the findings reported here on a one-year case study of a third-grade classroom, the teacher of whom has been one of our central participants in the GEAAR Project. The data from which we draw our results were taken from a 45-minute classroom episode that is part of a larger data corpus including student work, the teacher’s (Jan – pseudonym) reflections, and classroom field notes, all collected during one academic-year period. In the classroom episode, students solved an ‘algebrified’ version of the Handshake Problem, that is, they solved a task traditionally formulated as a single-numerical answer problem that had been transformed to the following:

If 5 people in a group shake hands with each other once, how many handshakes will there be? What if there are 6 people in the group? Seven people? Eight people? Twenty People? Write a number sentence that shows your result. Show how you got your solution.

We selected this problem because it reflects a genre of problems used in our seminars with teachers, and subsequently in their own classrooms, that illustrate the potential for arithmetic tasks to support algebraic thinking, particularly as it relates to generalizing numerical patterns in order to describe functional relationships. In what follows, we draw on students’ experiences with the Handshake Problem to describe several of the principles of these tasks that we see as supporting algebraic thinking in
conjunction with students’ experiences with arithmetic, particularly number and operation.

**PRINCIPLES OF PATTERN-ELICITING “ALGEBRAFIED” TASKS**

**Principle 1: The tasks promoted the use of number and number sentences as objects for reasoning algebraically.**

The tradition in elementary school mathematics of finding “the answer” (usually a single numerical value) can disguise the algebraic potential of tasks such as the Handshake Problem by diverting students to a process of finding patterns in a sequence of numbers rather than looking for a functional relationship between varying quantities. In the Handshake Problem, when students rushed to compute the total number of handshakes for groups of varying size they were left with a sequence of numbers, not number sentences, which limited their capacity to develop a predictive model. While finding patterns in a sequence of numbers is a useful task, we argue that it does not engage the full algebraic character of the task because it limits the scope of predictability to consecutive states. The power of functions rests ultimately in their capacity as mathematized objects to allow predictions beyond the scope of known data. To this end, we were interested in suspending computation so that students could reason with the *forms* of the number sentences and thereby deduce a functional relationship. With the Handshake Problem, we found that by using sequences of number sentences and deliberately not computing them, students were able to attend to the sums for their shapes as inscriptions, rather than as instructions to perform procedures. By analyzing these forms, they were able to determine a relationship between the size of any group and the number of handshakes. In essence, treating these non-executed sums as algebraic objects allowed for an analysis of co-variation in the data so that students were able to generalize that the number of handshakes in a group of any size would be “the sum of the numbers from one (or zero) up to one less than the number of people in the group”.

Another important feature of these tasks is that they allowed for the *algebraic use of number*. A mature understanding of the concept of function ultimately requires students to attend to the notion of arbitrariness. Numbers can be used algebraically when the type or size of number chosen requires the student to think about structure and relationship between quantities, not simply arithmetic operations on quantities. With the Handshake Problem, by asking students to determine the number of handshakes for a group of 20 people without knowing the previous cases, we maintain that ‘20’ was treated algebraically because it called on students to analyze the structure embedded in the *forms* of a sequence of arithmetic models, or number sentences.
Principle 2: The tasks involved sequences of computations that could be exploited to engage students arithmetically.

The dominant role of arithmetic in elementary schools requires that we think about how to make its role in the more complex processes of algebraic thinking explicit. Tasks such as the Handshake Problem can deeply support arithmetic while simultaneously engaging students in algebraic processes. For instance, mathematizing the act of shaking hands required students to understand the correspondence between a collection of counted handshakes and the number representing it, as well as how to operate additively to find a total amount. These particular aspects of the task were more significant for those teachers in earlier grades where counting and numeracy were in earlier stages of development. Students’ facility with number and operation were also strengthened by looking for efficient counting strategies, as the following excerpt illustrates. In it, students were calculating the number of handshakes in a group of size 12, that is, they were computing the sum ‘$11 + 10 + 9 + 8 + 7 + 6 + 5 + 4 + 3 + 2 + 1$’.

1 Teacher: Did anybody change the order of those numbers in any way when you added them?
2 Student: Yes. You can change them to tens.
3 Teacher: You made tens out of these?
4 Student: We put 11, 10, 9, 8...(voice trails off). You don’t need to [add 1 through 7] over again.
5 Student: All you have to do is put 11, 10, 9, 8 on top of all the numbers we had.
6 Student: You don’t say 12.
7 Teacher: You don’t say 12? Why don’t you say 12?
8 Student: Cause you can’t shake your own hand.
9 Teacher: Now, wait a minute. You just said...
10 Student: ...that we didn’t have to count 7, 6, 5, 4, 3, 2, 1, 0...because we knew they already equaled 28.
11 Teacher: Okay, that’s pretty good!...Zolan did something that I really liked.... What did you do?
12 Zolan: I added the 11 and 10 together. (From the result of 21, he then subtracted 1.) Then I added the extra 1 of the 11 to the 9 and that made a 10.

Zolan had commuted the numbers in such a way that he could add groups of 10. Later in the episode, another conversation occurred about a strategy for computing the sum of the number of handshakes for a group of size 20. At students’ suggestion, Jan had written ‘$0 + 1 + 2 + 3 + 4 + 5 + 6 + 7 + 8 + 9 + 10 + 11 + 12 + 13 + 14 + 15 + 16 + 17 + 18 + 19$’ on the board. She asked, “Is there a way that we can change the order of these numbers and make them easier to add up?”
13 Student: You can take the zero and put it, you can change it around by putting the 19 where the zero was and that would be easier. (We infer that the student meant to add '19 + 0'.)

14 Teacher: Can I do this? If I do this, 19 + 0....

15 Student: That equals 19.

16 Teacher: What else could I do?

17 Student: You could do 18 + 1.

18 Student: What about 17 + 2?

19 Teacher: What about 17 + 2? Wait a minute. Let me just try this. So I've used those two (19, 18) and these two numbers (0, 1). (Jan drew lines on the board connecting the numbers in each pair.) Let me see 17 + 2. Okay. These are pairs aren't they? How many pairs of numbers do you think we're going to be able to make out of these 20 numbers? ...Anthony, how many do you think we are going to make?

20 Anthony: Ten.

21 Teacher: Why?

22 Anthony: Because you need to get 1 from each side.

23 Teacher: Let's see if we do make 10 pairs of numbers.

24 Student: Each one (pair) is equal to 19.

After they had established that there would be 10 pairs of numbers, the sum of each being 19, Jan said, "Now I've got to add up all these 19's. What is this?"

25 Student: Repeated addition. You could do times.

26 Teacher: I could do times?

27 Student: Nineteen times 10....190.

28 Teacher: How did you figure that out so quickly?

29 Student: I just changed that to 9 and added a zero.

30 Teacher: Why?

31 Student: Because the one is a 100 and 9 is 90.

We found that when asked to find efficient strategies for computation, students looked for relationships in the arithmetic models in order to organize numbers in ways that exploited productive pairings. For example, recognizing that they could generate a sequence of sums of 19 by adding 0 to 19, 1 to 18, 2 to 17, and so forth, students used this to more effectively 'add' by multiplication. Moreover, students' proficiency with these maneuvers required an understanding of operation, particularly the generalized commutativity of addition and a sophisticated concept of 'counting on'. Indeed, while data from observations earlier in the year showed that 'counting on' was an emerging part of these students' cognitive schemes, the
Handshake Problem seemed to more fully form this concept in their thinking. In particular, students were able to count on from a previously determined sum and interact with that sum as an independent object. All of these processes, such as counting on, commuting numbers, and mathematizing handshakes, occurred in meaningful contexts in which students explored issues of numeracy and increased their facility with number and operation. Moreover, they were simultaneously engaged in the more complex processes of algebraic thinking about relationships and properties of whole numbers and, especially, attention to forms of the number sentences from which they could deduce general relationships. As a result, the arithmetic was not neglected but became an integral part of students' algebraic reasoning.

Principal 3: The tasks allowed for the enactment of actions and situations familiar to students.

By this we mean the tasks allowed students to construct a sequence of number sentences, or arithmetic models, from a context that accessed their everyday experiences (e.g., shaking hands) and in such a way that sequential cases could be explicitly examined to see how perturbations in one case affected other cases. We conjecture that to have these explicit cases, or number sentences, available as permanent artifacts of the task enabled students to move more easily between the abstraction of the models and the source for interpreting the models, namely the physical context of the problem. In contrast, reducing a model to a computed sum would have concealed the physical actions embodied by the representation. In essence, we maintain that students' analysis of the relationship between the number of handshakes and the amount of people in the group was facilitated by symbolizing a familiar action and by keeping that action explicit. To the extent that the sequential nature of these tasks and the explicit number sentences they generated made functional relationships more recognizable, we maintain that this principle supported students' opportunity for algebraic thinking.

CONCLUSION

Tasks such as the Handshake Problem represent one (of many) genre of 'algebrafiable' tasks that can enrich elementary school mathematics. We found that tasks which leveraged students' arithmetic knowledge and included some act of mathematizing a phenomenon so that a mathematical abstraction had its representation in a familiar context and where that abstraction was left in an explicit form (e.g. '1+2+3+4+5+6') could help access students' capacity for algebraic thinking. One significant feature of such tasks is that they embed the arithmetic in a context that requires more complex mathematical thinking, such as (a) knowing to and knowing how to represent data; (b) using arithmetic (number and operations) to model a phenomenon that involves variation; (c) examining how perturbations in a phenomenon affect a model; (d) reasoning algebraically about the forms of
sequences of number sentences; (e) deepening arithmetic reasoning to support the appropriate use and choice of operations and to understanding relationships between numbers in order to facilitate computation; and (f) the algebraic use of numbers and number sentences. Thus, it is our claim that these types of tasks offer students a mathematical experience where arithmetic and algebraic processes interact symbiotically.

NOTES

1 The research reported here was supported in part by a grant from the U.S. Department of Education, Office of Educational Research and Improvement to the National Center for Improving Student Learning and Achievement in Mathematics and Science (R305A600007-98). The opinions
expressed herein do not necessarily reflect the position, policy, or endorsement of supporting agencies.
In this paper I will trace a path through three different studies of mathematics learning in England and the United States. As different analytical lenses are cast upon students' experiences I will propose that notions of mathematical capability expand beyond knowledge, to include mathematical practices and the identities these encourage. Further that different classroom practices encourage students to develop different relationships with the discipline of mathematics that impact their capability in profound ways.

Researchers of mathematics education have, for many years, focused upon the knowledge students develop in classrooms, and the ways such knowledge is influenced by a number of different variables. Recently, situated theories of learning have led to the recognition that the practices of classrooms – the repeated actions in which students and teachers engage as they learn – are important, not only because they are vehicles for students' knowledge development, but because they come to constitute the knowledge that is produced (Cobb, 1998). Thus the field has moved to greater recognition of the intricate relationship between knowledge and practice and the need to study the practices of classrooms in order to understand students' mathematical capability in different situations. In this paper I will attempt to expand notions of mathematical capability yet further, to go beyond both knowledge and practice, to the identities students form in relation to different mathematical practices, and the disciplinary relationships that are afforded by different classroom experiences. Thus I will suggest that when students approach a new mathematics problem, the extent to which they are able to use mathematics depends partly on the knowledge they have developed, partly upon the practices in which they have engaged as they have learned, and partly upon the relationships they have developed with the discipline of mathematics. This focus on students' disciplinary relationships combines important mathematics education research on knowledge and practice (Cobb, 1998; Hershkowitz, 1999) with that on belief, disposition and identity (Christou & Philippou, 1998; DeBellis & Goldin, 1999).

The inter-relationship between the practices in which students engage in classrooms and the subsequent knowledge they develop, was demonstrated by a three-year study of students learning mathematics that I conducted in England.
(Boaler, 1997). In that study I monitored 300 students who learned mathematics in very different ways. Students at one school learned through 'traditional' methods of watching and repeating standard algorithms and procedures, students at the other schools learned through open-ended projects. One of the findings of the research was that students' knowledge development in the two schools was constituted by the pedagogical practices in which they engaged (Boaler, 1997, 1999). Thus it was shown that practices such as working through textbook exercises, in one school, or discussing and using mathematical ideas, in the other, were not merely vehicles for the development of more or less knowledge, they shaped the forms of knowledge produced. One outcome, was that the students who had learned mathematics working through textbook exercises, performed well in similar textbook situations, but found it difficult using mathematics in open, applied or discussion based situations. The students who had learned mathematics through open, group-based projects were able to use mathematics in a range of different situations, partly because the classroom practices in which they had engaged were represented elsewhere.

In that study the students who had learned through open-ended projects outperformed the other students in a range of assessments, including the national examination. One conclusion that may be drawn from such a result, that would fit with cognitive interpretations of learning, would be that the students in the traditional school did not learn as much as the students who learned mathematics through open-ended projects, and they did not understand in as much depth, thus they did not perform as well in different situations. That interpretation is partly correct, but it lacks important subtleties in its representation of learning. A different analytical frame that I found useful, was to recognize that the students learned a great deal in their traditional mathematics classrooms. They learned to watch and faithfully reproduce procedures and they learned to follow different textbook cues that allowed them to be successful as they worked through their books. Problems occurred because such practices were not useful in other situations (Winbourne & Watson, 1998). When the students did not use mathematics effectively in different assessments, it was not because they had not met and 'learned' the mathematical knowledge, but because they tried to repeat the mathematical practices they had learned in the classroom and which shaped their knowledge (such as searching for cues and repeating standard methods) and these did not help them in non-standard assessments. Thus I came to understand the students' mathematical capability as an intricate relationship between mathematical knowledge and mathematical practices.

That study revealed an important dimension of mathematical capability that extended beyond knowledge, to the practices in which students engaged, but two subsequent studies that I will briefly summarise have raised further aspects of mathematical capability that extend beyond knowledge and practice. In the first study I and fellow researchers interviewed eight students from each of 6 Northern Californian high schools (Boaler & Greeno, 2000). The 48 students we
interviewed were all attending advanced placement (AP) calculus classes. In that study four of the schools taught using traditional pedagogies – the teachers demonstrated methods and procedures to students, who were expected to reproduce them in exercises. In the other two schools, students used the same calculus textbooks, but the teachers did not rely on demonstration and practice, they asked the students to discuss the different ideas they met, in groups. In that study we found that students in the more traditional classes were offered a particular form of participation in class that we related to Belencky, Clinchy, Goldberger, & Tarule’s notion of ‘received knowing’ (1986, p4). Mathematics knowledge was *presented* to students and they were required to learn by attending carefully to both teachers’ and textbook demonstrations. The mathematical authority in the classrooms was external to the students, resting with the teacher and the textbooks, and the students’ knowledge was dependent upon these authoritative sources. In these classrooms the students were required to receive and absorb knowledge from the teacher and textbook and they responded to this experience by positioning themselves as *received knowers* (Belencky et al, 1986).

The students who were learning in these traditional classrooms were generally successful, but we found that many students experienced an important conflict between the practices in which they engaged, and their developing identities as people (Wenger, 1998). Thus many of the students talked about their dislike of mathematics, and their plans to leave the subject as soon as they were able, not because of the cognitive demand, but because they did not want to be positioned as received knowers, engaging in practices that left no room for their own interpretation or agency. The students all talked about the kinds of person they wanted to be – people who used their own ideas, engaged in social interaction, and exercised their own freedom and thought, but they experienced a conflict between the identities that were taking form in the ebb and flow of their lives and the requirements of their calculus classrooms:

K: I'm just not interested in, just, you give me a formula, I'm supposed to memorize the answer, apply it and that's it.

Int: Does math have to be like that?

B: I've just kind of learned it that way. I don't know if there's any other way.

K: At the point I am right now, that's all I know. (Kristina & Betsy, Apple school)

Most of the students who told us about their rejection of mathematics in the 4 didactic classrooms – 9 girls and 5 boys, all successful mathematics students – had decided to leave the discipline because they wanted to pursue subjects that offered opportunities for expression, interpretation and human agency. In contrast, those students who remained motivated and interested in the traditional
classes were those who seemed happy to 'receive' knowledge and to be relinquished of the requirement to think deeply:

J: I always like subjects where there is a definite right or wrong answer. That’s why I’m not a very inclined or good English student. Because I don’t really think about how or why something is the way it is. I just like math because it is or it isn’t. (Jerry, Lemon school)

The students in didactic classes who liked mathematics did so because there were only right and wrong answers, and because they did not have to consider different ideas and methods. They did not need to think about ‘how or why’ mathematics worked and they seemed to appreciate the passive positions that they adopted in relation to the discipline. For the rest of the students in the traditional classes, such passive participation was not appealing and this interfered with their affiliation and their learning.

In the other two calculus classes in which teachers engaged students in mathematical discussions, a completely different picture emerged. In the discussion oriented classes the students had formed very different relationships with mathematics that did not conflict with the identities they were forming in the rest of their lives. The students in these classes regarded their role to be learning and understanding mathematical relationships, they did not perceive mathematics classes to be a ritual of procedure reproduction. This lack of conflict was important – it meant that the students who wanted to do more than receive knowledge, were able to form plans for themselves as continued mathematics learners. The type of participation that is required of students who study in discussion-oriented mathematics classrooms is very different from that required of students who learn through the reception and reproduction of standard methods. Students are asked to contribute to the judgment of validity, and to generate questions and ideas. The students we interviewed who worked in discussion-based environments were not only required to contribute different aspects of their selves, they were required to contribute more of their selves. In this small study we found the notion of identity to be important. Students in the different schools were achieving at similar levels on tests but they were developing very different relationships with the knowledge they encountered (Daskal & Simpson, 2000). Those students who were only required to receive knowledge described their relationships with mathematics in passive terms and for many this made the discipline unattractive. Those who were required to contribute ideas and methods in class described their participation in active terms that were not inconsistent with the identities they were developing in the rest of their lives.
That was a small interview study but it served to illuminate the importance of students' relationship with the discipline of mathematics that emerged through the pedagogical practices in which they engaged. In the final study that I will describe, a team of researchers is monitoring the learning of approximately 600 students as they go through three different high schools in the US. Two of the schools offer a choice of mathematics curriculum, which they describe as 'traditional' and 'reform' oriented. In the 'reform' classrooms we observe very different patterns of interaction than those in 'traditional' classrooms and as we work to understand the capabilities that are being encouraged by these examples of classroom interaction we are finding notions of identity and agency to be important.

The students in the reform classrooms we are studying, as in the project based school in England, are given the opportunity to use and apply mathematics, a process which confers upon them considerable amounts of human agency. Students are required to propose 'theories', critique each other's ideas, suggest the direction of mathematical problem solving, ask questions, and 'author' some of the mathematical methods and directions in the classroom. We are finding that the nature of the agency in which students engage in these classrooms is related to the discipline of mathematics and the practices of mathematicians in important ways. Such insights have emanated from an analytic frame proposed by Andrew Pickering (1995). Pickering studied the work of professional mathematicians and concluded that their work requires them to engage in a 'dance of agency' (1995, p116). Pickering considers some of the world's important mathematical advances and identifies the times at which mathematicians use their own agency – in creating initial thoughts and ideas, or by taking established ideas and extending them. He also describes the times when they need to surrender to the 'agency of the discipline', when they need to follow standard procedures of mathematical proof, for example, subjecting their ideas to widely agreed methods of verification. Pickering draws attention to an important interplay that takes place between human and disciplinary agency in mathematical work and refers to this as 'the dance of agency' (1995, p116).

Pickering's framework seems important for our analyses of the different practices of teaching and learning we observe. 'Traditional' classrooms are commonly associated with disciplinary agency, as students follow standard procedures of the discipline. 'Reform' classrooms, by contrast, are associated with student agency, with the idea that students use their own ideas and methods. The idea that students use their own ideas instead of learning standard methods is part of the reason that many are concerned about 'reform' approaches in the US, but we do not see students failing to learn standard methods in our observations of 'reform' classrooms. Rather than a group of students wandering unproductively, inventing methods as they go, we see a collective engaged in the 'dance of agency'. The students spend part of their time using standard methods and procedures and part of the time 'bridging' (Pickering, 1995, p11) between
different methods, and modifying standard ideas to fit new situations. In many of
the traditional classrooms I have studied, in this and previous years, students have
received few opportunities to engage in the ‘dance of agency’, and when they
need to engage in that ‘dance’, in new and ‘real world’ situations, they are ill
prepared to do so. When I interviewed a class of students in the fourth year of the
reform program at one of the schools, the students all described an interesting
relationship with mathematics that contrasted with the students who had learned
calculus in traditional classes. As part of the interviews we asked students what
they do when they encounter new mathematical problems that they cannot
immediately solve. In the extracts below the students give their responses:

K: I’d generally just stare at the problem. If I get stuck I just think about it
really hard and then just start writing. Usually for everything I just start
writing some sort of formula. And if that doesn’t work I just adjust it, and
keep on adjusting it until it works. And then I figure it out. (Keith)

B: A lot of times we have to use what we’ve learned, like previous, and apply
it to what we’re doing right now, just to figure out what’s going on. It’s
never just, like, given. Like “use this formula to find this answer” You
always have to like, change it around somehow a lot of the time. (Benny)

These students seem to be describing a ‘dance of agency’ as they move between
the standard methods and procedures they know and the new situations to which
they would apply them. They do not only talk about their own ideas, they talk
about adapting and extending methods and the interchange between their own
ideas and standard mathematical methods. The student below talks in similar
terms:

E: Like, if nothing else, it’s breaking out of the pattern of just taking
something that’s given to you and accepting it and just going with it. It’s
just looking at it and you try and point yourself in a different angle and look
at it and reinterpret it. It’s like if you have this set of data that you need to
look at and find an answer to, you know, if people just go at it one way
straightforward you might hit a wall. But there might be a crack somewhere
else that you can fit through and get into the meaty part. (Ernie)

Many of the students in the traditional classrooms I have studied frequently
‘hit a wall’ when they were given mathematics problems to solve. They tried to
remember standard procedures, often using the cues they had learned. If they
could remember a method they would try it, but if it did not work, or if they could
not see an obvious method to use, they would give up. The students we interviewed in the reform classes described an important practice of their mathematics classroom – that of working at the interplay of their own and disciplinary agencies – that they used in different mathematical situations. Additionally the students seemed to have developed identities as mathematics learners who were willing to engage in the interplay of the two types of agency. The students had developed what we are regarding as a particular relationship with the discipline of mathematics that meant that when they met new mathematics problems they expected to adapt and apply methods to solve the problems. It seemed that their capability in different situations depended partly upon the knowledge they had learned, partly upon the practices in which they engaged and partly upon the relationships they had developed with the discipline of mathematics that emerged through the practices of their classrooms.

A number of researchers have written about the importance of productive beliefs and dispositions (Schoenfeld, 1992; McLeod, 1992) but the idea of a 'disciplinary relationship' serves to connect knowledge and belief in important ways. Herrenkohl and Wertsch (1999) have suggested a notion that addresses this connection, that they call the 'appropriation' of knowledge. They distinguish between mastery and appropriation, saying that too many analyses have focused only upon students' mastery of knowledge, overlooking the question of whether students 'appropriate' knowledge. They claim that students do not only need to develop the skills they need for critical thinking, they also need to develop a disposition to use these skills. In claiming that students need to 'appropriate' knowledge, they suggest a connection between the content students are learning and the ways they relate to that knowledge. The fact that the students who learned through open-ended projects in England were able to use mathematics in different situations may reflect the similarity in the practices they met in different places, but it also reflects the fact that they had developed a positive, active relationship with mathematics. They expected to be able to make use of their knowledge because of the opportunities they had received to engage in a disciplinary dance. Thus they were able to 'transfer' mathematics, partly because of their knowledge, partly because of the practices in which they engaged, and partly because they had developed an active and productive relationship with mathematics. This idea seems to pertain to theories of learning transfer and expertise in important ways, expanding notions of capability beyond knowledge and practice to the dispositions they produce and the relations between them.

AUTHENTIC LEARNING CONTEXTS AS AN INTERFACE FOR THEORY AND PRACTICE

Janette Bobis and Sharne Aldridge

University of Sydney, Australia

Our research over the past three years has explored the belief that authentic learning contexts in teacher education can provide an interface for theory and practice. We discuss key features in our teacher education program: constructivism, situated learning, and multiple authentic learning contexts. Data drawn from our research will be used to support our contention that the more authentic the contexts the more effective the learning.

Teacher education is in crisis in many countries of the world, with pressure to move to more school-based approaches an indication of the dissatisfaction with traditional approaches (Korthagen & Kessels, 1999). A major point of dissatisfaction is the apparent inability of beginning teachers to transfer the theory-based knowledge into classroom practice. This link—or lack of it—between theory and practice in teacher education is well documented (Richardson, 1996; Wubbels, Korthagen, & Brekelmans, 1997).

Research by Brouwer (in Korthagen et al. 1999) found that the degree to which teacher education programs integrated and alternated theory and practice was an important factor in determining the extent to which beginning teachers could translate their knowledge into practice. How educational programs and systems have tried to accommodate this factor into their courses has varied greatly. Few details pertaining to actual program structures is publicly available. However, our own experience within various institutions in Australia and contacts with other teacher educators indicates that programs most commonly try to achieve theory/practice integration via field-based assignments such as action research, by adopting realistic-based approaches such as constructivism, and the development of reflective skills. These approaches are not mutually exclusive, but implemented on an individual basis have not normally proved to be as successful as expected (Foss & Kleinsasser, 1996; Fuson, Carroll, & Drueck, 2000). For example, in response to the growing support for teaching mathematics from a constructivist perspective (Australian Education Council, 1990; Department of Employment, Education and Training, 1989), a number of teacher education programs adopted a constructivist approach in the way their courses were delivered. According to constructivist principles, this translated into establishing a learning environment in which students construct their own knowledge by linking prior experiences (including knowledge, beliefs and personal theories) to new knowledge (Jones & Vesilind, 1996), creating 'learning communities' in which students engage in rich discourse about important ideas (Putman & Borko, 2000) and using reflection as a vehicle for reconceptualising knowledge and beliefs (Beattie, 1997). It was anticipated that such modelling of a constructivist approach within teacher education programs would translate into
classroom practice. Unfortunately, accumulating evidence suggests that such initiatives have failed to strongly influence the practices of beginning teachers (Klein, 1999) and are often broken-down during practical experiences (Zeichner & Tabachnick, 1981).

The investigation reported here was undertaken after anecdotal evidence relating to the mathematics education courses taught by us directly contradicted the disappointing findings reported in the literature (e.g. Klein, 1999). Our research over the past three years has explored the belief that authentic learning contexts in teacher education can provide a theory/practice interface which will support graduates translate their knowledge into classroom practice. The following discussion describes the context for our study. It provides an introduction to the Master of Teaching program and outlines key features in the mathematics education component: constructivism, situated learning and multiple authentic learning contexts. Data drawn from our study will be used to support our contention that the more authentic the contexts the greater the integration of theory and practice. We also believe that multiple learning contexts will further enhance this interface.

CONTEXT OF THE STUDY

The Master of Teaching (MTeach) program within the Faculty of Education at the University of Sydney is a postgraduate initial teacher education course that adopts an inquiry and case-based approach. Such approaches typically provide students with opportunities to research their own teaching and learning. Generally, the students are mature-aged, have established careers in areas other than teaching and bring with them a variety of life experiences. Central to the MTeach program's philosophy is the importance of developing reflective practitioners.

Key features of the mathematics components

We have designed our primary mathematics education courses to integrate and encourage reflective practice within a constructivist approach to support the philosophy of the MTeach program. Inquiry into our own practices has led us to believe that adhering to constructivist principles in our teaching is a necessary but certainly not sufficient factor for engendering change in the way our graduates view and teach mathematics to primary school children. We now recognise the crucial role played by our use of multiple learning contexts, situated in a variety of environments.

A constructivist approach to teaching and learning recognises the importance of students’ prior experiences and uses these experiences to build knowledge of the field. It aims to create a learning environment in which peer tutoring and collaborative learning is highly valued. Associated with this is the idea that students need to have opportunities to engage in rich discourse as they share and build their knowledge. Another vital aspect of such an approach, and central to the MTeach philosophy, is the emphasis placed on reflection. For us, reflection is seen as a vehicle by which students make connections between theory and practice.
A situated perspective on learning (Greeno, 1997) acknowledges that: all knowledge is situated, that some types of knowledge are best constructed in one context rather than another and that the more authentic the context, the more effective the interplay between theory and practice (Aldridge & Bobis, 2001). This fits within the constructivist paradigm and supports our use of multiple learning contexts.

Our prospective primary school teachers experience four contexts whilst undertaking our mathematics education courses: The first context places students in workshops modelled on constructivist principles. A second context relates to in-school experiences associated with practice teaching. Students work in a school over an extended period (12-15 days) under the supervision of a practising teacher. This not only reflects the context in which they will ultimately work, but it is also a fairly typical experience provided by teacher education programs across various institutions.

Prior to undertaking their first traditional-style practical teaching experience we also provide our students with another vital context for learning—one that is not typically used by other institutions responsible for teacher education. This is best described as school-based small group teaching and is situated in schools (an authentic context) during normal tutorial timeslots. Students work in small groups (encouraging collaboration and reflection) with two or three children who are assigned to them for four weekly sessions. They individually assess the children, analyze the results and collaboratively prepare a program of work to build on each child’s level of thinking. Our role is to facilitate the process by providing advice at each stage of the process. After each teaching episode, there is a debriefing session. This provides opportunities for rich discourse stimulated by attempts to connect their practice to theory. It provides them with an authentic context in which to situate their new knowledge prior to undertaking their first extended practice teaching experience.

The fourth context is situated at the University in a clinical setting. Students work twice a week over a six week period with children from local schools in a one-on-one situation. This experience provides another context in which students’ learning is authentically situated. As facilitators in this context, we may model teaching if requested, or simply offer guidance and support students in their decision making. Students also work together to share ideas, discuss teaching strategies, team-teach and reflect upon the theory/practice integration.

DATA COLLECTION

Data was collected using two tools—concept mapping and semi-structured interviews. Concept mapping helped the students organise their knowledge and beliefs about mathematics and was used as a stimulus in the interviews to elicit explanations of their personal theories about mathematics and their teaching. Figures 1 and 2 were both constructed by the same preservice teacher, Cindy. While each participant’s maps were unique, we have selected Cindy’s as representative of an initial concept map and a map constructed at the third key point in the program. The
first concept map (see Figure 1) was undertaken prior to any courses in mathematics within the MTeach program and the second map was constructed after completing her first practice teaching experience. Each map provides a visual representation of how an individual's thinking about mathematics is organised at different points in the MTeach program. Key ideas are clearly identified for later discussion in semi-structured interviews.

![Concept Map](image)

**Figure 1.** Cindy's first concept map, constructed prior to undertaking any mathematics education units of study.

Comparing an individual's concept maps enabled us to see how each prospective teacher reconceptualised their knowledge during the course of the MTeach program. Figure 2 reflects a more complex understanding of mathematics and its teaching. This is evidenced by the increase in the number of concept 'nodes' and the links between separate branches of the map.

At four key points within the MTeach program, twelve preservice teachers undertook a concept mapping exercise followed by a semi-structured interview. These key points corresponded to the four different learning contexts within the mathematics education program. The results from the concept maps and the semi-structured interviews over the time of the project were combined and compared for analysis. Patterns in responses and changes in emphasis were also identified and coded for analysis.

Figure 2. Cindy’s third concept map, constructed after her first practice teaching experience.

KEY ASPECTS FOR A THEORY/PRACTICE INTERFACE

Analysis of the concept maps and semi-structured interviews revealed the emergence of a number of themes. For the purpose of this paper we will focus on two key aspects. Both aspects have been identified in the literature as playing significant roles in the integration of theory and practice (Korthagen, 1999, Wubbels, Korthagen & Brekelmans, 1997) and are supported by our findings.

The first aspect that was identified in the majority of interviews was the value of the school-based context. Examples of students’ comments reveal an awareness that this context provided a valuable link between the theory of the University-based work with their first practice teaching. For instance, Cindy commented in her third
interview that “we learnt it straight away, blew our minds, applied it and could see the benefits...that was a stepping stone and it wasn’t so daunting when we went into the classroom”. Similarly, Carmel remarked in her fourth interview that “the school experience was good because you get to use what you are learning”. She considered it influential because “when we go out there and have to do it...that is reality.” In her third interview, Carmel commented on the benefits of the course structure. She considered the change in contexts beneficial because they “required her to teach on a more complex scale” towards the end of program.

Comments from student teachers reflect what Brouwer (in Korthagen et al. 1999) describes as a teacher education curriculum that has an integrative design. This refers to the extent to which there is an alternation and integration between theory and practice within a program. Brouwer claims that programs designed in this way promote transfer from theory to practice.

A second theme to emerge from the interviews and supported in the concept maps was a reconceptualisation of mathematics and the teaching of mathematics. For example, Cindy’s first concept map (see Figure 1) reflects an emphasis on mathematics as content based (e.g. numbers, sums, algebra, geometry), a transmissive model of teaching and an attitude to mathematics that can be described as negative (e.g. boring). Cindy’s third concept map (see Figure 2) shows a much broader view of mathematics and reflects a growing awareness of her own personal theory about how to teach and how children learn mathematics.

One aspect of this reconceptualisation relevant to the current discussion involves the change in participants’ attitudes and beliefs about mathematics (see Aldridge & Bobis, 2001). Changing attitudes and beliefs is recognised as a vital aspect in a person’s ability to transfer theory to practice ( Corporal cited in Korthagan et al. 1999). This is particularly important because student teachers begin their courses with a history that corresponds to their initial personal theories. Often this theory contains notions about mathematics and its teaching that are very different from the theories espoused in the University-based context. The need to acknowledge the student teacher’s history and construct a teacher education theory that builds on and challenges this is seen as important if transfer between theory and practice is to take place.

A NEW PARADIGM FOR TEACHER EDUCATION

Evidence provided in this paper supports our contention that the utilisation of a multiplicity of authentic learning contexts, combined with a constructivist perspective can provide a vehicle for connecting theory and practice in teacher education programs. Such a theoretical base is akin to the ‘realistic approach’ to teacher education characteristic of the program at Utrecht University (Koetsier, Wubbels, & Korthagen, 1997) and represents a paradigm shift in teacher education. However, such an approach not only requires that the types of contexts be thoughtfully considered, it also has organisational implications for the program.
administrators. For example, to alternate between university-based and school-based contexts requires close co-operation between institutions. Flexibility in time-tabling, the proximity and suitability of the school-based setting, as well as the mutual benefits from such arrangements must all be considered.

Another element we consider important is our own credibility. To feel ‘comfortable’ in both school-based and university-based contexts our own knowledge and experience must be credible in our student teachers’ eyes.

The paradigm shift in teacher education has benefits to us as teacher educators. For example, researching and reflecting on our own practice has enabled us to anticipate barriers to the successful integration of theory and practice and has allowed us to deal with such obstacles prior to them surfacing in practical situations. For example, the reliance on mathematics textbooks in Australian primary classrooms is perceived to be an obstacle for the translation of theory into practice by our students.

In addition, utilising authentic learning situations allows us to “stay in-touch” with the realities of the school context and with the needs and concerns of our prospective teachers. Implications of such an approach extend beyond initial teacher education and have ramifications for the professional development of all teachers.

REFERENCES

I analysed a large amount of written verbal reports, produced by Grade IV and Grade VI students as a response to the task of communicating their knowledge about sun shadows. The texts were produced immediately before and soon after the introduction of the elementary geometric model of sun shadows by the teacher. Some relevant changes were detected; they concerned a much more frequent production of hypothetical and causal sentences expressing geometrical links in the ‘after’ texts. A discussion about related cognitive, cultural and educational issues is sketched.

INTRODUCTION

In a Vygotskian perspective (see Vygotsky, 1978, Chapters I and VI), important changes can intervene in students’ thinking strategies when the teacher introduces some peculiar signs as tools to solve problems. In particular, the signs introduced may allow students (by themselves, or with the help of more competent peers, or under the guidance of the teacher) to solve previously inaccessible problems. Still in a Vygotskian perspective (see Vygotskij, 1990, Chapter VI), spontaneous students’ conceptions can develop towards scientific conceptions when scientific conceptions are made accessible to them by the teacher through appropriate (external) representations. In the study reported in this paper I am interested in the effects of the introduction by the teacher of a specific sign (the elementary local geometric model of sun shadows – shortly, ELGMS) on the ways of thinking about the sun shadow phenomenon.

Fig. 1: The ELGMS

As reported in Boero et al (1995), and as we will see in details in the next Subsection, the ELGMS is not spontaneously produced by students neither in Grade IV, nor in Grade VI. Moreover, it is very far from the graphic representations of the sun shadow phenomenon, which are spontaneously produced by most of them (see later). And the ELGMS appeared relatively late in the historical development of human cultures as a relevant invention, whose cultural implications were very rich (see Serres, 1993). The research hypothesis underlying this study is that the appropriation of the ELGMS as a tool to solve elementary geometrical modelling problems concerning the sun shadow phenomenon can deeply change the way of thinking about this phenomenon. Some experimental evidence will be provided to support this hypothesis. In particular, by analysing students’ verbal reports concerning the sun shadow phenomenon we will see that an important change can be traced in students’ reports after the introduction of
the ELGMS: explicit hypothetical and causal links between the height of the sun and the lengths of the cast shadows become much more frequent. The final Discussion Section will elaborate on this result. Some cultural and educational implications will be discussed (in particular, as concerns the meaning of the ELGMS as a prototypical thinking tool belonging to the ‘rationality’ of the Western civilisation). In general, my hypothesis (together with the related cultural issues) agrees with recent developments of research in the Vygotskian perspective. Stetsenko (1995) wrote:

"The originality of the Vygotskian approach to children’s drawings is primarily that it addresses and clarifies the functional role of drawings in the overall development of the child – that is, in the entirely of cognitive, emotional, communicative and other aspects of this development." (page 147). "What the cultural-historical theory strives at is a precise specification of the unique ways making and looking at pictures help a child both to understand the world and come to terms with it" (page 148).

METHOD

The Students’ Educational Background

Since the second half of the 70s, both Genoa Group Projects for mathematics and science education in primary school (6-11) and lower secondary school (11-14) have devoted a wide interest to the sun shadow phenomenon: from early non-geometric conceptions to local geometric modelisation, till global considerations of the phenomenon on the sun system scale. The level of sophistication of the mathematical tools introduced and the difficulty of the mathematical problem situations tackled at the end of the activities is obviously different in the two Projects. Most of ‘our’ primary school students do not join classes that adopt the Lower Secondary School Project and most of ‘our’ lower secondary school students do not come from classes involved the Primary School Project, so the initial steps in the approach to the sun shadow phenomenon are the same in both Projects (even if they are introduced at a different pace). The activities concerning sun shadows take place over a very long period of time in primary school (from the second half of Grade III to the beginning of Grade V). They take place over the whole school year in Grade VI. In both cases, the activities start by provoking students to write and draw what they think about sun shadows; a number of games played in the courtyard follows; then the ‘shade space’ (between the object and the cast shadow) is discovered; finally, more and more systematic observations are organised (at different times of the same day) and verbally reported by students. In particular, these are common initial steps:

- standardised questions about the sun shadow phenomenon, and discussion about the answers. In particular, the following question is posed both in grade III and at the beginning of grade VI:

«Have you ever noticed that when you are walking in a sunny place your body casts a shadow on the ground? (YES / NOT option). Is your shadow longer at 9 a.m. or at noon? (9 a.m. / NOON option). Why?».
It is interesting to remark that the majority of students in Grade III, and still more than 40% in Grade VI, chooses the 'NOON' option "because the sun is stronger", "because I see it better", etc. (for details, see Boero, 1999)

- production of drawings representing the sun shadow phenomenon. We can notice that most of these drawings (both in Grade III and in Grade VI) are very far from the ELGMS and correspond to non-geometric conceptions. Here we present only some examples; for further details, see Boero, 1999.

![Fig.2: Three examples of students' initial drawings](image)

As remarked in Boero et al (1995) (for further details, see Boero, 1999), the ELGMS is spontaneously produced by very few students, both in grade III or IV and in grade VI, even after all the previously mentioned activities; and it does not spread spontaneously across the classroom. It can be observed that this fact is in accordance with the importance attributed to the invention of the ELGMS by historians of Science: the first traces of the model go back to the late developments of Babylonian and Egyptian civilisations and the early developments of Greek geometry, between the VII and the V century b.c. (Serres, 1993). In the Primary School Project classes, the teacher introduces the ELGMS at the beginning of Grade IV (after 3-4 months of activities in Grade III); in the case of the Lower Secondary School Project classes the introduction of the ELGMS takes place one month after the activities described above. The teaching strategies adopted by teachers to introduce the ELGMS may vary according to personal preferences, theoretical motivations and occasional circumstances: in some cases the teacher exploits the proto-geometrical drawings produced by some students, asking the other students to use them to solve other problems (but it can happen that no student produces an 'exploitable' drawing!); in some cases the teacher introduces the ELGMS as a device to solve problems; in other cases the teacher tries to guide the production of the sign by the students through suitable observations (e.g. the visualisation of the upper border of the shade space, and the task of drawing such situation), then some applications follow (for a discussion about these educational strategies see Scali, 1998).
Available Data and Selected Data

The fact that the sun shadow phenomenon was a crucial subject for both Projects for more than twenty years, together with some methodological choices (in particular, the systematic practice of written verbal reporting for all activities since the end of grade I, and the practice of frequent classroom discussions guided by the teacher), offered a big amount of interesting materials from the classroom: rich individual texts, videotapes and recordings of classroom discussions, etc., concerning the activities described in the previous Subsection. In particular, 24 teachers gathered individual students’ texts from 81 classes with detailed information about the activities performed! Given that I am interested in the consequences of the introduction of the ELGMS on students’ ways of thinking the sun shadow phenomenon, I looked at the texts produced immediately before, and/or soon after, the introduction of the ELGMS. I considered only the texts produced as a response to a standardised task:

«Write a letter to a friend of yours in order to explain him what you know about sun shadows at this moment».

I took into account the classroom activities between the introduction of the ELGMS and the production of the ‘after’ text, as reported by the teachers. My preliminary choice was to consider only texts coming from classes who had worked individually in that period on two or three applications of the ELGMS over a period of no more than two weeks. According to the collected information, in all these classes, after the introduction of the ELGMS, the students could look at it on the walls and also in their personal copybooks. Then only texts including explicit reference both to the sun and to the shadows were considered (about 60% in grade IV and 68% in grade VI).

Some preliminary analysis performed on relatively small samples of students (two or three classes in each case) had shown that:

- the way chosen by the teacher to introduce the ELGMS does not seem to affect the quality of the ‘after’ texts;
- concerning the use of texts produced by the same students or not (before and after the introduction of the ELGMS), the only difference was that the second production of the same student was in some cases less rich and less suitable to use than the first one (the repetition of the identical task at the distance of 10-15 days did not help motivation!). So I decided to select a rather big number of classes who had written only one report, immediately before or soon after the introduction of the ELGMS, for a large scale comparison between ‘before’ and ‘after’ texts. Selection was made in order to get similar social environments between the different groups of students. I have considered 202 ‘before’ texts and 206 ‘after’ texts for grade IV; and 182 ‘before’ texts and 170 ‘after’ texts for grade VI. I performed a more detailed analysis on other two smaller groups of students (80 for grade IV and 66 for grade VI) who had produced both the first and the second text, in order to trace the personal evolution of their performances (see table 3, concerning grade IV).
Criteria for Classifying Students' Reports

- **Conditional texts**: at least once in the report, the student expresses conditional links between the height of the sun and the length of the sun shadows, e.g.: «If the sun is high the shadows are short».

- **Causal texts**: at least once in the report, the student expresses causal links between the height of the sun and the length of the sun shadows: «At noon the shadows are shorter than at nine because the sun is higher»; «At noon the sun is higher than at nine, and so the shadows are shorter; “At noon the shadows are short because the sun is high”, etc.

- **Descriptive texts**: all the other reports. The student reports what he/she saw at different times of the day, with no explicit ‘conditional’ or causal link between the height of the sun and the length of the sun shadows: «At nine a.m. the sun is low and the shadows are long; at noon the sun is high and the shadows are short».

Some comments about the proposed classification follow.

- Some reports can belong both to the first and the second category. We can remark that causality is very close to ‘conditionality’ in many situations of communication. In particular, in everyday life situations people frequently use the clauses «If B, then A», «B, and so A» and «A because B» as if they were equivalent. I preferred to make a distinction between Conditional reports and Causal reports because I had observed that in our specific situation Conditional reports are usually produced by students in order to express a general ‘conditional’ link («if the sun is high the shadows are short»), while most of the causal reports refer to a specific situation («at noon shadows are short because the sun is high»).

- In Italian, like in other languages, the «A and B» clause can be used to suggest the idea of a causal link between A and B. In the sentence «The driver was running very fast and the car got out of the road» we can see the intention of implicitly stating a cause-effect relationship. As a consequence, part of the Descriptive reports (before as well after the introduction of the ELMGS) may have been produced by students who were thinking about a causal relationship between the height of the sun and the length of the shadows.

- There would be some reasons for the inclusion of reports containing a ‘when’ clause («when the sun is high, the shadow is short») in the category of Conditional reports: the 'A when B' and the 'if B, then A' clauses often have similar uses in everyday language; and the ‘conditional’ clause seems to represent a de-timing of the ‘when’ clause (see Arzarello, 2000). But in most of students’ reports presenting only the ‘when’ clause the whole linguistic context gives the impression that the ‘when’ clause merely expresses a temporal coincidence with no ‘conditional’ link between the information about the position of the sun and the information about the length of the cast shadow. Some interviews (performed immediately after the production of a written report containing one ‘when’ clause) confirmed this impression.
SOME RESULTS

The following tables display some outcomes of the analysis performed according to the criteria listed in the previous Subsection.

Table 3: ‘Before’ and ‘after’ texts of the same 80 IV-grade students

Table 3 provides information about the evolution of students’ productions within the same group of students. For instance, let us consider the last row. 59 students had produced Descriptive texts ‘before’ the introduction of the ELGMS. ‘After’ the introduction of the ELGMS, 17 out of them produced a Conditional text; 16 produced a Causal text; while 31 still produced a Descriptive text. By considering these numbers on the last row we get 64 texts: it means that 5 texts became “Conditional” and “Causal”.

Data concerning the comparison of ‘before’ and ‘after’ texts of the group of 66 VI-grade students were similar to those displayed in Table 3.

All tables show a common trend: a statistically relevant increase in the percentage of both Conditional and Causal texts between the ‘before’ texts and the ‘after’ texts. The increase is more relevant for Causal text (more than 100% increase in all tables).
By analysing students' verbal reports concerning the sun shadow phenomenon we have seen that, after the introduction of the ELGMS, an important change happened in students' reports: explicit hypothetical and causal links between the height of the sun and the length of the cast shadows became much more frequent. The fact that this change happened over a very short period of time (no more than two weeks), both in grade IV and in grade VI, suggests that spontaneous maturation cannot explain the change. The fact that no collective classroom activity intervened between the introduction of the ELMGS by the teacher and the second verbal report seems to exclude the possibility of the adoption of those "modes of saying" by imitation. And the very nature of the change suggests that the introduction of the ELGMS affects not only the way of describing the sun shadow phenomenon, but also the way of thinking about it (although in general it is difficult to infer the underlying thinking processes from verbal traces: cf Ericsson and Simon, 1981). It is interesting to examine this way of thinking more closely. Its importance does not seem to rely much on the fact that the ELGMS fits better with the sun shadow phenomenon in everyday life experiences, in comparison with other ways of conceiving it. Let us consider an example taken from some observations performed by Claudia Costa, a teacher working in the Italian school in Asmara (Eritrea) (see Boero, 1999). From individual interviews and classroom discussions it emerged that half of the students of two VII-grade classes thought that the shadows were longer in the early morning and in the late afternoon because then the Sun was less strong (or less bright), and so the shadow (a manifestation of the darkness, the opposite 'entity') succeeded in being longer. This non-geometrical conception fits rather well with many everyday life experiences! The cultural importance of the ELGMS relies on the fact that the 'rationality' inherent in it is different from the 'rationality' inherent in the non-geometrical conceptions that agree with empirical evidence. In order to understand this difference let us consider the following statements, produced by one of 'our' students and by an Asmara student:

"At noon the shadow is shorter than in the early morning because the sun is higher";

"At noon the shadow is shorter than at 9 because the sun is brighter and beats the darkness"

The validity of the first statement relies on geometrical necessity, while the validity of the second statement relies on the consideration of the increasing strength of the light, which changes the 'strength equilibrium' with the opposite 'entity'. The introduction of the ELGMS (a product of the cultural evolution) brings in a new kind of 'necessity' in the way of thinking about nature: a geometrical necessity. Western 'rationality' has strongly developed towards this direction over the last twenty five centuries, not only as concerns the geometrical models in astronomy, but also as regards for example the differential models, the stochastic models, etc.: it is like if 'something' happens, and will always happen in the future, because the inherent variables are constrained according to a given mathematical model. This provides us with a very efficient tool to solve quantitative problems, forecast the evolution of many phenomena, etc.
At the beginning of the activities concerning sun shadows, many students of 'our' classes produce 'causal' texts when they describe the sun shadows phenomenon, but causality does not concern the links between the height of the sun and the length of the cast shadows (e.g.: "The shadow is longer at noon, because the sun is stronger"; or "The shadow is longer at noon, because I see it better". The contradiction with empirical evidence and systematic observations gradually brings most of them to write that "At noon the shadow is short and the sun is high". This could be explained well in terms of the Piagetian "adaptation" of mental representations (see Piaget, 1926).

Afterwards, students use the ELGMS (introduced by the teacher) in few problem situations. This is sufficient to change the quality of the verbal reports of many of them (see our data). The following activities reinforce this trend. An entirely different situation happens with the Asmara students: even the Asmara students wrote (in their individual initial texts) a lot of rather complex causal and hypothetical sentences. The difference is that they produced those sentences coherently with a way of thinking about the sun shadow phenomenon, which seems to be strongly related to the environmental culture (and not in immediate contradiction with empirical evidence).

This means there is a potential richness that schools should not waste. Why, and especially how, to introduce another way of thinking (the one based on the ELGMS) in such a situation, without destroying the existing one, remains a difficult challenge for nowadays intercultural educational perspectives! (cf Barton, 1996)

LEARNING THROUGH IDENTITY: A NEW UNIT OF ANALYSIS FOR STUDYING TEACHER DEVELOPMENT

Jeffrey V. Bohl and Laura R. Van Zoest

Battle Creek Area Math & Science Center, Western Michigan University

Here we develop a unit of analysis for our study of new teacher development across varied communities of practice (Lave and Wenger, 1991). We do so by combining Shulman’s (1987) heuristic of important teacher knowledge with Wenger’s conception of learning as identity development while practicing in community. To align ourselves with the view that learning takes place across a spectrum of locations from in-the-mind to socially-embedded (St. Julien, 1997), and with Lerman’s call for researchers to consider a unit of analysis that is “person-in-practice-in-person” (2000, p. 38), we develop the overlapping aspects of self-in-mind and self-in-community. These span the spectrum of the cognitive-social continuum, and comprise what we consider to be a person’s mathematics teacher identity.

THE STUDY OF LEARNING

How people learn is clearly an open question, and for good reason. Learning how to do things like cry to get what one wants as an infant, add in one’s head, participate productively in a work environment, and split atoms certainly are complex and involve many forms of thinking. These can be viewed as happening in different contexts with different intentions, and done within different relationships between physical and social surroundings and mental effort. The learning of developing teachers – which entails the areas of content, pedagogy, and professional participation, and which happens in many contexts including university classrooms, school classrooms, and professional community interactions – involves a large cross-section of the various modes of thinking. As such, it presents a particularly difficult challenge to researchers of learning. This paper presents a framework that we are using to study this complicated landscape of things to be learned by mathematics teachers and ways to learn them.

Researchers have studied learning in mathematics along a broad spectrum of modes of thinking, from the abstracted types that happen largely in one’s brain, to those that happen in relation to a very specific context of use. Such work has been productively undertaken using various theoretical frameworks and different units of analysis. Carpenter and Fennema (Carpenter, Fennema et al., 1988) used a fully cognitive model to understand young people's learning of basic addition and subtraction of integers. Greeno (1994) expanded somewhat on the focus of strictly cognitive studies by adding aspects of the physical/structural environment as factors affecting individuals’ mental processes. Cobb and his colleagues (Cobb and Bauersfeld, 1995) moved further away from wholly psychological accounts of learning to include interactions between groups of individuals learning mathematics in classrooms, and the norms of interaction that develop. Taking a further step away
from the individual as a unit of analysis are situative theorists, led by Lave (1988), who have studied everyday mathematics and the ways that the learning and usage of such mathematics is completely tied to the embedding contexts.

Such research provides a continuum of entry points for studying learning. However, there has been much debate among leading scholars about what can be learned from each perspective (Anderson, Reder et al., 1996; Greeno, 1997). We agree that there are valid concerns. However, we follow others (Greeno and MMAP, 1998) in our belief that the different perspectives on this continuum each offer potentially valuable information about learning. The problem seems to be that in order to be truly useful for educators, cognitive studies need to consider more of the texture of specific contexts, and sociological studies need to provide a more specific analysis of individual cognition (Kirshner and Whitson, 1997). This paper presents our attempt to conceive a unit of analysis, mathematics teacher identity, that will provide us a means of considering a broader swath of the cognitive-social continuum than is normally taken into account in studies of mathematics teacher development. In doing this we draw on the work of situativity theorists, as well as on previously established ideas about what types of knowledge are important for teachers to develop.

OUR RESEARCH AGENDA

Our work focuses on the learning of soon-to-be and new mathematics teachers attempting to become teachers of reform mathematics in the United States. Teaching in schools is a form of social participation that takes place within distinct contexts of classrooms. Classrooms, and the teachers leading them, are themselves embedded in school and societal community contexts, and in relation to professional education communities. Each of these contexts provides different, sometimes competing, constraints and affordances (Greeno and MMAP, 1998) for teachers to make sense of and work within. To learn to teach, then, involves the coalescing of an individual’s history of interacting in other communities playing other roles – student in the classrooms of one’s own schooling, student in academic teacher education communities, and intern in other teachers’ classrooms – into a new role as professional teacher in its various attendant contexts (Bohl and Van Zoest, 2001). The interconnected nature of participation in pre-teaching communities, combined with multifaceted relationships between the various communities within which practicing teachers participate, makes for a highly complex web that previous studies and sets of learning theories have been unable to fully illuminate.

In our own attempts to understand how learning takes place within and across these contexts and communities, we have been faced with the need for a theoretical framework capable of providing (a) a sufficiently detailed framework for our qualitative case study analyses, and (b) a sufficiently broad view of the social embeddedness of teachers’ practice to provide a full and textured accounting of their development. Lerman (2000) has explicated the need for such a framework for the field of education in general, as well as the motivation behind an overall move to a
social direction in mathematics education research. Our work is consistent with that
direction, although it is couched in our study of the learning of teachers rather than
the learning of mathematics.

LEARNING, IDENTITY, AND DIMENSIONS OF KNOWLEDGE

Wenger (1998) provides a social theory of learning within communities of practice
that lends focus to our work. He posits that to learn is to develop an identity through
modes of participating with others in communities of practice. Such communities are
both defined and cohered by shared goals, mutuality in working to achieve them,
and a shared set of social and physical resources to achieve them with. As an
individual grows and learns, she develops an identity. Wenger’s (1998) take on
identity is broader and more socially-oriented than the colloquial term, which tends
to focus on the idea of self-identification and on the existence of a personal cache of
characteristics. For Wenger and others (Holland, Lachicotte et al., 1998; Boaler and
Greeno, 2000), identity is, in the biggest sense, the who-we-are that develops in our
own minds and in the minds of others as we interact. It includes our knowledge and
experiences, but also our perceptions of ourselves (i.e., our values, beliefs, desires,
motivations, and self-identifications), others’ perceptions of us, our perceptions of
others, and our perceptions of others’ perceptions of us that develop as we
participate in communities with one another. As such, our identities exist not only
within ourselves, but are also strung across a continuum between ourselves and
others. They are defined as we interact with others and react or reformulate our
participation in response to others’ reactions to us. This development of identity in
These are experiences wherein people develop beliefs, commitments, and intentions
with regard to the form and content of a particular community and how they ought
to interact within it. They give individuals a sense of who they are in relation to the
community and its goals, how they might best participate, and where they belong
and what they are becoming in the community.

We take Wenger’s proposition that development of identity is the same as learning
within communities (Lerman, personal communication, December 2001) as the basis
of our analytic framework. However, like much work in situative theory, this
characterization leaves something to be desired in terms of concrete reference to
individual cognition (Kirshner and Whitsen, 1997) as well as in terms of reference
to particular areas in which people develop. Taking a measure of mathematics
teacher development in terms of effective competence requires a set of explicit
dimensions upon which to focus. We use Shulman’s (1987) broadly accepted
conceptions of important teachers’ knowledge as a starting point.

For Shulman, the areas in which competent teachers learn fall into seven categories:
1. content knowledge, 2. curricular knowledge, 3. general pedagogical knowledge,
4. pedagogical content knowledge, 5. knowledge of learners, 6. knowledge of
educational contexts, and 7. knowledge of educational ends. For our purposes, we
have fit these forms of teacher knowledge into three broader dimensions. First, content knowledge and curricular knowledge both deal with what is to be taught. We collapse these two into one new domain we call the content area and curriculum dimension. This dimension relates to the types of knowledge that cognitivists might be most likely to focus on because it is relatively clearly defined. Next, pedagogical knowledge, pedagogical content knowledge, and knowledge of learners all relate to who is to be taught, and how they should be taught. We combine these three into a domain called the pedagogical dimension. This dimension relates to the competencies required for participating as the leader of a classroom community and orchestrating activities to ensure the broadest possible development of student understanding. This is the dimension of teacher knowledge that most directly impacts students, and thus is most often the focus of studies in mathematics teacher education. Finally, we encompass knowledge of educational contexts and knowledge of educational ends into a broader domain we call the professional participatory dimension. This dimension includes the arenas of knowledge required to participate productively within the various communities outside of the classroom that are related to the act of teaching. These communities include one’s own mathematics department and school communities, as well as the broader professional and university communities that support one’s efforts to teach. This dimension is key to our research since we are studying the impact on teacher learning of individuals’ participation across a range of communities.

The above understanding of Wenger’s conception of identity and list of particular dimensions across which to track development form the foundation for our construction of a unit of analysis. In the remainder of this paper, we attempt to wed the conception of identity development as learning with ideas about the things that mathematics teachers in particular must learn.

IDENTITY AS ASPECTS OF SELF-IN-MIND AND SELF-IN-COMMUNITY

Lerman (1998) suggests that a unit of analysis for educational research must allow one to zoom in and out, changing one’s focus to take into account the full spectrum of locations of cognitive development, from in-the-head to socially dependent. Bernstein’s conception of identities as composed of “relations within” as well as “relations between” suggests endpoints on such a continuum of locations for identity development (2000, p. 205). Bearing this in mind, Shulman’s delineation of knowledge types is problematic as it does not address the relational nature between knowledge and social context. That is, it leaves open the possibility that all the knowledge referred to is entirely “in-the-head” (St. Julien, 1997, p. 267). We believe that many of the bases for teachers’ everyday participatory decisions are fully socially connected and value based, and fall outside of what one might term “objective knowledge” (of the type “if I curse at a student, I will be disciplined”). Thus it is appropriate to distinguish a continuum of types of cognition (not unrelated to that of identity) from largely in-the-head to largely socially-negotiated (St. Julien, 1997). For that reason, we will use the term knowledge to refer to ideas that are
universally socially accepted (or nearly so) and not open for public debate (although socially constructed). We refer to ideas that are not universally held and thus are subject to public debate as beliefs. Beliefs include values and conceptions founded on values, and provide justifications for action in particular ways in response to particular types of knowledge in given situations. The place for these in Shulman’s heuristic is unclear. Other important types of cognition that are clearly not included are commitments and intentions. These encompass one’s desires to either act or not in response to particular situations, as well as impetus and justifications for doing so.

Thus it is not only the development of teachers’ knowledge across three dimensions that is important, but also the development of their beliefs, commitments, and intentions with regard to them. This is a fundamental aspect of our formulation of identity: each dimension relating to teacher development consists of aspects of knowledge as well as parallel aspects of beliefs, commitments, and intentions. Taken together, we refer to these as aspects of self-in-mind. Figure 1 provides a depiction of this part of identity as the portion within the single bolded border.

To illuminate this we offer an example of the contents of the table in Figure 1 that represents aspects of self-in-mind. Consider the row Pedagogy Dimension. Related knowledge that teachers ought to have is a variety of means of orchestrating classroom activity. This might include an understanding in the broadest sense of what “small group work” and “lecture” are. These fall under the Knowledge column. Related to this knowledge, teachers hold beliefs (e.g., what types of discourse patterns are most effective during small group work), commitments (e.g., promoting those discourse patterns), and intentions (e.g., to improve student understanding). These related concerns fall under the Beliefs, Commitments, and Intentions column. Knowledge (or lack thereof) of different means of orchestrating the classroom can impact what one believes, commits to, or intends to achieve. Likewise, one’s Beliefs, Commitments and Intentions affect the knowledge that one seeks. This is represented by the dual-direction arrows between the columns.

The aspects of self-in-mind related to the contents of the three dimensions make up the cognitive portion of a person’s identity. In keeping with his desire for a unit of analysis that allows an adjusting of zoom from individual to social, Lerman suggests the “person-in-practice-in-person” (2000, p. 38). As a step in this direction, we introduce another aspect of teacher identity that we call aspects of self-in-community. In Figure 1, these are encompassed within the double bolded border. Part of competent practice is reaction and adjustment based on our perceptions of others, and of their perceptions, in practice. As one becomes more familiar with the modes of participating that are productive and/or acceptable in the eyes of others, one adjusts to those perceptions by either modifying one’s actions, or changing one’s beliefs, intentions, or commitments. Perceptions, and the adjustment to feedback from them, are depicted as the large back and forth arrows positioned across the community of practice (the shaded oval), and represent Wenger’s negotiated experiences of self. It is important to note the overlap in the aspects of self-in-mind
Figure 1: Identity as Combination of Aspects of Self-in-Mind and Aspects of Self-in-Community
and self-in-community in the area of Beliefs, Commitments, and Intentions. This is the arena in which we conceive of the cognitive aspects of thinking as being stretched over and into the social sphere. Also, as people learn to participate productively (or not), their knowledge is affected. This is depicted by the arching arrow at the top of the diagram from the community of practice to knowledge.

As an example, consider a teacher whose beliefs, commitments, and intentions related to effective discourse patterns in class do not align with those of the school in which she is newly employed. Depending on the strength of her commitments, and on the types of feedback she receives through her perceptions of others’ (e.g., students, peers, administrators) perceptions of her own practice, she may adjust her beliefs to align with those of the community, or may work to convince the community that her preferred discourse methods work. In either case she learns in the process, and her identity changes as a result.

A further critical concern for studies of learning in practice is its embeddedness in greater social spaces. Lerman (in preparation) points to the need to zoom out further than depicted in our diagram so as to understand the impact of broader social factors. Such zooming can help answer questions such as “How are the accepted practices within a community impacted by other communities and broader social structures that overlap or subsume the community in question?” Such communities and structures would be depicted in the diagram as more shaded ovals overlapping and/or subsuming the depicted community of practice. Thus, they can be understood as intertwined with, and in some ways defining, practices within the local community. The effects on individual identities of such other communities and social structures could then be considered by studying the constraints and affordances (Wenger, 1988) they help make available to participants in the local community.

Our conceptualisation of mathematics teacher identity as aspects of self-in-mind and self-in-community within a practice spans the continuum from in-the-brain to socially embedded learning. We believe that this will allow us to zoom our analytic gaze further out as we attempt to describe the various factors impacting the development of our subject teachers across multiple communities.

WHAT DO THE PUPILS THINK?

PUPILS' PERCEPTIONS OF THEIR MATHEMATICS LESSONS

ALISON BORTHWICK
University of East Anglia, UK

Abstract: The work described here was carried out in two primary classrooms. This research forms part of a wider study investigating the nature of teacher-pupil interaction in the mathematics classroom and focuses on pupil's perceptions about mathematics lessons as seen in the pictures drawn by the children. The data suggests that the pupils perceive their lessons in very different ways to each other, often choosing different things to include in their pictures. The findings in this paper, which are part of an ongoing doctoral study, will contribute to the wider discussion of teacher-pupil interaction within the mathematics lesson.

BACKGROUND

Theories about how children think and learn have been put forward and debated by philosophers, educators and psychologists for centuries. E. B. Castle, in his book "The Teacher" (1970) explores the historical influences that have helped to shape modern views about children. One of the observations Bruner (1966) made in his book "Toward a Theory of Instruction" was that schools and the social roles they have created (such as 'teacher' and 'pupil') are relatively modern inventions. However, now that we do have these inventions, accounts from children, teachers and researchers all contribute to the image of classroom events. Each view is necessary for a full picture, and each perspective should be treated equally.

My previous research towards an MA dissertation considered the importance of identifying particular opportunities within the classroom from a teacher’s perspective, and examined the impact of these moments for both teacher and pupil (Borthwick 1999). Jaworski (1994) recognises the importance of the relationship between teacher and learner, while Bausforfeld (1985) also addresses this teacher-pupil partnership when he writes of "the delicate process of negotiation about acceptance and rejection." This paper begins to look at the pupils and their perceptions of the mathematics classroom in the hope to contribute to the wider discussion of teacher-pupil interaction.

Desforges and Cockburn (1987) reported that to understand how children respond to mathematical activities in the classroom, the teachers need to grasp the children’s responses: "Were the children happy and successful with their work? What work practices did they employ? What skills did they evince? What feedback was potentially available to the teachers as their children set about the tasks assigned?"
These are important questions, and while some of them are addressed in this paper, Doyle (1986) is also one to acknowledge that children’s responses to their work might play a part in informing the role of the teacher.

METHOD

The findings reported here form the first part of a study into pupil’s perceptions concerning their mathematics lessons. The project will consist of three phases. Phase one involved the children drawing a picture of their mathematics lesson. Phase two will be discussions with the children about their pictures, and phase three will involve discussions with the teachers and will consider their response to the children’s drawings. While the first two phases focus on the children, phase three is intended to return to the teacher to consider their views of the study. Phase one is being conducted at the time of writing this paper, while phase two is due to be completed in the next 3 months.

The choice of methodology for phase one of this project was inspired from reading Patricia Palmer’s book “The Lively Audience” (1986). This is a study of children around the TV set, where she examines the relationship children have with the television and what this means in today’s media driven world. Various methods of research were used, but paramount to this project was the perceptions the children had. She writes that “the perspective of children should be sought and used in delineating research questions” (1986). The book includes children’s drawings, which form part of the analysis of their views and perceptions.

My own data was collected in two Primary schools in Norfolk, UK. One hundred children from four different classes (Years 5 and 6; ages ten and eleven) were asked, by their class teacher to draw their perceptions of a mathematics lesson. The written brief to the teachers specified that no guidance or details must be given; the only criterion necessary was that the children must include themselves within the picture. Each teacher was given a set of A4 paper, which had several different computer drawn borders on them. The borders were intended to act as the frame for the picture. The choice of border was left up to the children. They were given approximately an hour to draw their pictures. The lesson took place in the children’s usual learning environment.

While these single types of observations yield interesting and informative data, I recognise it provides only a limited view of the situation. As Smith (1975) says ‘research methods act as filters’, however, phase two of this project is an attempt to validate the data further through talking to the artists about their drawings. The drawings are, however, a rich source of enquiry, and allow the research to focus in and narrow down on the significant issues (Delamont and Hamilton 1984).

One of the features of this research is the way the data will be derived from three different sources, but integrated in a way which makes sense and allows the teacher-pupil interaction to be viewed coherently. Jick (1979) is one of the many researchers to write about this process. His view that the researcher is like a “builder or creator,
piecing together many pieces of a complex puzzle into a coherent whole" suggests that this enables the researcher to "capture a more complete, holistic and contextual portrayal of the unit(s) under study." The final report will be written as a single account of pupil’s perceptions within the study of teacher-pupil interactions.

In this paper I focus on two characteristic drawings from the set of one hundred collected from the children for the purposes of Phase 1.

FINDINGS

Five questions were written prior to the collection of the data:

1. Is the teacher included in the picture?
2. Is there any mathematical equipment included?
3. Is there any mathematical notation drawn?
4. Is it a happy picture?
5. Are the children working together?

(These questions – their meanings and origins - are described in more detail further on in this paper). Each drawing was then analysed against these questions and the overall responses were collated.

<table>

<td></td>
</tr>
</tbody>
</table>

These questions are written in a closed format ensuring a ‘yes/no’ response as an initial source of quantitative data. If a ‘yes’ answer is produced further questions are then asked to provide more specific data. For example, if the teacher is in the picture, what does s/he appear to be doing? All the questions bear a certain relevance to today’s mathematics curriculum and the influence of the National Numeracy Strategy (DfEE 1999). The Strategy talks about the teacher as key to the teaching process, and encourages ‘interactive teaching’ throughout the lesson; an increase in the use of mathematical equipment used is encouraged, such as hundred squares, number lines and digit cards; the use of mental jottings as aide memoirs to solve calculations is central to the approach on calculation strategies; the importance on children enjoying their mathematics is supported through both the Strategy and also outside projects such as ‘Count On’ (the government endorsed project which
aims to change the public image of mathematics); children working in different groupings, such as pair or group work is also a feature of the Strategy.

For this paper, I examine two drawings in more detail. These two drawings are quite contrasting in their content and are characteristic of the many views the children expressed in the whole sample.

**Picture A**

![Picture A]

**Picture B**

![Picture B]

**Is the Teacher Included in the Picture?**

For this question, I had to be able to identify the teacher in the drawing by their name, the clothes they are wearing (if the other persons were wearing school uniform for example) or the written speech included.

Picture A does not include a drawing of the teacher, although the work on the board suggests that s/he is present somewhere in the lesson. The two children also have their hands up and are holding some type of card with possibly an answer on which
would suggest a question has just been asked. Furthermore, one child has actually turned around in his chair, perhaps to look at the teacher, with his answer.

In picture B I assume the person at the board is the teacher, determined from the clothes, the body language, the speech bubble and the children’s reactions. However, in contrast to picture A, the teacher does not appear welcome in the room, or is seen to be valued as an important part of the learning process – notice the children’s comments, “boring, whisper, whisper” and also their reactions – ‘zzzz’ indicating that two pupil’s appear to be asleep!

Is there any mathematical equipment included?

By mathematical equipment, I am referring to items such as number fans, hundred squares, number lines and calculators, not pencils and rulers.

Picture A includes three pieces of mathematical equipment: a hundred square, a board protractor and the number cards the children are holding. The way the protractor has been drawn – on its own hook – indicates its permanent residence. The portrayal of the hundred square is interesting as it represents the most common type of hundred square currently seen in primary classrooms. i.e. one which starts with one in the top left hand corner, and then consecutive numbers follow up to ten and a new line begins with eleven. However, this square, while following these conventions, appears to ‘run out of space’ at seven! The third piece of equipment is the cards the two children are holding. Many teachers will give out cards for children to select, in response to questions, while others will ask children to write down answers or parts to questions they want. Either way, it is interesting to see these included in the picture, as it suggests their regular use and association with the mathematics lesson.

Picture B, in contrast, has no equipment included, even though it is quite a detailed picture.

Is there any Mathematical Notation Drawn?

By mathematical notation I am referring to universal signs and symbols, either drawn individually or within a calculation. If any notation was drawn, I categorised it into three areas of primary mathematics: number and calculation, shape and space and handling data.

Picture A contains lots of mathematical notation within it. On the right hand board an example of the commutative law for multiplication is drawn, while underneath, place value for tens and units appear. The signs and symbols drawn all appear to be presented in a neat and organised way and suggest it is part of the current lesson. To the left of the picture, mathematical signs are displayed and include addition, subtraction and the equals symbol. These appear to be drawn on card and therefore suggest that they are permanently displayed on the wall.

Picture B also contains mathematical notation. The signs and symbols are all drawn onto the board, with no evidence of a wall display. The notation is drawn in a rather
haphazard and disorganised way, but perhaps they are questions or answers to a test, which may explain the range of notation included. Percentages, metric distances, fractions, decimals and whole numbers are drawn with the subtraction, multiplication, division and equals signs also represented.

Is it a Happy Picture?

For this question the children needed to look happy (e.g. with smiles on their faces) or have included positive comments. If they appeared unhappy (e.g. down turned mouths) or negative comments were written, this was counted as a ‘no’. If neither conclusion could be drawn, it was attributed a ‘can’t tell’.

Picture A appears to be a very happy picture. The child turning around has a smile on his face, both children have their hands in the air, indicating their desire to participate, and there are even two ‘faces’ drawn on the wall with huge smiles on them. Work is neatly displayed on the boards. The display is a central part of this picture, suggesting that pupil’s work is valued and worthy of display. Even the waste paper bin is ‘steaming’ with the amount of work (perhaps jottings now not needed) produced this lesson, which indicates a good working environment.

Picture B, in contrast, portrays the children as either asleep or bored, suggesting scenes of unhappiness, while the teacher seems to be the only happy person. Other indications are the scribbles on the books and the writing on the board, which is written without care. While there are several pieces of work on display, the artist has managed to convey scenes of a bare undervalued classroom by the lack of work on display. Another contributory factor to this interpretation of unhappiness is the speech bubble coming from the teacher. The “blah blah” phrase could suggest either boredom on the part of the children listening to it, the monotony of the teacher’s voice, or even the length of time she has been speaking for. Perhaps she has been speaking for so long, the words pale into insignificance as their concentration wanes.

Are the Children Working Together?

For this question, working together meant children sitting together in either pairs or groups. Often whole classes will work together, although the children will still be working alone, and therefore this was not included in this phrase.

In picture A the two children appear to be sitting next to each other at one table, although from their individual cards I assume they are working alone in this activity. However, the fact that a pair of children are sitting together indicates this group work occurs.

In picture B children also are drawn sitting next to each other, but as in picture A, there is little indication that they are working together currently.

DISCUSSION

The evidence examined in this phase of the study and exemplified in this paper raises several questions about how pupils perceive their mathematics lessons. At this stage
of the study, the analysis provided is preliminary and further commentary from the artists themselves will support further interpretation. While Palmer (1986) provided the inspiration to use drawings as a source of evidence, the ongoing research will look to form a theoretical framework from which to analyse further the visual data.

Perceptions remain a fascinating source of data. What do you think you are thinking? While you may think you are drawing an accurate representation of your thoughts, perhaps you are not. Perhaps you are clouded by other influences, such as the pencil you are using, the border you have chosen or even how you are feeling at this particular moment? Often thoughts are only challenged when you are questioned about them and are asked to justify and exemplify them. This is what makes the data at this stage so interesting to analyse.

However, while the data remains somewhat tentative, it still offers much to celebrate. The images offered are rich and quite versatile. There are many different interpretations to draw upon in this initial stage. For example, have the children chosen one aspect of mathematics to draw, such as a problem solving lesson or even taking a test, or did they choose to represent a holistic image of their lesson? This would certainly influence the outcome of their picture. The decision to include the teacher or otherwise may have been a conscious decision depending on the type of lesson they are thinking about, or simply a forgotten element. Only talking to the children can verify or falsify these points. However, this absence of the teacher or equipment for example, is arguably attributable to the pupil’s own experience and perceptions of mathematics.

These findings suggest different children perceive their mathematics lessons differently. These two drawings suggest very different views. Picture A appears to emit many of the values the mathematics curriculum aspires to today – children enjoying their lesson while actively contributing to it and using mathematical equipment, unlike picture B, which does not. It is possible through my analysis that I have focussed attention on some things to the neglect of others, as observed by McIntyre and Maclead (1978) and so the information must be treated with caution. However, the two pictures do raise issues, which based on how pupils perceive their mathematics lessons raises concerns for the teachers in them.

Research shows that “pupils learn more when their teachers know their attainment and can act on this information” (Askew and Wiliam 1995). Picture B suggests the teacher was not aware of the children’s desire not to learn. There is an increasing interest into consulting children. Kings College in the UK, as part of its Leverhulme Project (Brown 1997 – 2002), interviews children into what makes an effective teacher, while Essex County Council undertook a year long action research project into the use of children’s perceptions as a tool for school self-evaluation and development (McCarthy 2001). They concluded that asking children does make a difference, both for celebration and development issues.
All teachers have considerable scope to influence the quality of experience in their classrooms. One way is the recognition of potential teaching and learning experiences (Borthwick 1999) and another is the value that the perceptions of pupils can offer. The ongoing research will continue to explore possible answers to the issues raised above.

SUPPORTING STUDENTS’ REASONING WITH DECIMAL NUMBERS: A STUDY OF A CLASSROOM’S MATHEMATICAL DEVELOPMENT

Ada Boufi  Frosso Skaftourou
University of Athens

The focus of this paper is on students’ developing conceptions about decimal numbers in a fifth grade classroom. To collect our data we organized a teaching experiment that lasted four weeks. Our students’ progress was significant. Their development was supported by activities in the context of metric system measurement and with the model of the number line. In the analysis of our data we delineate the mathematical practices institutionalized by the classroom community. The shifts in this classroom’s practices confirm our anticipated learning path.

Introduction

Research shows that students have many misconceptions about decimal numbers. In a recent comprehensive review of these studies (Stacey, 1998), we can notice that these misconceptions are mostly accounted for in psychological terms and they are not analyzed in relation to students’ instructional experiences from their classrooms. In this way, teaching decimal numbers can not be adequately informed by available research data. How could teachers by just knowing the prospect of these misconceptions appearing avoid them? The only alternative we can imagine is for them to give their students detailed instructions at the risk of making mathematics more algorithmic than it is. On the other hand, if teachers try to follow the suggestions which are usually given for remedying these misconceptions, they will end up with a top-down structuralist teaching approach. Notwithstanding that, this approach has repeatedly been criticized as insufficient to assure quality in students’ learning experiences (Gravemeijer, 1994).

A relational understanding of decimal numbers might be built if teaching had a different orientation. Such new teaching approaches are developed by researchers to promote a meaningful understanding in several mathematical areas (Carpenter, 1997; Cobb, 1999; Lampert, 1989; etc.). In these attempts, teaching is based on students’ informal understandings and strategies, it supports the gradual mathematization of their contributions, and encourages communication in the classroom. We tried to develop a similar orientation in teaching fractions and decimals in a fifth grade classroom. At the end of our classroom teaching experiment our students did not show any misconceptions about decimals and their understanding was meaningful. Accounting for students’ learning in this classroom could be useful for instructional design research. Also, the results of such an analysis might help teachers to reflect on their current instructional practices. In fact, it was on the basis of preliminary
analyses of our students’ learning that we were trying to support their developing understandings of decimals. Therefore, this paper presents a first attempt to account for our students’ learning in the social context of their classroom by documenting their increasing understandings of decimals.

Theoretical framework

Our focus in presenting our results will be on the ways that taken-as-shared meanings of decimal numbers emerged in our classroom. This is particularly important if we consider these meanings, which originate in students’ contributions, as constraining or enabling their individual activity. This consideration stems from the emergent perspective developed by Cobb and his colleagues (Cobb & Yackel, 1996). In this perspective mathematical learning is treated as both a social and an individual activity. More specifically, these two aspects of learning are taken as reflexively related. Individual students reorganize their activity as they participate and contribute to their classroom’s mathematical activities. On the other hand, the students’ collective activity does not exist separately from individual students’ diverse ways of reasoning.

Methodology

The data we will analyze come from a fifth grade classroom in a school of Athens. These data include: 1. the videorecordings of all 17 lessons on decimal numbers, 2. the videorecorded interviews taken from most of the students upon the completion of our teaching experiment, and 3. the 21 students’ notebooks. The presenting author taught most of the lessons in this unit, immediately after a fraction instructional sequence.

The activities used in our teaching experiment were a crucial factor for our students’ developing understandings of decimals. But our students’ activity as well as their further mathematical development was also influencing the selection and development of appropriate activities. Thus the set of instructional activities used in this teaching experiment (see the results section below) was not fixed in advance. However, our overall purpose guided the selection of an initial set of activities. This purpose was to support students’ flexibility in reasoning with decimal numbers. For example, we wanted them to compare decimals like 0,06 and 0,6 by reasoning that 0,6 is bigger because it is ten times larger than 0,06, or by reasoning that 0,06 is very close to 0,5, while 0,06 is far from it as it is closer to 0,1. Gravemeijer’s (1998) idea that students can reinvent decimals through the activity of repeated decimating along with his heuristic of emergent models were instrumental in helping us to foresee a path through which we could guide them to develop their understanding of decimals.

The lack of a decimal monetary system in our country at that time was a serious difficulty. We thought that our students could be offered the opportunity to see decimals as describing the results of repeated decimating in the context of activities related to the standard metric system measures, which are commonly used
in our country. Before involving students in activities in the context of measuring lengths, we decided to start from a fictitious scenario, similar to one found in the “Mathematics in Context” curriculum unit “Measure for Measure” (Britannica, 1997). Our students heard a story about a visit to an amusement park where a competition was organized on a special wheel of power. The winner would be the person who managed to turn this wheel more than the other participants would. In the context of this narrative the problem of finding the winner brought to the fore the issue of precisely measuring the turn of the wheel. Students made a number of suggestions including: halving the wheel and then again halving the half of the wheel, or making divisions like those on a clock face. Next, the teacher announced that this wheel was repeatedly divided by ten and students accepted this as an efficient way of measuring precisely the players’ strength. The relationships among decimal fractions were then explicitly discussed. This was meant to prepare the exploration of the subunits’ relationships on the meter stick, which was familiar from previous grades. So, when the meter stick was introduced students compared it to the decimally subdivided wheel and easily identified their similarities. These discussions concerning the wheel of power and the meter stick together with the students’ learning history from fractions constituted the background for their engagement with the decimal instructional sequence. Also, we took into account that students had had a few lessons on decimals in the fourth grade. We hoped that students’ reasoning with the meter stick, would come to function as a model of their activity on the wheel, i.e. of measuring in “ones”, “tenths”, “hundredths”, etc. Eventually, we anticipated that reasoning with the meter stick would serve as a model for reasoning with decimal numbers. Through this shift, by embodying the results of repeated decimating, the symbol of decimal number would evolve into an experientially real mathematical object independent of their activity.

The above mentioned hypothesized path will be documented by utilizing the construct of practice (cf. Cobb&Yackel, 1996). Thus, the criterion we will use in describing the mathematical practices that emerged in our classroom community will be the legitimacy / acceptability of the students’ explanations in the classroom as well as their content.

Results

After the introductory discussions on the wheel of power and the meter stick, the teacher asked students how they would find 75 cm on a double number line that she had drawn on the board as a simplified form of their meter sticks. Students offered several partitionings (see Figure 1). The variety of students’ partitionings was not totally unexpected. Students had already connected the idea of refined measurement with the use of common fractions. From the outset, it seems that students’ prior experiences from fractions were going to influence the course of their decimal understanding, just like in history where the origin of decimals can not be separated from fractions.
The number line seems to have played a significant role in this episode. As our instructional intent is for students to reason with decimals independently of the imagery of the number line, inevitably the meaning of the number line will change: from students' using it with a context-specific meaning (measuring strength on the wheel or length with a meter stick) to using it in order to think about relations among units of a different rank. Therefore, analysis of subsequent episodes will be focused on students' interpretations of their activity as they reason with the number line.

After the first student’s double decimating in order to place 75 cm on the number line, the teacher asked students to describe the result of his repeated decimating in meters. Apart from students' response $\frac{75}{100}m$, the request for a decimal number in meters resulted in several answers: 75,0cm, 7,5m, 7,5cm, 0,75m. These answers became a topic of discussion and invalid answers were rejected. There were students however, who were unwilling to accept 0,75m as a legitimate way of notating. A possible explanation might be that in their prior experiences from mixed numbers “0” was not used to describe the absence of whole units. As students negotiated their different ways of symbolizing the results of repeated decimating, the first practice of connecting decimals to the records of decimally partitioning the number line seems to emerge. Subsequent episodes gave students additional opportunities to negotiate their ways of symbolizing the results of repeated decimating. For example, a few days later, the difference between 0,10 and 0,100 emerged as a topic of discussion. As students had not yet created the decimal number as a true symbol of decimating, the equivalence of these two decimals was not self-evident.

The “75cm episode” showed us that a possible source of students’ difficulties was their familiarity with arbitrary partitioning. By including tasks that involved students in enlarging the unit of measurement for lengths not convenient for the use of different than decimal partitionings, we tried to support their attempts to create an
operational meaning for decimals. As an example, 9cm were easily converted to a decimal after decimating the number line (see Figure 2).

Figure 2: Place 9cm on the number line

Christos’ activity on this number line was still dependent on the imagery of the meter stick. How else could he place 9cm on the number line? On the other hand, in contrast to other students, he consistently used decimal fractions before attempting to write down the equivalent decimal number, in this as well as in other similar tasks. Moreover, his behavior is representative of what some few other students were also doing in this type of activity. In accounting for these behaviors we conjectured that these students were applying the well-known trick of writing the numerator of the decimal fraction and then holding so many digits after the decimal point as the number of zeros in the denominator of the decimal fraction. Instead of coordinating the records of decimating with the digits of the decimal number, these students seemed to rely on numerical patterns. At the same time, their participation in the classroom mathematical practice of connecting decimals to the records of their decimating activity was unhindered. Their solutions based on their reasoning with decimal fractions were not challenged. In fact, it can be argued that these students were not in a position to see decimals in relation to repeated decimating, as they were not reasoning with the number line. In the Greek language the prefixes used for the subunits of the meter are identical to the fractional names used to describe their relationships to it. “Tenth-meter” is the word used for decimeter, “hundredth-meter” for centimeter, and so on. So they could well write the decimal fraction without paying any attention to what they had been doing on the number line. In such a case, the only purpose for carrying out the decimating process could be to specify the distance of a given length on the number line. Therefore, for these students understanding of place value would remain instrumental if further opportunities to reflect on the results of their decimating activity in connection to decimal numbers were not given. To this end, we involved students in the following activity.

Students were asked to place different decimal numbers with up to two decimal digits on schematized rulers. These rulers were already divided in centimeters or decimeters. Our main purpose in introducing this activity was for students to realize how repeated decimating was signified by the decimal digits. Students were encouraged to describe the decimal digits of the given decimals in terms of their actions of placing them on these rulers. The topics of conversation that emerged in the context of this activity provided opportunities for students who relied on tricks to reorganize their activity. Now, it seemed that the classroom’s activity with the number line implied the numerical values of the decimal digits. In other words, it became a true model of measuring with units of different decimal rank.
With the next activities we tried to support students' reasoning with decimal numbers. We thought that if the values of the decimal digits would become independent of students' activity on the number line, this would allow students to focus on relationships among decimal numbers. Students’ activity on the number line would evolve into a model for reasoning with decimal numbers. Gravemeijer (1997) notes that: “This transition from ‘model-of’ to ‘model-for’ implies a process of ‘reification’. […] what is reified is the process of acting with the model, not the means of symbolization itself”. In our case, the activity of repeated decimating had to be reified. Signs for this reification emerged, in the context of several activities. The following episodes will clarify how this process took place in our classroom.

In one of the first lessons, the teacher asked students to find a length that would be very close to 3 meters. She drew a number line on the board (see Figure 3) and the first offer of 2,99 meters was placed on it. She then asked for a decimal number even closer to 3 meters. The number 3,0 was offered by a second student but it was rejected by other students as being equal to 3 meters. Another student suggested 2,999 meters. To the teacher’s question of how far is 2,99m from 3m this student answered 1 cm and when he was asked to place his number on the number line, he said: “I would divide it in 10 pieces, and it will be at the ninth small line”. This episode closed with the specification of the distance that 2,999m had from 3m.

![Figure 3: Find decimals close to 3m](image)

The student’s reasoning concerning the placement of 2,999m on this empty number line shows that for him the decimating process was already reified. The fact that other students did not ask any clarifying questions suggests that they could follow his argument. However, the focus of their comments indicates that they were not in a position to anticipate decimating activity. Many students objected that their classmate’s drawing was not precise. As they said the small lines were not equidistant and the distance of 2,999 from 3 was longer than 1mm. The imagery of the meter stick was still too dominant. Therefore, reasoning in terms of repeated decimating was not yet a practice.

Later, students’ work in the context of the activity with the schematized rulers might be considered as providing opportunities for many students to reflect on their decimating activity. So when for example, students had to place decimals with two decimal digits on the ruler with decimeters, they started anticipating their decimating activity. However, their anticipations did not become an explicit topic of discussion. Discussions were mostly focused on the results of their decimating activity and not on the students’ intentions. An activity where students were asked to find decimal numbers in between other given numbers allowed students to make their reasoning in
terms of repeated decimating explicit. When the teacher asked for a decimal at the midpoint of the distance between 8,6 and 8,7 students explained their solutions as follows: Stavroula said that the number will be 8,65 and then she explained her thinking by drawing a number line on which she had first placed 8,6 and 8,7. Then she divided the distance between the two numbers in ten parts and she showed 8,65 on the fifth line. Costas placed the two given numbers on a number line and then he explained that the wanted number will be at 865cm. In his mind, he had already transformed the given numbers in centimeters. Then he placed 8,65 at the midpoint of the distance separating the two given numbers. Helias tried to find 1/2 of 1dm. He said that it will be 5cm and then he added 0,05 to 8,6.

In all of the above solutions, students reasoned with the decimating process. Moreover, in the last two solutions the decimating process has already been concealed behind students’ reasoning. The same finding concerns students’ reasoning in converting fractions to decimals. Progressively they institutionalized a formalization of the decimating process in a long division scheme. For example, students jointly transformed 1/3m to 0,3333...m by making three successive divisions (100cm:3, 10mm:3, 10dmm:3). It was in this task that the notion of the infinite number of decimal places first struck them. However, the presence of the metric unit names in students’ explanations might be considered as showing students’ inability to escape from the imagery of measuring length. But the adaptability of their ways of acting as we posed tasks in different contexts, documents that their understanding of decimals was not context dependent. Without losing their ties to the phenomena that gave rise to them, decimal numbers have now become mathematical objects that students could reason with.

The practice of reasoning with decimal numbers seemed to be well established by the end of the decimal instructional sequence. Actually, students were able to reason not only with decimal numbers but at the same time to incorporate it into reasoning with fractions or whole numbers. Their sense of decimals is illustrated by students’ reasoning on the task 4X0,75. The teacher had notated their solutions on the board as follows:

| 0,75 | 75cm×4 | 0,75=0,25+0,25+0,25 |
| + 0,75 | 1/\ | 1←0,75+ |
| 150 cm→1,5m | (70+5) ×4 | 1←0,75+ |
| +150 cm→1,5m | (70×4)+(5×4) | +1←0,75+ |
| \ / | 280cm+20cm | 3m |
| 3 m | 2,8m+2dm | |
| | \ / | |
| | 3m | |
Conclusion

In studying our classroom’s mathematical development through an introductory course on decimal numbers, we identified three mathematical practices. These practices represent a joint accomplishment of this particular classroom community. Individual students’ participation in these practices was varied. For example, at the end of our teaching experiment, most of our students could reason with decimal numbers. However, there were students who were still reasoning in terms of repeated decimating. As the final episode shows, these students’ participation in the classroom discourse was by no means insignificant.

References

The purpose of this paper is to share some of the results of a year-long teaching experiment in which fourth grade students were provided with opportunities to develop an understanding of fraction concepts before the introduction of formal algorithms. In particular, we will address the role of the teacher/researcher's questions in prompting students to build these ideas. Our results indicate that the students were successful in building models to explain division of fractions.

Introduction and Theoretical Framework:

This research examines one portion of a teaching experiment that focused on the development of fraction knowledge in a class of fourth grade students. In the sections that follow, we will briefly discuss the role that the teacher can play in helping students deepen their understanding of this content, and several instances that document one teacher/researcher's skillful use of questions to help children overcome difficulties with a problem dealing with division of fractions.

Many students have experienced difficulty in solving problems involving fractions (Tzur, 1999; Davis, Hunting, and, Pearn, 1993; Davis, Alston, and Maher, 1991; Steffe, von Glasersfeld, Richards and Cobb, 1983; and Steffe, Cobb and von Glasersfeld, 1988). When considering these difficulties, Towers (1998) states that traditionally, the teacher has been seen as separated from the student, and that teaching and learning have been regarded as discrete entities. Tower's research examines the role of teacher interventions in the development of students' mathematical understanding, and her findings suggest that children can overcome some difficulties traditionally related to fractions, when appropriate conditions are in place. Other researchers have also documented how teachers can help in facilitating the development of ideas relating to fractions (c.f. Steencken, 2001; Steencken and Maher, in press; Ma, 1999; Cobb, Boufi, McClain and Whitenack, 1997).

The role of the teacher in helping children develop insight into ideas relating to fractions was a central topic of the year-long teaching experiment that is the focus of this paper. The fundamental premise was that in order to help students build a conceptual basis for considering these ideas, teachers must move away from more
teacher-centered instructional approaches which emphasize rote memorization and the execution of rules and procedures, and move toward instructional practices which are more student centered and provide them with the opportunity to build concepts and ideas as they are engaged in mathematical activities that promote understanding (Davis & Maher, 1997; Maher, 1998; Cobb, Wood, Yackel & McNeal, 1993; NCTM, 2000; Klein and Tirosh, 2000; Schorr, 2000; Schorr and Lesh, 2001). A more student-centered classroom requires teachers who listen to the explanations of their students, probe them for justifications, encourage them to share their solutions with their peers as they work together to refine, revise and extend their solutions.

Teacher questioning is a critical component of a more student-centered classroom, and the topic of this paper. International studies have documented the effects of teacher questioning in helping children advance their mathematical thinking (Klinzing, Klinzing-Eurich and Teicher, 1985; Sullivan and Clarke, 1992; Martino and Maher, 1999). In each of these studies, it was found that asking more “open-ended questions aimed at conceptual knowledge and problem-solving strategies can contribute to the construction of more sophisticated mathematical knowledge by students” (p. 55, Martino and Maher, 1999). In addition, Cobb, Boufi, McClain & Whitenack (1997) propose that when students are engaged in discourse with peers, there is growth and development of mathematical ideas. In this study, the researcher used responsive questioning to elicit explanations, to help students develop appropriate justifications and to redirect them when they were engaged in faulty reasoning. In the sections that follow, we will describe how questions were used in this study, and the types of student responses that were elicited.

**Methods and Procedures:**

**Background, Setting and Subjects:** This research took place in a small suburban NJ district, over the course of a year, as part of a teaching experiment. The focus of this intervention was to investigate the development of children’s mathematical ideas about fractions. A 4th grade class was chosen because these students had not been introduced to the formal algorithms usually associated with learning fractions. This particular class consisted of 25 students, 14 girls and 11 boys. Each of the approximately 50 classroom sessions lasted approximately sixty to ninety minutes. This paper reports on the 21st session of the study.

One of the goals of this teaching experiment was to create a classroom community in which student inquiry and discovery were of paramount importance. Teachers and researchers did not tell students that their work was correct or incorrect. Rather, students were questioned and encouraged to justify their solutions so that they could develop their own sense of accuracy, not based on the approval of an outside authority. The overarching perspective was that if students were invited to work together and conduct thoughtful investigations with appropriate materials, they
would be able to build mathematical ideas relating to fractions (Maher, Martino, Davis, 1994). Throughout this experiment, the teacher/researchers worked to promote a classroom culture that supported children as they explained, explored, and reflected upon mathematical ideas. They were always invited to talk about their thinking, and they were challenged to defend and justify their ideas. The expectation was that each child, or group of children, would be able to build a model or representation of their idea, talk about their idea, and share their ideas with the teacher and their classmates. The children were always encouraged to build models of their solutions and share them with each other and the class. In discussing their solutions, children listened to each other and developed convincing arguments to support their ideas. They often raised questions that triggered further exploration. They drew pictures, labeled the pictures and eventually developed notations for their ideas. Steencken (2001) studied the earliest sessions of this project in depth, and documented the emergence of sophisticated mathematical thinking about fractions.

**Data:** All sessions were videotaped using two or three video cameras, one or two of which attempted to capture students’ work and classroom interactions. An additional camera was frequently set up to record explanations by students, which were presented at the overhead projector. Students’ written work and Teacher/Researchers’ notes were also carefully collected. Transcriptions and detailed narratives of the data were recorded.

**Coding:** A coding scheme was designed to flag elements for study. The four classifications of codes used were intended to record teacher interventions, ideas expressed, representations used by students, and justification and reasoning by students. In all, there were twenty teacher intervention codes that fall into six categories. Codes relating to teacher’s intervention included: T₁) giving information, Tₑ) rephrasing or requesting that another student rephrase what a student said, T₉) asking questions, Tᵣ) requesting justification, Tᵣ) directing students to construct a representation, consider an existing representation, or to the work or ideas of others, to discussion with others or towards previously done work; and, Tₐ) seeming to do nothing. In this research, we will focus on these teacher codes as well as the outcome of these interventions in eliciting students’ justification and reasoning.

**Results and Discussion:**

The episodes that are portrayed here occurred as students participated in an activity called, “Holiday Bows” (c.f. Bellesio, 1999), created to provide an opportunity for students to consider ideas relating to division of a natural number by a fraction. Questions that Teacher/Researchers asked were designed to be responsive to what students were doing and to help them to clarify and express their thinking by justifying their solutions.
In the first episode, the teacher intervention occurs when a Teacher/Researcher joins two boys who are working on a problem involving $2 ÷ 2/3$. The Teacher/Researcher employs various types of interventions: questions, reiterating what the students say, requesting justification and explanations. When the students do not know how to begin, she asks, “What do you think you know?” In the excerpt that follows, the teacher is working with one student, Andrew. Her previous question has invited him to look at the ribbon and begin to “imagine dividing” it into three pieces.

Andrew: I think it’s three umm because when you divide thirds up it’s...it’s ummm... 1/3, 2/3, 3/3 [places his finger on the ribbon which is lying on top of the meter stick indicating approximately where 1/3 m, 2/3 m and 3/3 m would be] so it would be like this would be one ribbon if you made it into a ribbon [places his finger at approximately the 1/3 m mark]

Teacher/Researcher: uh huh

Andrew: this would be another ribbon [indicating approximately 2/3 meter]

Teacher/Researcher: uh huh

Andrew: and this would be another ribbon [indicating end of meter stick] so if you divide it into thirds, you would have 3 [inaudible] bows, but we want to make sure.

By reminding the students to use what “you think you know” the teacher has offered that the students consider a technique that they had used before in similar types of problems. When the Teacher/Researcher posed this question, the student, Andrew, spontaneously solved the problem of finding out how many bows, each 1/3 meter in length, could be made from one meter of ribbon.

The Teacher/Researcher then asked the students in the group to justify their solutions. Justification of solutions often drives students to examine the validity of their own ideas. In this excerpt, one student, James, believes that the solution to the problem is 4 bows. At this point, the Teacher/Researcher asks: “Why are you going to get 4 bows, cause I’m...I’m confused...convince me.” As the children consider their justification, she requests that they clarify what appear to be conflicting statements and provide valid mathematical evidence for them. While working on the problem, how many bows, each 1/2 meter in length, can be made from a blue piece of ribbon which is two meters long, students confuse the idea of dividing two by one-half with taking one-half of two. Questioning by the Teacher/Researcher helped the students to examine their own and each other’s ideas.

Teacher/Researcher: What’s... What’s...Ok, Let... Let me go back because I think you’re telling me a lot of things and I just want to be sure I understand. Um...
If you have the blue ribbon and we want to figure out how many bows we could make and each one is 1/2 meter how did you figure out, first you told me it was 2 and then you said no, it's 4.

James: It's 4 because...

Andrew: It could be either way.

Teacher/Researcher: It could be either? What do you think about that, James? Could it be either?

At this point, the Teacher/Researcher uses the strategy of rephrasing in order to help James consider the ideas that Andrew is referring to. She attempts to refocus the discussion back to James, the student who has correctly stated that there would be four bows.

James: I don’t know. [Inaudible] 1/2 of a meter.

Teacher/Researcher: Right,

James: Not 1/2 of two meters, so...

Andrew: He’s saying 1/2 of two meters not 1/2 of one meter.

It appears that James is now considering what Andrew has said and he verbalizes that there is a distinction between taking 1/2 of a meter and 1/2 of the entire ribbon, which is 2 meters long. Andrew states that he thinks that James is referring to 1/2 of the ribbon, not 1/2 of a meter, which would be the length of one of the bows.

Teacher/Researcher: Ok. I think what it’s saying is the ribbon length of the bow is a 1/2 a meter so each ribbon is going to be a 1/2 a meter long; OK, and the question is how many bows can you get out of that blue ribbon if each bow is going to be a 1/2 a meter long?

James: Four ‘cause this [holding up blue ribbon] is two meters long

Andrew: It’s saying 1/2 of two meters

Teacher/Researcher: Ok, Let me see if I can understand what James is saying.

Andrew: It’s saying it’s a 1/2 of 2 meters because the blue ribbon here is 2 meters, is the whole

Here Andrew has indicated that he believes the problem is to find out what 1/2 of 2 meters would be. The Teacher/Researcher again directs the attention to James, who is interpreting the problem correctly.

Andrew: So then this is a 1/2 of 2 meters... that would only be 2

Teacher/Researcher: Ok. What does this [points to the paper with the problem on it] say to you? What is a 1/2 m?
Andrew: Half of this \textit{[holds up white ribbon which is one meter long]} Here, the Teacher/Researcher’s question helps Andrew to focus on the fact that the 1/2 in the problem refers to 1/2 meter in length, which would be the length of each bow. Andrew indicates his understanding of this by holding up the white ribbon, which is one meter in length and saying that each bow would be half that length.

James: Yes. So that would be four (referring to the blue ribbon, which is 2 meters long) and this would be 6 (referring to 3 m gold ribbon in the next problem)

Andrew: And so this [the white ribbon] is 2 and both of these [white ribbons]...[inaudible] would be 2 halves and another one we’d put on then that would be 4.

Andrew uses the white ribbon as a metaphor for 2 bows. He communicates his representation of two bows being made from each one-meter piece of white ribbon. The teacher’s interventions invite him to clarify the question and to formulate and explain his metaphor, the white ribbon, for 2 bows. Her manner of questioning encourages the boys to talk not only to her, but also to each other. When it appears that Andrew believes there are two possible solutions, she probes further to encourage him to state that both his answer and James’s answer are correct but that they are answering different questions. Andrew ultimately explains the difference between finding out how many bows, each 1/2 m in length can be made from 2 m of ribbon and finding 1/2 of 2 m of ribbon.

Conclusions

The preceding episodes were intended to highlight how one teacher/researcher helped students build a solution to a task involving division of fractions. Her interventions invited the students to listen to each other, to consider each other’s arguments, to express their ideas and to create a representation to help them solve the problem. In this case, the children did not rely exclusively upon the authority to supply affirmation for their work or to impart information which they were expected to acquire without understanding. Rather, the students built a solution that made sense and they did this by exchanging information with each other and with the teacher/researcher. The task of monitoring children’s construction of ideas, and posing timely questions is a challenge to teachers. Polya (1985) states, “This task is not quite easy; it demands time, practice, devotion, and sound principles.” (p.1). The above episodes are instances of how, in a research setting, attention can be directed to the students' thinking. The interventions and questions were designed to engage the students in working out a model that made sense to them. Questions can become a catalyst for urging learners to justify their ideas and explain them to each other. This, in turn, has the effect fostering deeper thinking about the ideas involved in the problem situations.
Davis advocated a learning environment for the teaching of mathematics, which fosters the connection between the representations in the mind of the teacher and the mind of the student. This implies that a teacher makes sense of the developing ideas of students by the representations they build, explanations they give, and arguments they make, and, as the late Bob Davis suggested, “taking their ideas seriously”. Davis (1992, p.349)

We contend that some representative studies about affect, even if they seek support based on psychoanalytical theory, miss the interpretation of cognition in terms of transfer. We introduce Lacan’s concepts of transference and affect which make it possible to touch the dimension of love. For the sake of the reader’s understanding we add an example from our psychoanalysis-inspired learning experience. This is a theoretical paper with one example from practice to facilitate understanding.

INTRODUCTION

After gathering data showing that “student writings convey an overwhelming sense of fear and anxiety engendered by their encounters with mathematics”, Breen [2000] points out that “the links between psychoanalysis and mathematics education seem to have largely been silent themes at PME with only a few discernible exceptions (...) and neither of these directly address the encountered dominance of fear in the mathematics classroom” [Breen, 2000:108].

Fear and anxiety are signifiers that fall under the general heading of affect in a vast research literature. McLeod’s survey [McLeod, 1992] displays an impressive list of 219 references with none referring directly to psychoanalysis; Freud is mentioned en passant in the article. McLeod says that “the affective domain refers to a wide range of beliefs, feelings and moods that are generally regarded as going beyond the domain of cognition“ [576], however “research on affect in mathematics education continues to reside on the periphery of the field” [575], “a major difficulty being that research on affect has not usually been grounded in a strong theoretical foundation” [590]. Indeed, from the survey we get the feeling that the affective domain is a union of its common sense connotations such as: Aha!, anguish, anxiety, attitudes, autonomy, beliefs, confidence, curiosity, dislike, emotions, enthusiasm, fear, feelings, frustration, gender, hostility, interest, intuition, moods, panic, perseverance, sadness, satisfaction, self-concept, self-efficacy, suffering, tension, worry. We note a remarkable absence: love. It is a small paradox that the alleged intellectual unemotional Lacan, as we intend to show, is the one whose theory allows the restoration of this omitted dimension.

Affect and its connotations have been the capture object of research reports in recent PMEs. Vinner [1996] reports on teachers’ discussions about their professional lives brought about by their written answers to a set of questions. Analysis of videotapes led to interpretations under the headings of frustration, humiliation and hope connected to the cause and the way teachers coped with difficulties in teaching several content topics. DeBellis and Goldin [1997] use the term self-acknowledgment
referring to a learner’s willingness to acknowledge an insufficiency of mathematical understanding in a context of problem solving. Da Rocha Falcão and Hazin [2001] compare measures of self-esteem with mathematical performance and conclude that there is a need to take into account both affective and cognitive aspects in research about mathematical learning.

The two reports under the framework of psychoanalysis [Baldino and Cabral, 1998, 1999], as remarked by Breen [2000], do not directly address any of the affective connotations listed above. There are, however, some attempts in the literature to approach affect issues from the psychoanalytical perspective. The most consequential ones, Blanchard-Laville [1997], Wilson [1995] and Breen [2000], evoke the concept of transfer.

Blanchard-Laville [1997] postulates a certain psychical reality that could only be known through its effects, while remaining unknown in itself, like Kant’s thing-in-itself. She acknowledges the paradox that, in order to study the human psyche, we must pass through another human psyche, namely, our own. The solution she proposes to the paradox consists of a direct appeal to the conscious ego: “A minimum of conscious intentions is required of the observer in order to perceive the unconscious dynamic of exchanges and its reflections and let oneself impress by the implicit aspect of messages among the participants of the didactical exchange” [Blanchard-Laville, 1997:158].

Wilson [1995] aims at studying his own feelings in his relationship with the students. He describes his method thus: “At the end of each day, or week, I sat quietly and allowed an incident from my teaching to enter my mind (...) writing (it) as objectively as I could” [Wilson, 1995:1]. To this introspective method he adds the concept or transference described in these terms: "The transference relationship describes distorted perceptions of counselors which arise because of clients' previous relationships" [Wilson, 1995, quoting C. Lago, Notes from Manchester Counseling Course, Sheffield University].

Breen [2000] reports on his teaching experience with adults who were seeking a primary school teaching diploma or who have blocks about doing mathematics and were given a second chance. Transfer is considered as “the imposition of an actual or imagined previous relationship onto a present one” [Breen 2000:110].

In spite of all appeals for the need to approximate research on Mathematics Education and affect, we could not find any learning experience organized according to, and interpreted in terms of, psychoanalytical theory. The foci of the studies are not on the direct interaction of student or teacher with the mathematical object that characterizes cognition studies. Whenever the interaction between the subject and a mathematical object is brought about, the focus is on the subject’s feelings, described from the point of view of a superior conscious ego who relies on introspection to evaluate imaginary distortions from an exacting pattern. It seems researchers strongly
believe that psychoanalytic theories and affective studies refer to what happens on the periphery of cognition and have nothing to say about cognition itself.

In all the above-mentioned works about affect or its connotations, using either a direct approach or via psychoanalysis, the researcher assumes an exterior position either as an observer and interpreter, as in Vinner [1996], Da Rocha Falcão and Hazin [2001] or assumes a conscious position of judge, as in DeBellis and Goldin [1997], Blanchard-Laville [1997], Wilson [1995]. In doing so, the researcher approaches the transfer via an “alliance with the healthful part of his own self” [Lacan, 1973 chap. X.4] which generally runs in an opposite direction to the unconscious reality that psychoanalysis is meant to actualize.

In addition, all the research on affect seems to be pervaded by a more or less explicit intention of improving practice. For instance, Breen [2000] concludes his paper appealing to “the need for further work to be done to identify and research contributions that a knowledge of psychoanalytic processes can make to understanding and improving the teaching of mathematics” [Breen, 2000:112]. If psychoanalysis were to be called for in such circumstances, it would start by asking: Why do you think that the teaching of mathematics should be improved? Why is it not good as it stands? These questions, as far as we know, have never been addressed in PME. In calling on psychoanalysis to solve the distressing problem of practice, the teacher becomes part of the problem to be solved, a not very comfortable position. We intend to show how Lacan’s theory allows us to cope with this discomfort.

THE THEORETICAL BACKGROUND

The theory elaborated by Lacan in order to orient and explain the dialogic encounter with his patients may be characterized as the dialectics of the subject and the other [Lacan, 1973: 205, 239]. This theory models what happens whenever a human subject address an audience in a common language. In particular, it is fit both to explain and orient the learning/teaching experience in a mathematics classroom provided its concepts are conveniently specialized.

According to common-sense opinions about psychoanalysis, the transfer is a substance transmitted between subjects via communication such as the “transmissions psychiques” of Blanchard-Laville [1997], or a catharsis of unconscious elements displaying a distortion to be rectified by the counter transfer, as in Wilson [1995], or “the imposition of an actual or imagined previous relationship onto a present one” as in Breen [2000]. The transfer is also thought of as an affect that may be positive or negative. Positive transfer is identified with love. Lacan [1973] starts from this last common sense conception and takes it elsewhere. According to its meaning in the clinical experience, “the transfer is a phenomenon where both the subject and the psychoanalyst are included together” [210], hence two unconscious are simultaneously involved and it cannot be separated to “transfer” and “counter transfer”; “the transfer is the actualization (mise en acte) of the reality of the unconscious” [137] with all the implications the unconscious presupposes, including desire and sexuality. What has
to be analyzed in the clinic is the transfer itself. In addition “according to its nature, the transfer is not the shadow of something that has been lived in the past. On the contrary, the subject as subjected to the analyst’s desire, desires to cheat him about this subjection making himself loved by the analyst” [229, our emphasis].

The four fundamental concepts of psychoanalysis, the repetition, the unconscious, the transfer and the triebel¹, should not be treated separately. However, due to lack of space, we will only take up the transfer, and this only under the aspect of imaginary and symbolic identifications. What we lose in fidelity we hope to gain in clarity.

Specializing the transfer to the teaching/learning mathematics experience leads to the concept of pedagogical transfer [Cabral, 1998]. The pedagogical transfer implies that listening is not unrestricted, as it is in the clinic, but is restricted to mathematical listening, that is, restricted to the possibility of attributing mathematical meaning to what is heard. Mathematical listening is defined as occurring when the listener is able to repeat the speaker’s discourse until the speaker agrees that it is exactly what he meant. Of course, the speaker can always disagree and say that something else was meant. Therefore the activation of restricted listening presupposes an agreement, tacitly established prior to the talking situation.

The pedagogical transfer occurs when 1) the student manages to adjust the image of himself that he sees in the mirror to his expectation of being loved by the teacher and 2) the teacher accepts this image as capable of being loved. This love is to be distrusted, since the student is only seeking the way to produce the right answer, so that the teacher and the parents will be satisfied, and he will be recognized as one who knows and will get credit for this. The identification process of the subject with the image that he supposes to be loved by the teacher is called the imaginary identification and denoted i(a), a “I” for “image” and “a” for the object of desire around which the image is built. Schematically, in pedagogical transfer, this object is represented by the ability displayed by the teacher in producing answers and deciding what is right or wrong, an ability offered to the student as one to be imitated.

Whereas the image produced by i(a) is perfect, the unconscious reality that commands the production of this image is not so nice. This is an obscure reality that the subject perceives as his own qualities and commitments. He needs to love what he perceives, so he fabricates a high representation of himself out of ideological commitments that the culture offers him. The process leading to these commitments is called the symbolic identification, or the super-ego and denoted I(A), a “I” for identification and “A” for the Other, approximately, the culture.

In the pedagogical transfer, the commitment is mingled with the ability to produce answers, leading generally to strong rote learning efforts. Lacan [1973] says that this mingling of I and a “is the safest structural definition of hypnosis that has ever been produced” [245]. Plainly: in transfer, the student is in a state of hypnotic trance, a

¹ This German word has tentatively been translated by instinct.
most delicate situation. However, the teacher’s object of desire may well be represented by a student who produces the right answers according to mathematical canons, not by rote. She may be incapable of including among the representatives of her object of desire a nonsensical student-mathematics relation. Up to a certain point she may pretend that the student’s rote answers are produced according to mathematical principles and accept them... up to a certain point. At this point she snaps and the student awakes from his trance without having been prepared for this moment by an adequate analysis of the transfer. It is not only the student’s love message i(a) that is rejected, it is the student’s unconscious commitments I(A) that supported i(a) that are impaired: his super ego crashes. Hence the emergence of fear and anxiety. If this does not happen as intensely with other subject matters, it is because rote learning is easier to disguise in them and, in certain cases, is compatible.

On the other hand, if the teachers desire is related to the analysis of transfer, than affect comes in: “What the psychoanalytical discourse leads to is that there is only one knowledge about affect: affect is the capture of the talking being in a discourse that determines him/her as object. (...) Of this object we know nothing except that it is the cause of desire”. [Lacan, 1991:176-7].

This implies, first, that, in dealing with affect and its connotations, language is absolutely primary, not a “means of communication”, since the constitution of the subject (students, teachers, researchers) depends on it. Second, if we want our practice to have anything to do with affect, that is, if we want the student to be captured as an object of desire in the discourse of our practices, we had better stop talking and start listening to him. Stopping talking requires the modification of our own commitments I(A) that support our cherished self image as good explainers i(a). However, we must assume the initial position that installs the pedagogic transfer, indicating to the student our position as the subject supposed-to-know (sujet supposé savoir). The student must believe that the teacher knows about his learning. It is from this initial position that we must provoke the student to work towards the production of his own knowledge. Like Blanchard-Laville [1997:168] we do not seek to eliminate suffering because it is what commands the moments of successive opening and closing of the unconscious whose reality transfer is expected to actualize, so that the subject can check his I(A) and assume it.

The capture of the nonsensical student-mathematics relation as an object of desire inverts the hypnotic situation. It is the teacher who must be hypnotized by the student’s discourse, trying to make sense of it to the satisfaction of the student. In this way the teacher keeps himself at the largest possible distance from the object a around which the student seeks to constitute his imaginary identification [Lacan, 1973:245]. Let us see how this theory works in an example from practice.

THE SETTING AND THE EXAMPLE

The basic unit of our psychoanalysis-inspired learning experience is a weekly meeting assembling teachers and graduate students of a mathematics education
program, undergraduate students of a mathematics teacher formation program, and mathematics teachers from the neighboring school district, totaling about 10 to 15 people. We call these meetings integrated sessions. They started several years ago when an undergraduate student asked for help in solving his special difficulties: he had failed all his freshmen courses. Gradually, other undergraduates joined in and took advantage of the teaching dispensed to him. Now these meetings provide course credits for undergraduates as well as research material for graduate dissertations and papers. They provided us with the experimental base to adapt Lacanian concepts to the classroom.

In these sessions, teacher and student are not labels attached to people, but positions of speech. Whoever is at the blackboard, generally an undergraduate student, is called “the student”. The student is expected to work in order to produce some sort of knowledge in the connection of the mathematical object and his ignorance. “The teachers” are those who put restricted mathematical listening into practice and provide guidance. The teacher’s position consists of sustaining the student’s speech. We follow a lemma: “It is through speaking that one learns and through listening that one teaches” [Leal et al. 1996:243]. In the sessions the didactical, pedagogical and mathematical objects are treated simultaneously.

We shall report on the integrated session of August 24, 2001. In the dialogue, “teacher”, of course, does not always refer to the same person. The student who volunteered, proposed a problem from his mathematical analysis course: every interior point of a subset of R is an accumulation point. Following the teachers’ orientations, the student reproduced the definitions and concluded that, if \( x \) belongs to \( \text{int}(X) \), then \( x \) belongs to the derivate set \( X' \). When everything seemed to be over and done with, the student expressed the following doubt:

Student: Alright, I have proved that if this \( x \) is in \( \text{int}(X) \) then it is in \( X' \), but this is not enough, since here, in \( X' \), I have ALL the accumulation points and I proved only for this particular \( x \).

Notice that he did not say that “here in \( \text{int}(X) \) are all interior points and I only proved for this \( x \)”. If it had been so, any of the teachers would have been able to help. Everybody offered suggestions but the student remained immovable:

Student: I understand that I have proved for this \( x \) which is any generic one, so that it is proved for all \( x \). But there, in \( X' \), are all the accumulation points, not only this \( x \).

What now? The discussion lasted for more than one hour. Everyone was eager to make a contribution. Voices grew louder, from student and teachers, denoting enthusiasm. But at each turn the student said:

Student: I know what you want me to say, but I am not convinced.

And he repeated his doubt. When the session time was over, one of the teachers asked permission to try her approach without interruption. In a low voice, she asked
the student to repeat the whole reasoning. He summarized it while the teacher wrote on a clean blackboard what the student said, always asking him: — “Like this?” or “Is this right?” The teacher exhibited a genuine effort to understand every word the student said and did not write anything beyond what she heard. Finally the teacher expressed her doubt.

Teacher: Where do I write this “all”? Here, at int(\(X\)) or there at \(X'\)?

Student: At \(X'\).

Teacher: This is the difficult point for us. If this “all” were here at int(\(X\)) we would know how to orient you. It is the old story about proving that every cat has a tail. It does not suffice to pick one cat. You have either to bring them all or to consider that something is nothing more than a cat, a generic cat, and so on. OK?

The student agreed and the teacher went on, always in a low voice.

Teacher: But since you put the “all” here, at \(X'\), we don’t really get you. Can you explain?

Her mood was of attentive invitation. The student thought for a while and looked embarrassed.

Student: I do not know what I want to say, confessed the student.

Teacher: Try and say it, insisted the teacher.

The essential point is that this “try and say it” was not uttered in a mood such as to mean: now do you understand? or do you see your nonsense now? The meeting ended in a happy mismatch.

When the session was over, the ability of the teacher was praised, but she replied that she was really curious to see what was the student was thinking. She had assumed that there was indeed a meaning and she wanted to find it out. Since the student could no longer remember the content of his doubt, she confessed that she felt somewhat deceived. She had been playing the hypnotized party, the nonsense produced by the student playing the role of her \(a\). The evaluation was made that in every previous attempt to orient the student, the teachers always presumed that they knew something about the student’s difficulty (assumed the position of the subject supposed to know) or intended to reach some foreseen point (rectify the transfer). These evaluations were made live, in the presence of the student.

Later on, the authors conjectured that the student was mostly demanding some sort of affect, inserting himself as the object of desire of our discourse, which he knew was possible from our previous joint experience. Being recognized in his attempt he received a form of love that was not feigned. However, he was not spared his suffering: no one told him that what he was saying was nonsense, nor was he praised for abandoning his previous view. He had to take responsibility for his I(A).

DIDACTICAL REFLECTIONS ABOUT SOME PROOFS OF THE PYTHAGOREAN PROPOSITION
Consuelo Cañasas, Encarnación Castro, Pedro Gómez.
Universidad de Granada, Spain.

This theoretical paper presents some dimensions considered in the literature to analyze proof in the teaching and learning of mathematics. In order to show how different types of proofs can be used with students of different levels, we use these dimensions to analyze four proofs of the Pythagorean proposition.

This essay consists of three main parts. First, we show some classifications of previous work on mathematical proof according to dimensions that we consider useful in the teaching and learning of the subject. The second part presents mathematical proof as an important but problematic issue in mathematics education. This is shown in different contexts. In the classroom, on the one hand, students have difficulties with the notion of proof and, on the other, teachers do not know how to teach proof. Finally, we show how some research results can help teachers in their task in order to improve students' understanding of the Pythagorean proposition.

Classifications

Many studies on mathematical proof try to delimit, characterize, specify or define the term proof. We find different words with similar meanings such as explanation, argument, justification, confirmation, verification or validation. These meanings appear with no clear delimitation and sometimes even with quite confusing connotations. But, in spite of this and the differences between their theoretical frameworks, all of the studies consulted assign to mathematical proof a logical character that implies an unequivocal mathematical statement. Some researchers use the different terms to establish a rank between them. We have found two big groups of authors that use rigor to propose their classification. Rigor is a dimension, which conforms analytic dimensions that will help us in our later reflections. We have classified the meanings given to the notion of proof in some studies (see table 1).

In both groups we find different terms for the same kind of proof. They base their work on similar criteria to do their own classifications in terms of rigor. That is why heuristic argument, informal proof and so on are in the same stage. In the same sense, if we find a proof in which drawings or concrete numbers are involved and where inductive reasoning is predominant, all the authors who consider two levels would classify the proof in the less rigorous stage. On the other hand, as much deductive reasoning involves a proof, more formal it is considered.
Other researchers who also consider the rigor dimension find more than three big groups. Miyazaki (2000) establishes six levels of proof in lower secondary school from inductive proof to an algebraic demonstration basing on three axis: contents of proof, representation of proof and students' thinking (see table 2). We shall apply them to some geometric cases.

The previous classifications lead us to think about the uses of proof in different contexts, particularly in mathematics education and in mathematics research. An explanation that can be considered as a proof in mathematics education, maybe not be a proof in mathematics research. And even if we focus on the field of mathematics education, we find differences depending on the educational level. These levels are going to determine the role of proof in teaching. The function of the proof shall be a dimension in our analysis. In this regard, we consider the classification proposed by Hanna (2000) (who presents a compilation from Bell (1976) and de Villiers (1996)).
She presents the following functions that she considers useful for thinking and doing research on the topic: *verification, explanation, systematization, discovery, communication, construction* of an empirical theory, *exploration* of the meaning of a definition or the consequences of an assumption, and *incorporation* of a well-known fact into a new framework and thus viewing it from a fresh perspective. (p.8) De Villiers (1996) criticizes the almost exclusive function of verification that traditionally has been given to proof. He argues that this is an important function but not the only one. We shall support this idea with our reflections.

We can consider other useful criteria to classify proofs. For instance, Ibañes & Ortega (1996) concentrate on the reasoning done and the technique used. They distinguish between methods, styles and modes (see table 3).

### Teaching and learning of proof

We would like to start from two assumptions related to the teaching-learning procedure:

- We argue that proof is an important and useful process in mathematics teaching at all levels.
- However, teachers do not need to present all the proofs of a concrete theorem to their students.

We find studies on proof according to educational level: involving students, from primary school to university levels; and involving teachers, ranging from prospective mathematics teachers to practicing teachers. Inductive reasoning is the most common type of proof used with the young students. Based on this idea and
trying to develop deductive reasoning in some elementary school pupils, Lobo-Mesquita (1996) highlights the role of visualization in the learning of geometry. Some studies show how proof is an obstacle in the educational process. Ibáñes (2001) shows that pupils in the third course of high school have problems with proof outlines, recognition of procedures, and the use of some expressions. Almeida (1996) suggests that, at the university level, it may be desirable to use semi-formal or preformal proofs as a bridge to formal proofs. Rico, González and Segovia (1999) study different heuristics used by pre-service mathematics teachers trying to prove a geometric proposition.

Proofs and the implied process is also a problem for teachers, who do not have a method to teach proof and sometimes don’t know about the convenience of teaching a concrete proof (Cañadas, Nieto & Pizarro, 2001). Garnica (1996) analyzes answers given by mathematics teachers in terms of the modes of reading: technical and critical. Van Ash (1993; mentioned by Ibáñes, 2001, p. 18) gives some ideas to help teachers to decide when to do a proof in class: to convince when we are not sure about a statement, to memorize a theorem, to learn useful algorithms, to end a search process, to expose a work method and to show meanings of definitions.

So proof seems to be an obstacle in the teaching-learning procedure. We are going to use the results of the mentioned studies to suggest ways to help both students and teachers in their daily task. In what follows, we try to connect the ideas related to proof mentioned before with a concrete case: the proof of the Pythagorean proposition.

The case of the Pythagorean proposition

The Pythagorean proposition establishes a relationship in a right-angle triangle: *the square of the hypotenuse is the sum of the squares of the legs*. It has hundreds of different proofs. Scott (1972) classifies many of them in four groups: 1. those based upon linear relations; 2. those based upon comparison of areas; 3. those based upon vector operation; and 4. those based upon mass and velocity. We will focus on the geometrical ones due to their didactical interest and their accessibility to students of different levels. The geometrical formulation of the proposition is as follows: *the square described upon the hypotenuse of a right-angled triangle is equal to the sum of the squares described upon the other two sides*. The common objective of all the proofs is to verify this proposition. We shall present four geometrical proofs of the Pythagorean proposition and shall comment on the dimensions we have mentioned: rigor, contents, representation, students’ thinking, method, style and mode.

(1)

(2)
These proofs make evident the importance of visualization in geometry. Furthermore, they allow to communicate mathematical knowledge, to construct theory basing on empirical actions, to explore the meaning of the proposition and to incorporate a new knowledge into a framework.

According to Ibañes & Ortega's classification, the proofs taken are direct proofs by cases, having a geometric style (although as we will see some of them involved other styles).

Focussing on rigor dimension (see table 1), most authors who consider two levels would situate these proofs as informal ones because they have been done with drawings and some of them do not need analytical reasoning. On the other hand, authors who consider three levels would situate proofs (2), (3) and (4) in the second rigor level because they are not the formal proofs we are used to in pure mathematics, but they are not just examples neither; and proof (1) would be classified in the lowest rigor level because is a concrete case that can be used as an example or an explanation.

We shall differentiate each proof from the others, pointing out differences and common points. Let us begin with proofs (1), (2) and (3), which follow the same strategy: to build the square upon the hypotenuse with the pieces given in the other squares.

In proofs (1) and (2) students just need to know the surface area concept. We have to avoid presenting the situation as a game and try to give meaning to the change of pieces. So we think that proofs (1) and (2) would be appropriate for primary school pupils, whose inductive reasoning is predominant, and for whom visualization and manipulation processes are very important. Let us remember that at this age, students' reasoning is mainly based in concrete and real objects. With the Ibañes & Ortega's classification, both proofs are purely geometric. We notice that there are differences between them. In proof (1), the pieces have the same area and the same shape, and they are situated in the same position regarding the big square. The proof follows easily from the comparison of the number of unit squares in the big squares. It consists of inductive reasoning and it is represented with numerals. So it is
a "proof C" according to Miyazaki (2000) (see table 2). In proof (2), the pieces have different shapes with different positions as a consequence of having drawn parallel and perpendicular lines. This implies that students have to understand the meaning of the Pythagorean proposition instead of just solving a puzzle (Cañadas, 2001). According to contents and representation is a "proof B", according to Miyazaki (2000) with concrete operations because it consists of consecutive actions on concrete objects and it includes deductive reasoning supporting these actions. So proof (1) could be used as an introduction to the proposition, inducing the discovery of the theorem. Proof (2) could be useful as an exercise of reasoning in order for pupils to show their understanding.

Proof (3) does not correspond to the geometrical formulation because we cannot visualize the right-angle triangle where we must build the three triangles to whose areas the proposition relates. In a Piagetian sense, this proof style follows “action strategies”. This proof could be clearly situated in the second of the three rigor levels mentioned before. To finish the explanation process, we would have to draw and write as follows:

\[
\begin{array}{c}
\text{And comparing the areas of the two figures showed, we have that } h^2 = a^2 + b^2.
\end{array}
\]

It has an algebraic reasoning added to the general geometric position aforementioned. This is the characteristic that could differentiate “proof B with concrete operations” from “proof B with formal operations” (Miyazaki, 2000) in geometric proofs. So we think proof (3) is of the second kind. It is mainly the implicated reasoning with algebraic terms what allow to conclude that we should work with this proof at secondary level.

Proof (4) implies the highest level. The following reasoning is necessary to finish the proof:

Produce CA to S, draw SO parallel to FB, take HT = HB, draw TR parallel to HA.
Produce GA to M, making AM = GA. Produce DB to L, draw KP and CN parallel resp. to BH and AH. Draw QD.
Rectangle RH = rectangle UB.
Then: **Square AK** = triang. CKN (= triang. ASG) + triang. KBP (=triangle SAQ) + triangle BAL (=triangle DQO) + triang. ACM (=triang. QDE) + sq. LN (=sq. ST) = rectang. GQ + rectang. OE + sq. ST = rectang. GQ + sq. EB + rectang. QB + sq. ST = rectang. GQ + sq. EB + rectang. RH + sq. ST = **square BE + square GH**.
According to Ibañes & Ortega's classification, it is a pure geometric proof. Lines drawing and reasoning bear concepts like parallelism, perpendicularity, similarity and congruence. We add systematization of some results into a deductive system to the mentioned functions for the other proofs. According to Miyazaki (2000), proof (4) could be classified as "proof A" because it represents the most advanced level in a geometric proof. It involves deductive reasoning with a functional language of demonstration. So the appropriate level for this proof would be the end of secondary school or even the university level. Students at these levels are better used to abstract concepts and their deductive reasoning is more developed.

Discussion

We have shown how we can use different proofs of the Pythagorean proposition at different educational levels. For this task, we have used different dimensions drawn from the literature. These dimensions are: rigor, contents, representation, students' thinking, method, style and mode. This kind of analysis provides us with knowledge about which proof is more suitable for each educational level, keeping in mind students' characteristics in order to obtain better results in teaching and learning. The knowledge of the different proofs from this point of view help teachers to decide why (function), when (students' thinking, content and style) and how (representation) to do a proof in class. In this sense, teachers could be better informed about the convenience of teaching a concrete proof. We feel that this analytical process (that we have put into practice for the Pythagorean theorem) can be used for other propositions for which presenting a proof might be relevant.

Abstract: These analyses form part of a three-year project looking at mathematical thinking as a socially organised activity. We revisit data from a University Calculus class using tools from two theoretical perspectives, used increasingly in mathematics education research: (1) semiotic mediation and (2) discursive practices. We highlight how different theory-driven analyses taking a sociocultural view of thinking and learning can offer insights into the conceptualisation of the 'transfer' of learning.

Recent research on transfer

Mathematics educators have always maintained that the mathematical knowledge that students acquire in school should be able to be adapted and applied in workplace and everyday situations. It has also been recognised by the community that, far too often, it does not happen. Theoretical explanations for this failure depend on the author's views on the nature of the boundaries between the practices involved (see Muller & Taylor, 1995; Evans, 1999). Three main positions can be identified in the literature:

1. The boundary between the everyday and school mathematics as permeable and theoretically unproblematic, if practically a considerable challenge for pedagogy. Inadequate instruction or inadequate learning can result in instrumental understanding (Skemp, 1976). Here, some authors emphasise the value to students' learning of the use of authentic contexts (Sullivan, Warren & White, 1999).

2. Transfer is not possible, because of the impermeable boundaries between contexts and practices. These include the strongly situated view (often drawing on Lave (1988)) that meanings are produced and remain within specific social and cultural practices.

3. Transfer is problematical, since boundaries exist, and are not automatically crossed, but still it is possible to enable something like 'transfer'. This includes the use of concepts such as 'consequential transitions' (Beach, 1999), 'translation' (Evans, 1999, 2000), and 'recontextualisation' (Cooper & Dunne, 1999). Amongst those who consider the boundary as problematic, Boaler (1998) argues that developing identities in communities of practice in which "students are enculturated and apprenticed into a system of knowing, thinking and doing" (Boaler, 1998, p. 118) might be helpful in enabling students to transfer their knowledge (see also Goodchild, 1999).

* The project "Teaching and Learning - Mathematical Thinking" was supported by Fundação Ciência Tecnologia, Grant no. PRAXIS/P/CED/13015/98. It included, in addition to the authors, João Filipe Matos, Madalena Santos, Anna Tsatsaroni.
In our larger project, we have focused on three key issues—emotion (Matos & Evans, 2001), assessment (Morgan & Lerman, 2000) and transfer—as aspects of mathematical thinking, and we have deployed a range of theoretical perspectives to look at mathematical thinking as socially organised. We have taken data produced for other purposes and developed tools from those perspectives in order to read the data for when and how transfer occurs as interpreted through those theoretical lenses.

The context of the production of the data

In this case, the data were collected during the second semester of 1996 in a First Calculus Course for university students taking a Business degree. The work reported was developed at the University of Algarve, as part of a research project aimed at studying the process of meaning making in mathematics learning and, particularly, the influence of real world situations in the meanings produced (Carreira, 1998).

From a methodological point of view, the research design assumed the double character of teaching experiment and curriculum development program. The teacher had very firm intentions of innovating and questioning the traditional format that such courses tend to assume. One premise that became central to the structure of the course was privileging the activity of mathematisation over the mastering of mathematical techniques and proficiency on specific topics (Moreira & Carreira, 1998).

On such a basis, the guiding lines of the curriculum emphasised: (1) the development of connections between mathematics and reality; (2) students' co-operative work on applied problem situations; (3) students' oral and written presentations of the work developed; (4) whole-class discussions on critical mathematical models and applications.

At the beginning of the session, students were given some information on a particular model describing the 'utility' of wine and beer. Their subsequent activity evolved around open questions that guided their exploration and investigation of the model.

*We say that two commodities are competitive when the consumer tries not to exclude the consumption of neither of them. Assuming that the consumer's satisfaction can be measured in some way, economists have created the notion of utility to describe the degree of the consumer's satisfaction. In particular, this concept may be used to describe the utility of both wine and beer to a certain consumer.*

*Consider the utility function \( U(x,y) = (x+1)(y+2) \) as representing the utility that a certain consumer gets from the consumption of \( x \) units of wine and \( y \) units of beer.*

Previously, the teacher had explained to the class what level curves are, in the context of multivariable functions. Afterwards students were asked to interpret the designation of indifference curves used in Economics for contexts like the given utility model.

33. Cristina: I have heard of level curves in cartography and I worked a lot with that.

34. Isabel: But that kind of curve is only used in economics.

35. Cristina: Excuse me! In cartography there are also level curves! If you want to represent the terrain elevation on a system of axes, you get something like this... You can mark the heights above the sea... for instance 200 meters, 300 meters.
Figure 1. Cristina's representation of level curves

36. Isabel: No. In economics it's different, it's like this...

Figure 2. Isabel's representation of level curves

37. Cristina: In geography, level curves are usually defined with the help of a land survey, that is, a collection of data on the elevation of the land.

38. Eduardo: Those curves indicate different altitudes on a map.

39. Cristina: Well, in economics it must be something of the kind, I mean, in the same line of reasoning.

40. Isabel: No. What I think is that it must be more or less this... To have the same degree of satisfaction, we have to... follow one of these curves.

41. Cristina: What you're saying is that to get the same satisfaction, if the amount of beer increases, the amount of wine must decrease.

42. Isabel: Each of these curves is one utility...

43. Cristina: Yes, it shows that utility is always the same. And to have the utility unchanged, the variables have to change. If one increases, the other decreases.

44. Miguel: Each of the curves gives a different relationship between the variables x and y.

45. Cristina: Of course. It's like in geography. For instance, this utility is different from that one.

46. Miguel: But along each curve the utility doesn't change.

47. Cristina: It only changes from curve to curve.

48. Isabel: Each curve is a different level of utility.

49. Eduardo: But why are they called indifference curves?

50. Cristina: Because regardless of the values of the variables, the utility is indifferent.

51. Eduardo: I see. They're indifference curves because each curve has always the same level of utility. A curve is different only in relation to the other curves.

52. Cristina: The utility stays constant. Only the x and y change to make the utility unchanged.

53. Isabel: But what has that to do with cartography?

54. Cristina: It must have something. Look, I have this mountain. This inside area tells me the maximum height...

55. Eduardo: The point is that you have several levels. Except that here you have utility levels. Here the mountain is the utility. The consumers' satisfaction is also rising isn't it?

A semiotic mediation analysis

From a semiotic mediation point of view, transfer is seen as a process that is not automatically an outcome of learning. On the contrary, the conditions of learning are
given a decisive role in facilitating the occurrence of transfer. Transfer would be conceived as something that can and needs to be taught if one of the aims of teaching is to help students to make connections between different semiotic and conceptual systems. To allow for transfer may be thought of as creating the opportunities for students to engage with different conceptual tools, and to work with them simultaneously as happens in the case of metaphorical thinking (Carreira 1997, 1998). In addressing the data from this perspective, we will focus on the following aspects:

(a) students’ verbal interactions as instances of the production of interpretants (that is, what makes the sign mean something to a particular individual, in a particular context) for mathematical signs

(b) students' mathematical thinking as instances of metaphorical thinking

Chains of interpretants: The interweaving between mathematics and other conceptual domains. A significant semiotic chain can be traced from the way students thought about the concept of level curve. At first, two of the students showed different conceptions of level curve, one coming from the field of cartography [33] and the other from economics [34]. They tended to see them as completely independent things: there seemed to be no clear connection between their contrasting sketches of level curves.

In spite of the apparent disconnection, students struggled to find some way of bridging the two conceptual domains. It was a shared effort which highlights an on-going social process of introducing successive interpretants based on the articulation of diverse semiotic means supported by student’s differently experienced ideas. Cristina, for instance, tried to add information on the process underlying the depiction of level curves (contour lines) in cartography [35], [37]. She talks about altitude, about a land survey and explains how the different curves indicate different heights on a map. Other students recognise that in economics, level curves outline points for which the utility remains constant. They were also able to understand these curves as formal mathematical representations of a relationship between the independent variables [44], [52]. From the sketch produced by Isabel, we see that they observe the fact that an increase of one variable corresponds to a decrease of the other.

The overall process of interpreting the concept of level curve can be mapped as a sequence of interpretants, each of them tied to a certain referential domain:

- **Representation of terrain elevation**: "cartography", "land survey", "elevation of the land", "different altitudes on a map".
- **Path defining a certain constant utility**: "economics", "the same degree of satisfaction", "follow the curve", "along each curve the utility doesn't change", "each curve is one utility".
- **Representation of the relationship between x and y, for a given value of U**: "the variables have to change", "if one increases, the other decreases", "a different relationship between the variables x and y", "only the x and y change to make the utility unchanged".

Chains of interpretants: The interweaving between mathematics and other conceptual domains. A significant semiotic chain can be traced from the way students thought about the concept of level curve. Transfer: Models as the surface of conceptual metaphors. One aspect that is quite central in the data is that students insisted on finding some way of bridging two apparently separate conceptual fields. They wondered what the possible link might be and in their search they eventually came up with a metaphor to describe it — "the mountain is the utility" [55]. This is an outline of the implicit mapping contained in the metaphor:

In a mountain there are several height levels / Consumers experience different levels of satisfaction
The mountain rises up / Utility increases with the increase of consumption
To walk on a level curve of a mountain is to keep a certain altitude, in spite of the change of position / To follow a level curve of utility is to preserve a certain satisfaction, in spite of the change of the amounts of wine and beer.

The anchoring in two situations, which is visible in this metaphor, namely by tying utility, indifference, and consumption to mountains, heights, altitudes, reveals how students brought into their reasoning their specific knowledge and familiarity with different meaningful contexts. This takes us to the claim that transfer is closely related to the production of meanings in mathematics classrooms and that such meanings are not independent from the pedagogical scenario where learning takes place.

From a semiotic mediation point of view, mathematical models of real situations are important mediating tools in uncovering powerful underlying metaphors and in fostering metaphorical thinking. If students engage in exploring the multiple facets of a model, they have the opportunity to come up with genuine mathematical thinking in light of other cultural and semiotic systems. This is a mathematical practice and it can also be a school mathematical practice if models are to be seen as revealing something rather than conveying some frozen and fixed school mathematical content.

A discursive practice analysis

From a discursive practice perspective, we conceptualise transfer as occurring when concepts originating in one discourse are linked to concepts of another discourse through a chain of signification (Evans, 2000). Such chains do not have an independent existence but arise for each participant (or, as in this case, for a group of participants) as they use their personal discursive resources, history and positionings to make meanings within a specific context (cf. Morgan, 1996). In addressing the data from this perspective, we need to identify the resources available to the participants and attempt to follow possible chains of signification through the developing conversation in the classroom. We also need to identify the available positions and their potentials for promoting or preventing shifts between discourses but, for reasons of space, we omit this part of the analysis.

The tasks for the analyst:

a) Identify the discourses available and the relevant concepts, values and relationships within these discourses.

b) In the transcript, look at the text as a whole and trace the discursive resources through the text. Identify whether there are key signifiers that play a role across discourses
and attempt to follow the chains of signification. What is the contribution of each discourse to the solution of the problem and how are links between discourses constructed by and for the group as a whole?

The discourses available: The consumption of wine and beer may involve a number of ‘everyday’ discourses with which the students are familiar. At the same time, there are a number of ‘esoteric’ or academic discourses that are relevant to the problem as posed by the teacher and that the students may be able to draw on. The students are, of course, also participating in a classroom discourse with its own norms and available positions.

Everyday discourses: Consumption of wine and beer is generally located within particular patterns of social engagement – in various settings, with family or friends, at specific times. There is often strong regulation of the amount and type of consumption in a particular setting and the sort of behaviour that may accompany it and the meanings of consumption may vary considerably from one everyday practice to another. The everyday consumption of beer and wine may also involve a type of economic discourse. Unlike the esoteric economic discourse, however, this generally involves a local calculation – “Shall I buy beer or wine today, given my circumstances (my needs, desires, finances) today or this week?”

Esoteric discourses: The problem posed for the students and their identities in the context of this university class as students of Business Studies and of mathematics highlights certain discourses of academic subjects. In particular, resources from both economics and mathematics are to be seen in the form of the problem itself. As we see in the transcript, the students may also be able to draw on resources from other areas of their academic experience. The discourse of academic economics objectifies the experience of individuals and incorporates it into a global calculation, using terms such as ‘indifference’ that have meanings different from those associated with their use in everyday discourse. In everyday discourse the individual consumer is not indifferent to the specific make-up of a basket of purchases but will have preferences based on a range of non-financial criteria. It is only when ‘the consumer’ is conceived as an abstract generalised agent that ‘indifference’ occurs. Drawing on mathematical discourse creates a further abstraction. It is no longer important that the formula or the curve on the graph represents ‘indifference’ or that the purchase of beer or wine is involved. What is important is the algebraic and graphical representation of the problem, the relationships between these and the mathematical techniques for solving the problem that are facilitated by these representations.

Classroom discourses: The discourse of this classroom lays explicit value on making connections and on co-operation and communication between students. However, these students are likely also to be familiar with more traditional pedagogic discourses in which different subjects are strongly insulated and where individual work is more highly valued than group co-operation.
Tracing discursive resources in the transcript: Several aspects of the transcript might be analysed to give insight into transfer processes from a discursive perspective, for example: the ways the different students engage (or not) with the geographical discourse; the chain of signification formed by the shifting use of the terms same, different, change, indifferent and indifference; relationships between each student's positioning within the class and their use of resources from particular discourses. In the limited space available in this paper, however, we will focus on a brief section of the transcript in which may be seen a move from use of resources from everyday discourse and economics discourse to use of resources from mathematical discourse [lines 40-44]. The key terms are abstracted in the table below, showing three chains of signification.

The move from satisfaction [40 & 41] to utility [42 & 43] is one that is provided by the wording of the given problem but this shift away from everyday to esoteric economic discourse is associated with a parallel move from the everyday discourse of beer and wine [41] to the esoteric mathematical discourse of variables [43]. A similar move is made from the everyday notion of increase and decrease [41 & 43] towards the mathematical relationship [44]. The final move is achieved by Miguel rather than by the two women who dominate the discussion, though Cristina, at least, seems to accept it as meaningful [45]. The students play different roles in the process of making links between the concepts arising in everyday, economics and mathematics discourses. Miguel, in particular, introduces the mathematical resources that are later picked up by Cristina [52]; this role seems compatible with other descriptions (Carreira, 1998) of his behaviour in the group but would need confirmation by further data. We see the group as a whole achieving success with each member contributing to the chains of signification leading from everyday concepts to mathematical ones. ‘Transfer’ arises as a product of the play among the resources each participant brings to the group interaction.

Conclusions and some methodological remarks

Both of our analyses are located in position (3) on transfer (see above): we see it as problematical, but capable of being supported by the conditions of learning and the chains of signification set up. These two approaches pay detailed attention to the (choices of) words used by the participants, emphasising the role of language both as a resource for structuring the individual's participation in the social practice(s) and methodologically as the primary means by which we as researchers construct meanings for the practices we observe. Further both analyses presuppose the social organisation of
learning and transfer, and in particular, depend on ideas of practices and discourses and the boundaries between them.

Following the semiotic mediation position, it is possible to understand the term ‘transfer’ as a metaphor (Beach, 1999) for the processes occurring, when ‘anything like transfer’ takes place. Such would be the case, too, for the production of metaphorical meaning here described as a ‘double-anchored meaning’, in the sense that it reflects a connection between two objects (mountain, utility) and two interpretants (height, level) that are primarily tied to distinctive semiotic chains. Our analyses show that these processes – all them ‘translations’ or ‘transitions’ - are much more complicated than traditional views (see (1) above) suspect. They also suggest that mathematics educators can be more hopeful than the strongly insulationist positions ((2) above) allow.

References
In this study we have analyzed the estimation strategies employed by preservice elementary teachers. It has been used an alternative model for the description of computational estimation strategies. In this model, strategies are integrated by approximation skills, mental computation algorithms, cognitive processes (reformulation, translation and compensation) and metacognitive processes (as the assessment of the outcome). The adoption of this model allows making the identification and characterization of estimation strategies and to complete a systematical classification of the strategies, attending to the estimation processes intertwined with them.

In the analysis of strategies used in computational estimation tasks, Reys, Bestgen, Rybolt, and Wyatt (1982) identified three high-level cognitive processes that are intertwined with these strategies: reformulation, translation and compensation. Reformulation is "the process of altering numerical data to produce a more mentally manageable form. This process leaves the structure of the problem intact" (p. 187); translation is "the process of changing the mathematical structure of the problem to a more mentally manageable form" (p. 188); it is considered that there is a change in the mathematical structure of the problem (and, in consequence, a translation process) when the substitution of the initial data produces a change in the computation algorithm employed to find the result; this change can be produced in the operations effectuated or in the order in which the operations are executed. Finally, compensation is manifested in the "adjustments made to reflect numerical variation that came about as a result of translation or reformulation of the problem" (p. 189).

In most of the investigations devoted to the identification and characterization of computational estimation strategies (Dowker, 1992; Hanson and Hogan, 2000; LeFevre, Greenham, and Waheed, 1993; Lemaire, Lecacheur, and Farioli, 2000; Levine, 1982; Reys and et al., 1982) it has been considered that the "specific strategies" are the approximation skills used to substitute the initial data by other more mentally manageable (rounding, truncation, substitution of a decimal number by a fraction, use of compatible numbers, etc.). However, they have also been considered "specific strategies" the computational algorithms ("proceeding algorithmically" and "incomplete partial products"), the properties of the operations (distributive strategy), the general estimation processes (intermediate compensation, final compensation), and even the performances of the students in which is manifested that they are not accomplishing an estimation (trying to make an exact
mental computation, or the cited "proceeding algorithmically") or those in which there is not a genuine mathematical procedure (attempting to guess the result or refusing to solve). This absence of criterion when making a systematical classification of the estimation strategies leads to the fact that each author uses a different classification and causes that it is difficult to make a coherent synthesis with the results of these studies on strategies.

On the contrary, this study is different from the previous one in the sense that the term "strategy" is taken here in a broader sense. We consider the approximation skills as constitutive elements of the strategies, but within them it can also be included the estimation processes, the mental computation algorithms and the assessment of the outcome. Adopting this position enables us to include within estimation strategies metacognitive processes as those described by Sowder (1994). This authoress asserts that: "individuals who are considered to be successful at computational estimation are usually characterized as flexible, self-confident, tolerant of error in estimates and [...] seek the reasonableness in results"—(p. 142). Thus, the subject that accomplishes an estimation must be capable of choosing in a flexible way a strategy adapted for the estimation problem and assessing the process (modifying it if it would be appropriate) as well as the result (examining its reasonableness). Sowder (1994) considers the flexible choice of strategies and the valuation of the process and the result as examples of "self-regulation" and "self-monitoring" that constitute metacognitive processes.

The present study analyzes the computational estimation strategies employed by preservice elementary teachers through a model described in Segovia, E. Castro, Rico and E. Castro (1989). In this model, all the estimation processes identified in previous studies are collected. In the approach adopted in this work, producing an estimation consists basically in: Substituting the original data by approximations that enable to reduce the complexity of the calculations, maintaining the necessary proximity to the exact result; applying a mental computation algorithm to these approximations; effectuating a compensation (previous or subsequent to the computation); and making a valuation of the obtained result. As has been exposed, it depends on the type of substitution that is made with the initial data, and if this implies (or not) a change in the computation algorithm, we will face a process of reformulation or one of translation.

The characteristics of this model for the estimation strategies can be summarized in figure 1, taken from Segovia et al. (p. 152). In previous pages some general strategies that stem from this model are presented in various schemas. An example of them is the following diagram:

CEP → Reform → Translation → Compensation → Computation → Outcome → Assessment

The main objective of this research is to describe the general strategies employed by preservice elementary teachers in the accomplishment of computational estimation
tasks without context, and proving if these strategies can be explained through the model described in the previous paragraph.

Figure 1. Flowchart of computational estimation strategies. The symbol D represents the points of the procedure where one must to take a decision.
METHOD

This investigation belongs to a most general work (Castro, 2001) in which it is studied the influence of number type in computational estimation tasks. With this objective it has been used the test TEA (Test of Estimation Ability) (Levine, 1982) that consists of ten multiplications and ten divisions and combines different types of numbers: whole, decimal greater than one and decimal less than one. In this section, it is given the description of the methodological part corresponding to the strategy analysis.

Subjects

The sample used is constituted, in the general framework of the investigation, by 53 preservice elementary teachers of different first course specialties of the Escuela Universitaria La Salle, assigned to the Universidad Autónoma de Madrid. From this sample 10 subjects were selected for the strategies exploration. All the students had a period of instruction on computational estimation of 10 hours, during which they received teaching of computational estimation strategies and estimation was practiced in direct and applied computations.

Instruments and application

After the administration of the Test of Levine (1982) to all the participants, the results were used to select subjects for the phase of strategy analysis that is described in this work. The analysis of the strategies used by the subjects was accomplished through an interview in which it was requested to the subjects to give an estimation for a proposed calculation and, afterwards, they had to explain the procedure used to produce their estimation. In the interview they used the items of the test of Levine (1982) in which appear decimal numbers less than one (187.5 × 0.06; 64.5 × 0.16; 424 × 0.76; 0.47 × 0.26; 66 ÷ 0.86; 943 ± 0.48; 0.76 ÷ 0.89). The subjects were selected for the interview when their estimations for the cited items were all compatible (or all incompatible) with the adequate knowledge of the relative effect of the operations. We consider that an estimation for the calculation 187.5 × 0.06 is compatible with an adequate knowledge of the relative effect of the operations, if it is within the interval (0.06, 187.5); in other words, if the student does not incur in misconceptions such as: "multiplication makes bigger" or "the division makes smaller". The interviews have been accomplished individually. They were registered using a recorder and transcribed to paper for their subsequent analysis.

RESULTS

The strategies produced by the subjects have been classified taking into account the estimation processes appearing in them. Thus, there are strategies in which only it is given a process of reformulation; in other strategies, the reformulation is produced together with a compensation process (intermediate or final); a third group of strategies is formed by those in which we can detect processes of reformulation and translation; and finally, in some strategies we found all the estimation processes
(reformulation, translation and compensation) considered by Reys et al. (1982). Now, we are going to present some examples of analysis of strategies belonging to each one of the cited groups. The analysis of each strategy begins with a fragment of the transcription of the interviews accomplished by the participants of the study, that comes accompanied with a diagram of the strategy.

**Reformulation**

In some strategies, it has been only identified a process of reformulation. We propose the following example to illustrate this situation:

Interviewer: \(0.47 \times 0.26\)

Student 41: 0.3... [Rounding the second factor]. I have multiplied 50 by 30, 0.150.

<table>
<thead>
<tr>
<th>Computational estimation problem (CEP)</th>
<th>Reformulation</th>
<th>Computation</th>
</tr>
</thead>
<tbody>
<tr>
<td>(0.47 \times 0.26)</td>
<td>((50 \times 30) \div 10000)</td>
<td>0.150</td>
</tr>
</tbody>
</table>

In this case, the reformulation has been carried out through the rounding of both numbers. Taking into account that both roundings have been accomplished upward, it would be suitable to make a final compensation "downward". However, it has been observed that some subjects refuse to accomplish any type of compensation. Maybe because of the complexity of this process, some subjects prefer not using it instead of taking the risk of committing an error, even in clear situations as the previous ones.

**Reformulation and compensation**

In the following examples, besides a process of reformulation, we can found intermediate and final compensations accomplished for trying to "repair" the error produced in the substitution of the initial data in the reformulation.

Interviewer: \(0.47 \times 0.26\)

Student 2: 0.1. Rounding this [pointing 0.47] up and this [pointing 0.26] down. \(0.5 \times 0.2\).

<table>
<thead>
<tr>
<th>CEP</th>
<th>Reformulation + intermediate compensation</th>
<th>Computation</th>
</tr>
</thead>
<tbody>
<tr>
<td>(0.47 \times 0.26)</td>
<td>(0.5 \times 0.2)</td>
<td>0.1</td>
</tr>
</tbody>
</table>

Interviewer: \(66 \div 0.86\)

Student 42: Let's see. When we are dividing, the number increases ... This number [pointing to 66], if we divide it by one it doesn't change. But it's smaller and then this number makes bigger. Then it would be... 0.86 [the student returns to check the size of the divisor for adjusting the compensation] ... it would be almost ... 75.

<table>
<thead>
<tr>
<th>CEP</th>
<th>Reformulation</th>
<th>Computation</th>
<th>Final compensation</th>
</tr>
</thead>
<tbody>
<tr>
<td>(66 \div 0.86)</td>
<td>(0.66 \div 1)</td>
<td>66</td>
<td>75</td>
</tr>
</tbody>
</table>
In the first case, 0.47 is rounded to 0.5 and, in order to compensate the increase in one of the factors, the other factor is rounded down. Thus, we have an intermediate compensation (previous to the calculation). In the second case the compensation is subsequent to the accomplishment of the calculation and is produced at the end of the process.

**Reformulation and translation**

In other strategies the processes of reformulation and translation are combined. These strategies usually have a greater conceptual wealth, manifested in the abundance of relationships that are established (especially those which emphasize connecting decimal numbers with fractions).

Interviewer: $0.47 \times 0.26$

Student 53: Multiplying by 0.25 is approximately multiplying by 1/4. Then, I divide 0.47 by 4, well... 0.12.

\[
\begin{array}{c|c|c|c|c}
CEP & \text{Reformulation} & \text{Translation} & \text{Reformulation} & \text{Computation} \\
0.47 \times 0.26 & 0.47 \times \frac{1}{4} & 0.47 + 4 & 0.48 + 4 & 0.12 \\
\end{array}
\]

This strategy begins rounding 0.26 to 0.25. Then 0.25 is substituted by 1/4. This substitution supposes a change of operation (multiplication by division) that implies a translation process. After translation, it has been realized another reformulation to simplify the calculation, substituting the dividend by a multiple of the divisor (use of compatible numbers). The first reformulation carries implicitly an "intermediate compensation" that has not been indicated in the diagram because it does not seem intentioned. Another example of translation is the following:

Interviewer: $424 \times 0.76$

Student 53: Multiplying by 0.76 is approximately multiplying by 3/4. Then, this is approximately... First I divide by 4 and get 424, then it is 106 by 3, 318.

\[
\begin{array}{c|c|c|c|c}
CEP & \text{Reformulation} & \text{Translation} & \text{Computation} \\
424 \times 0.76 & 424 \times \frac{3}{4} & (424 \div 4) \times 3 & 106 \\
\end{array}
\]

In this case, instead of multiplying by 76 (or by 7 or 8 in the case of using only one significant digit) and then dividing by 100 (or by 10), 424 is divided by four and then multiplied by three. Thus, in addition to changing the numbers in the operations, there is a change in the order of the operations and, by so much, changes the mathematical structure of the problem.

**Reformulation, translation and compensation**

Only in some few cases, the three computational estimation processes –described in Reys et al. (1982)– have been combined in the same estimation strategy. In the following examples it is produced a substitution of a decimal by a fraction that thereafter leads to a translation process (because in both cases is produced an operation change).
Interviewer: 64.6 \times 0.16
Student 42: This is 16\% of 64, which becomes the sixth part; a little more... 12 would be my estimate.

\[
\begin{array}{c|c|c|c|c|c}
\text{CEP} & \text{Reformulation} & \text{Reformulation} & \text{Translation} & \text{Computation} & \text{Compensation} \\
64.6 \times 0.16 & 16\% \text{ of } 64 & 1/6 \text{ of } 64 & 64 \div 6 & \text{¿10?} & 12 \\
\end{array}
\]

Interviewer: 943 \div 0.48
Student 42: 943 divided by... 1750. If we multiply this [pointing to 943] by 0.5 this becomes the double, it is like multiplying by two. And this [multiplied] by 2 is almost... 1900, then would be a little less 1800 or 1750.

\[
\begin{array}{c|c|c|c|c|c}
\text{CEP} & \text{Reformulation} & \text{Translation} & \text{Computation} & \text{Compensation} \\
943 \div 0.48 & 943 \div 0.5 & 950 \times 2 & 1900 & 1750 \\
\end{array}
\]

Concerning the two final compensations, there have been errors in the direction given to them.

**Metacognitive processes**

Now we present examples in which it is manifested the presence of metacognitive processes as those described by Sowder (1994).

Interviewer: 64.6 \times 0.16
Student 45: Here I make... 64.6... I put 65 and 0.16... I put 2 and then they are 170. Then I put 168... the point?... No, because it isn't the same 65 for 2 than... [The student adjusts the decimal point and gives the estimation] 0.170.

\[
\begin{array}{c|c|c|c|c|c}
\text{CEP} & \text{Reformulation} & \text{Computation} & \text{Assessment} & \text{Adjustment} \\
64.6 \times 0.16 & 65 \times 2 & 170 & \text{Decimal point?} & 0.170 \\
\end{array}
\]

There have also been estimation processes where the subject has made an assessment conducive to a change in the strategy:

Interviewer: 66 + 0.86
Student 53: 66 [divided] by 0.86 is like multiplying by 85 hundredths. Then I divide by 100 and remains... Oh! It's very difficult. I multiply this [pointing to 66] by... more or less... I'm going to approximate it to 0.9. Then 9 \times 10^{-1}, it is a division, then this would remain me approximately 660 [divided] by 9 and will be... [9 multiplied] by 7... 63, is approximately 70.

\[
\begin{array}{c|c|c|c|c|c}
\text{CEP} & \text{Translation} & \text{Assessment} & \text{It is difficult} & \\
66 \div 0.86 & 66 \times (85/100) & & \\
\end{array}
\]

In the second attempt, the subject uses the substitution through the use of exponents and this supposes a translation process. This substitution is complemented –as in the
two previous cases— with the use of compatible numbers, replacing 660 by 630 (that it is multiple of 9).

CONCLUSIONS AND IMPLICATIONS

In this work, we have used an alternative model based on a "global" conception of the estimation strategies. In this model, strategies are integrated by approximation skills, mental computation algorithms, cognitive processes (reformulation, translation and compensation) and metacognitive processes (as the assessment of the outcome). The adoption of this model has allowed us to accomplish a classification of the computational estimation strategies (attending to the cognitive processes appearing in them). We think that this approach enables us to make the description and the analysis of the strategies produced in the performance of computational estimation tasks, in a more systematical way than the approach provided by previous theoretical frameworks. The results obtained in this study have permitted to validate the flowchart of strategies analysis shown as a comprehensive theoretical model for the estimation processes accomplished by the subjects of the sample.

REFERENCES

In this study we analyze the difficulty of computational estimation tasks—with operations without context—in function of the operation type—multiplication and division—and number type—whole, decimal greater than one and decimal less than one—that appears in them. Errors made in estimating with decimal numbers less than one are also analyzed. The research counts with the participation of 53 preservice elementary teachers. An estimation test is administered to the teachers and some of them are selected to accomplish interviews. The conclusion is that estimating with decimals less than one is more difficult than with whole numbers or decimals greater than one, and most of the errors—but not all—produced in estimation processes is due to teachers' misconceptions about operations of multiplication and division.

The influence of number type in the difficulty of computational estimation tasks has been studied in several investigations. Bestgen et al. (1980) found out that items with decimal numbers were more difficult than those in which only whole numbers appeared. Rubenstein (1985) attains in her study—in which 309 eighth grade students participate—the same result that Bestgen et al. (1980). However, Goodman (1991) obtains results in his investigation—with the participation of 46 preservice elementary teachers—that contradict the results of the investigations cited before. This author does not find significant differences of difficulty between items with decimal numbers and those in which there are only whole numbers. An important difference between these studies is that, whereas all the decimals appearing in the estimation test used by Goodman (1991) are greater than one, the estimation tests employed by Bestgen et al. (1980) and Rubenstein (1985) includes decimals greater and less than one. Nevertheless, that none of the investigators cited distinguishes explicitly if the decimals appearing in the items used in their tests are greater or less than one.

The distinction between decimals greater and less than one has been crucial in other studies in mathematical education. Thus, one of the aspects that has received more attention in the investigations on multiplicative structure problem solving has been the influence of number type (whole or decimal less than one) in the choice of an adequate operation for the resolution of the problem. Greer (1992) and De Corte & Verschaffel (1996) made a review of these investigations summarized in the following paragraphs:
a) Children have difficulties in the choice of the appropriate operation for solving multiplicative verbal problems with decimal numbers less than one.

b) These difficulties are due to children’s misconceptions about the effect of multiplying or dividing by decimal numbers less than one. Many children believe that "multiplication always makes bigger", "division always makes smaller" and "we always divide a large number by a smaller number". These ideas, valid for certain types of numbers (whole numbers), do not work when they are extrapolated to decimal numbers less than one.

c) Misconceptions in multiplication and division are originated by the predominance in the teaching of operations of the repeated addition model for multiplication and the partitive model of division. In the interpretation of multiplication as repeated addition, the multiplier should be a whole number and the product greater than the multiplicand. On the other hand, if division is interpreted as “sharing out”, the divisor should be a whole number and the divisor and the quotient less than the dividend.

These results have also been found in studies with preservice elementary teachers. Tirosh and Graeber (1989) detected that 10% of the teachers held explicitly that "multiplication makes bigger", whereas almost the majority (more than 50%) of the teachers held explicitly that in a division problem, the result should be less than the dividend. In the case of multiplication, the belief "multiplication makes bigger" is implicit for a majority. It appears in the solutions that students give to the problems but it is not maintained explicitly. Students show a very strong dependency on the operations with whole numbers and their procedural knowledge of the operations. They have also a strong dependency on the repeated addition model for multiplication and the partitive model of division.

On the other hand, Levine (1980) and Morgan (1990) have also found difficulties in estimation tasks with decimal numbers less than one. Both authors attribute these difficulties to the presence of misconceptions about the operations.

According to all these antecedents, the hypothesis outlined in this work is that the real difference of difficulty in computational estimation tasks appears when items with whole numbers or decimals greater than one are compared with those with decimal numbers less than one. Thus, the main objective of this study is to analyze the relative difficulty of computational estimation tasks—with operations without context—depending on the operation type—multiplication and division—and the number type—whole, decimals greater than one, and decimals less than one—that appears in them. Another objective is to analyze teachers’ errors in estimating the results of operations with decimal numbers less than one. In this paper the term “error” is considered in a broad sense as a lacking and incomplete knowledge. For example, misconceptions about the operations—as the belief "multiplication always makes bigger"—reflect a knowledge that has a certain validity domain—operations with whole numbers—but constitute an error when it is attempted its extrapolation to
operations with decimals less than one. The analysis of errors performed in this study has the purpose of determining if all the errors produced in the estimation processes— in tasks with decimals less than one— have their origin in misconceptions about the operations or if, on the contrary, there are other types of characteristic errors in these estimation tasks.

**METHOD**

Two independent variables have been considered: "operation type"—multiplication and division—and "number type"—whole, decimal greater than one, and decimal less than one. The dependent variable is the score obtained by a subject when performing an estimate. When an estimation is performed, we can calculate its percentage of error. If it is greater than 30%, zero points are scored; if it is greater than 20% but no more than 30%, one point is scored; if it is greater than 10% but no more than 20%, two points are scored; and if the percent of error is no more than 10%, three points are scored. Furthermore, some variables have been controlled: considering the format of the questions, the test is constituted by estimation items with direct—not applied—computations; all the computations have been presented in horizontal format; and finally, only opened response items have been used.

**Subjects**

The research has counted with the participation of 53 preservice elementary teachers of different first course specialties of the Escuela Universitaria La Salle, assigned to the Universidad Autónoma de Madrid. The ages of the participants were from 18 to 24 years. Ten subjects were selected from this sample to accomplish—through an interview—the analysis of errors in computational estimation. All the students participated in a period of instruction about computational estimation of ten hours, during which they received explicit teaching about estimation strategies. Estimation was also practiced in both direct and applied computations. At the end of the period of instruction, the participants realized the estimation test.

**Instruments and application**

The Test of Estimation Ability (Levine, 1980) was administered to the students. This test consists on estimating mentally the results of ten multiplications and ten divisions. Items are of three types: (a) operations with whole numbers, (b) operations with a decimal number greater than one, and (c) operations with a decimal number less than one. Numbers in the test have zero, one, or two decimal digits. Furthermore, no number has more than five digits in total.

The test was administered in the computer science classroom during a period of class using PCs. The participants came into the classroom without carrying anything with them. These limitations were established to avoid the students’ usage of any computational procedure that was not mental. There was no direct limitation of the response time for each item or for the whole the test. However, the students received indications to realize their estimates briefly.
The results of the estimation test have also been used to select subjects for the phase of the study of error analysis, realized through an interview. The subjects were requested for giving an estimate for a proposed calculation and then, they explained the procedure used to produce their estimate. In the interview we used the items from the test of Levine (1980) with decimal numbers less than one (187.5 × 0.06; 64.5 × 0.16; 424 × 0.76; 0.47 × 0.26; 66 ÷ 0.86; 943 ÷ 0.48; 0.76 ÷ 0.89). The subjects selected for the interview were those whose estimates—for the cited items—were all compatible (or all incompatible) with an adequate knowledge of the relative effect of operations. For example, an estimation for 187.5 × 0.06 fulfils this condition if it is within the interval (0.06, 187.5). In other words, if the student does not incur in misconceptions as: "multiplication always makes bigger" or "division always makes smaller". The interviews have been done individually. They were registered using a recorder and transcribed for their subsequent analysis.

RESULTS

To study the possible effect of the independent variables in the dependent variable, a factorial design of two factors, with repeated measures in both factors has been accomplished. The factor “operation type” has two levels: multiplication and division; and the “number type” has three levels: whole numbers, decimals greater than one, and decimals less than one. The statistical analysis has been performed with the Statistical Package for the Social Sciences (SPSS) for Windows (version 9.0.1). Table 1 gives the mean scores and the standard deviations for the estimation test.

Results of the analysis of variance

There are statistically significant effects for the factor "type of number" (F = 20.056, p = 0.000) and for the interaction between the factors "type of operation" and "type of number" (F = 8.895, p = 0.000). On the contrary, there is no statistically significant effect for the factor "type of operation".

646
In order to know between which levels of the factor "type of number" the significant differences have been produced, we have used the test T with the Dunn–Bonferroni correction. We have been found statistically significant differences between level 3 –decimals less than one– and level 1 –whole numbers– (T = 7.090, p = 0.000) and between level 3 and level 2 –decimals greater than one– (T = 3.991, p = 0.001). However, there is no significant difference between the mean scores corresponding to levels 1 and 2 of the factor.

In spite of the fact that the mean scores for multiplication and division items are very similar, the study of the interaction allows to clarify that this equality is not maintained through all levels of the factor "number type". Table 1 gives the mean scores corresponding to all the combinations of levels of the factors in the design. We can observe in this table that the mean score for multiplication is much greater than for division when decimal numbers greater than one are operated, and smaller when decimals less than one appear. As we have seen before, the interaction between operation type and number type has a significant effect in the scores. To determine between which combinations of levels these significant differences have been produced, we have accomplished the within-subjects contrast test –simple contrasts option –. There is a significant interaction for levels 1 and 2 of the factor 1 and levels 1 and 2 of the factor 2 (F = 9.463, p = 0.003). The other significant interaction is given between levels 1 and 2 of the factor 1 and levels 2 and 3 of the factor 2 (F = 16.739, p = 0.000).

Results of the analysis of errors

To accomplish the error analysis we have used the diagrams for the description of estimation strategies proposed by Segovia, E. Castro, Rico and E. Castro (1989). The errors have been classified attending to the estimation processes –identified by Reys, Bestgen, Rybolt and Wyatt (1982)– in which they have been produced. Thus, errors may be found in reformulation, translation, and compensation processes.

Within some strategies, errors have been detected in the process of reformulation. We can find among them the following example:

Interviewer: 187.5 × 0.06

Subject: 1.2. I have rounded the first to 200, multiplied by 6 and then I have put the three decimals.

<table>
<thead>
<tr>
<th>Computational estimation problem (CEP)</th>
<th>→ Reformulation</th>
<th>→ Computation</th>
</tr>
</thead>
<tbody>
<tr>
<td>187.5 × 0.06</td>
<td>→ (200 × 6) ÷ 1000</td>
<td>→ 1.2</td>
</tr>
</tbody>
</table>

In this case the subject has reformulated the initial problem rounding one of the numbers. In this reformulation, an error has been produced. In fact, the subject operates decimal numbers as if they were whole numbers, ignoring the decimal points. Afterwards, he puts as many decimals on the result as there are in total in the multiplied numbers. However, the rounding of 187.5 (substituting this number in the calculation by 200) supposes the loss of a decimal figure, so that 187.5 × 0.06 should
have been substituted in the reformulation by \((200 \times 6) \div 100 = 12\). These errors in reformulation are caused by an inadequate combination of the rules of operating decimal numbers with the rules of rounding.

In other strategies, errors appear as a consequence of the application of students misconceptions about the operations with decimals and, particularly, due to an inadequate knowledge of the effect of multiplying or dividing a number by a decimal less than one. An example of this situation is the following fragment of the interview:

**Interviewer:** 943 ÷ 0.48

**Subject:** And that [pointing to 943] [divided] by half. Or [multiplied] by a half. 943, the half... and then... Four hundred and fifty something.

<td>943 ÷ 0.48</td>
<td>943 ÷ 1/2</td>
<td>943 × 1/2</td>
<td>943 ÷ 2</td>
<td>900 ÷ 2</td>
<td>450</td>
</tr>
</tbody>
</table>

The subject decides to substitute 0.48 by 1/2. This substitution leads to a translation process (where the division is changed by a multiplication). In this first translation process the error is found. This error is caused by the mixture of the misconception "division always makes smaller" with the substitution of 0.48 by 1/2, and the interpretation of 1/2 as "making the half".

Finally, in the following examples, errors are located in the intermediate compensation or in the final compensation.

**Interviewer:** 424 ÷ 0.76

**Subject:** 400. I have rounded down, 400, and this [pointing to 0.76] up, by 1.

<table>
<thead>
<tr>
<th>CEP</th>
<th>Reformulation + Intermediate compensation</th>
<th>Computation</th>
</tr>
</thead>
<tbody>
<tr>
<td>424 ÷ 0.76</td>
<td>400 × 1</td>
<td>400</td>
</tr>
</tbody>
</table>

Here, the subject has employed the substitution by "powers of ten" changing 0.76 by 1 and, after, but previous to the calculation, he has been attempted to compensate that first substitution changing 424 by 400. This intermediate compensation has had an adequate direction but not enough "intensity". The same circumstance has occurred in the following example. The only difference is that the compensation in this case is accomplished at the end of the process (after the calculation).

**Interviewer:** 424 ÷ 0.76

**Student:** That [Pointing to 0.76]... [Rounded] to 1. Well, it would be a little less than 424, 420.

<table>
<thead>
<tr>
<th>CEP</th>
<th>Reformulation</th>
<th>Computation</th>
<th>Final compensation</th>
</tr>
</thead>
<tbody>
<tr>
<td>424 ÷ 0.76</td>
<td>424 × 1</td>
<td>424</td>
<td>420</td>
</tr>
</tbody>
</table>

As in the previous case, the size of the compensation is too small. It has been observed that sometimes, if the student does not know a better criterion—as would be in this case the use of the distributive property—, an intuitive compensation is
effectuated. Many times, this intuitive compensation consists simply in a rounding in the adequate direction (as 424 rounded to 420).

In the following estimation, a final compensation has been accomplished with an error in its direction. It has been used as an approximation skill the substitution by a power of 10.

Interviewer: 66 ÷ 0.86
Subject: I would divide this [pointing to 66] by one. Well, but then I would subtract from it a little. It would be 60.

<table>
<thead>

CONCLUSIONS

As we have seen in the review of literature about the problem, there was a disagreement between the results obtained in the studies of Bestgen et al. (1980) and Rubenstein (1985), and those of Goodman (1991) with respect to the relative difficulty of the computational estimation tasks depending on the number type. In the first two studies the authors arrived to the conclusion that it was more difficult estimating with decimals than with whole numbers. However, in the study of Goodman (1991), there were no significant differences of difficulty between these two types of items. This contradiction guided the elaboration of the main hypothesis of this research, after proving that in the study of Goodman (1991) –to the opposite that in the others– items with decimal numbers less than one did not appear in the estimation test. In this paper, items with decimal numbers less than one have been more difficult than those with whole numbers or decimals greater than one. This circumstance can explain the apparent contradiction derived from the results of Bestgen et al. (1980), Rubenstein (1985), and Goodman (1991).

In this research it has been crucial to make the distinction between the decimals greater than one and less than one. This distinction had not been made in the studies cited before and allows relating the results found in this work with the ones originated from other research fields in mathematical education. For example, as we have been seen in the introduction, in the field of problem solving, it has been found that there are students with misconceptions about multiplication and division that emerge when decimals less than one appear. The difficulty of the estimation tasks as well as the difficulty in choosing the appropriate operation for solving a problem seem to be different demonstrations of these misconceptions.

Misconceptions in the operations are also responsible for some of the errors produced in the estimation processes. Within this type of errors, there are those produced by giving an improper direction to the compensations and other errors in the translation processes –as the substitution of "dividing by 2" by "making the half"–. These types of errors had been already described by Levine (1980). However, the error found in the processes of reformulation –absence of coordination of
rounding with the adjustment of the decimal point—had not been described before. It is a characteristic error in estimation processes that is not originated by misconceptions in the operations. Consequently, we think that it will be necessary to accomplish—in a future research—a more detailed analysis of students’ errors in making estimations. This type of analysis can facilitate the determination of the factors that, together with the misconceptions on the operations, influence in the greater difficulty of the computational estimation tasks with decimal numbers less than one.

DESIGNING TO EXPLOIT DYNAMIC-GEOMETRIC INTUITIONS TO MAKE SENSE OF FUNCTIONS AND GRAPHS

Shinwha Cha and Richard Noss
Institute of Education, University of London, U.K.

ABSTRACT. We report on the results of two exploratory experiments which are part of a broader study seeking to find ways for students to express their knowledge of functions and graphs within dynamic geometry-based situations that do not explicitly involve algebraic representations. In the first experiment, the students displayed an intuitive appreciation of coordinates and graphs, understood geometrically without any algebraic representation. We attempted to capitalise on this intuition in a second experiment, designed to assist them in finding ways of expressing themselves algebraically. The findings suggest that this approach might be effective in activating new ways of viewing graphic representations and, from a research point of view, for helping to appreciate the expressivity of dynamic-geometrical media.

INTRODUCTION

This paper is based on an exploratory study in the area of using dynamic geometry (DG) to look at simple locus problems and conic sections. The overall aim is to link Euclidean geometry and analytic geometry, which tend to be regarded by students as separated subjects, often poorly understood. The aim of this phase of the work is to elaborate principles for design, and to study in some detail, the epistemological and cognitive opportunities and constraints of our approach.

It seems that students rarely see the geometrical sense underlying analytic geometry because tends to be dominated by algebraic formalism: as Mason (1997) points out, algebra is usually developed in the curriculum as a form of generalised arithmetic, with a “rush to symbolism” that is divorced from geometry. We are interested in developing an approach which preserves and extends geometric intuition and it turns out that there is an historical precedent for this: ideas for linking Euclidean and analytic geometry can be found in the history of mathematics, in particular in the ways that the ancient Greeks (Menaechmus, Apollonius, Pappus) developed an understanding of conic sections as loci and their ‘equations’ without any algebraic symbolism, using geometric constructions to express ‘algebraic’ relationships (Coolidge, 1940). This was a fundamental inspiration for the later inventors of analytic geometry and algebra (Vieta, Descartes, Fermat). What is notable about the Greek work is how the lack of an algebraic notation severely hampered their ability to appreciate the generality of what they had discovered. As Boyer notes:

there appear to be no cases in ancient geometry in which a coordinate frame of reference was laid down a priori for purposes of graphical representation of an equation or relationship, whether symbolically or rhetorically expressed. Of Greek geometry we may say that equations are determined by curves, but not that curves were defined by
equations. Coordinates, variables, and equations were subsidiary notions from a specific geometrical situation (Boyer 1968, p.173).

BACKGROUND
The examples of locus first encountered by students are typically the circle, perpendicular bisector, and angle bisector. UK students are often simply taught to solve these simple locus problems in terms of a geometric construction, neglecting the ‘pointwise’ structure — i.e. they are seldom encouraged to express the properties common to points on the locus. Unsurprisingly, students often develop a superficial impression of the locus idea which can be summed up as: ‘To solve this locus problem, construct this geometrical figure’. For example, to find the locus of points equidistant from two given points, you construct the perpendicular bisector. Or, as one student put it, “You just find two points and then join them up.” This is a ‘global’ meaning for locus, seeing it as a whole shape, in contrast to a ‘local’ understanding, which means seeing the properties of individual points on the locus. The pointwise idea is fundamental in analytic geometry, beginning with an arbitrary point which satisfies given conditions and then generalising the point into an algebraic form so that the locus can be plotted in a Cartesian system.

METHODOLOGY
We carried out some experiments with several 14 year-old students, designed to compare students’ understandings of the ‘local’ and ‘global’ structure of loci under the different cognitive and cultural influences of working with conventional tools (compass and straight-edge) or DG. In Experiment 1, the students were provided with worksheets that consisted of two tasks to be attempted, first using compass/straight edge and then with Cabri. For Experiment 2, working with Cabri only, we selected the two best students from those who participated in Experiment 1. The data shown here are based on audio transcripts of the students’ conversations working with Cabri, their written responses to the worksheets, and their Cabri files.

EXPERIMENT 1: AN INTERESTING STRATEGY
For reasons of relevance and space, we report only the result of one part of this experiment. In this, we asked students to find the locus of points which have twice the distance from one given point as the distance from a second given point (a construction known as the Apollonius Circle). This is a difficult task for students who are not versed in geometry, and was certainly more complex than any simple standard loci question they had encountered.

The students needed to find points P where AP:BP is 2:1. The point P can be dragged by the mouse, and the two bars on the left represent the lengths of the segments AP and BP, dependent on the point P. Note that it was made easier for the students because they had to look for equal bars when the lengths are 2:1.
Figure 1: Students drag the point P so that the dynamic segments AP and BQ stays roughly the same length. Points can be dropped onto the screen by dragging them from the box at top right.

When the student finds a point P that has $AP = 2BP$ she marks it with a cross ($\times$), dragged from the box at top right (Arzarello et al, 1998, describe this kind of systematic dragging as “dummy locus”, in which “dragging can act as a mediator between figures and concepts”, ibid, p. 37). The points marked in Figure 1 indicate the order in which the students found them. Notice that they did not first find the ‘internal’ and ‘external’ points on AB, which one would normally start with in an analytic approach.

The locus is a (Apollonius) circle, and given that a circle is the most familiar curve, the students all identified it as such without further justification. However, a different Cabri situation provoked an interestingly different response.

Figure 2: The Apollonius Circle using Cabri’s Trace function

Given the set-up as shown in Figure 2, the students were firstly asked to make a guess about the shape of the locus as the control point F is dragged along OG (which determines the radii AP and BP). Before turning on Trace (used in preference to
Locus for reasons of simplicity), their first conjecture was that the locus might be a circle or an arc. But, suddenly, they shifted to say it is a line:

Alice: It’s like an arc isn’t it?
Jackie: It would be a circle. Can you move it [F] further?
Alice: (repeatedly) Always arc.
Jackie: They get, close it together. It’s just part of a circle. It always is a circle.
Alice: It’s a straight line. It’s a straight line isn’t it? It is between P and Q. *(keeps saying ‘straight line’).*

Jackie: Agreed.

They turned on Trace and then they saw the circle. They said, “Uh... no its a circle”. When they were asked why it’s a circle, they replied as follows:

“The distance between P and Q is a straight line. But they [the circles] move, they are together and then they are separate [and then] together again”

Clearly, they are using some mental image of a line. Of course, they have a limited range of experience to explain and make sense of geometric images. For example, in their experience having two points is often a cue to join them up, and this becomes a prototype strategy for what they are supposed to do with two points. Also, they had recently worked on a task involving a perpendicular bisector where they had joined two intersection points P and Q to make a line. However, notice that they say “they are together and then they are separate [and then] together”. They are, it seems, imagining the line joining up points P and Q as they drag the point F, and have described the locus in these terms (see Figure 3).

![Figure 3](image_url)

**Figure 3:** Visualising the locus as the end points of a changing line segment

We think that the students have hit upon a rather interesting way of making sense of the Apollonius circle. Seeing the dynamic image of the points P and Q (Figure 2) moving seems to have stimulated their geometric intuition in a novel way. Although it is not ‘pointwise’, it is a ‘local’ understanding. This kind of intuition, something like ‘slicing a disc’, can be found in the history of mathematics. It is very like the techniques of Apollonius and Dürer for constructing conic sections, which use a pre-Cartesian form of coordinates. And in the 17th century, Kepler used the idea of
‘slicing’ to find a formula for the area of an ellipse, which was a significant step in the development of the calculus (Boyer, 1968).

In the early 16th century, Dürer described a method to construct the conic sections of a right circular cone (Pedoe, 1976), based on Apollonius’ study of the conic sections (Boyer, 1968, pp.164-5). Dürer’s approach seems to be related to the strategy we observed with our students, in that it is a rather intuitive technique to draw a ‘graph’ without using algebraic representation. Figure 4 illustrates the method using Cabri. Suppose a cone is sliced by a plane. The triangle DEF shows the situation at the centre of the cone, where the plane cuts the cone at points A and A’. We make an object point M on the segment AA’. The distance A’M is the first quantity that we want to plot. For each value of A’M we need to know the width of the conic section at that point. Dürer found this by drawing the circle corresponding to the height of the cone at that point, and finds the width PQ by locating the intersection of a horizontal line through M with the circle. Finally, on the “axis” A’M we add the segment PQ perpendicular to A’M. And finally if we do Locus, we can see the locus of the conic section.

Figure 4: A Cabri version of Dürer’s construction of the conic sections.

It seemed to us that ‘Apollonian coordinates’ in Cabri might provide some similar cue for our students, allowing us to build on their existing intuitions to extend, geometrically, their knowledge of functional relationships without necessary recourse to algebra.
EXPERIMENT 2: GRAPHING WITH ‘GEOMETRICAL COORDINATES’ WITHOUT ALGEBRA

We designed an exploratory sequence in which two students were invited to make geometric constructions and to investigate the relationships between different distances and areas in the construction, plotting the relationships on Cartesian axes using the Measurement Transfer function of Cabri. In these tasks we were interested to see how students interacted with and interpreted the Cabri situations, rather than (at this stage anyway) looking for learning outcomes.

One task was the familiar optimisation problem of finding the maximum area for a rectangle whose perimeter is fixed. As the construction was explained to the students, we discussed for some time what would be the shape of the graph of the area as the side lengths are varied by dragging a vertex. They easily sketched a parabola-like shape.

They constructed, by following instructions from a worksheet, the rectangle (Figure 5) and informally (without measurement) observed how dragging the point C affects the area and perimeter of the rectangle, and in particular, where the greatest area occurs. Afterwards we turned on the measurements for them to view, and by looking at the change of the numerical value for the area they noticed it had a maximum when the rectangle become a square. These students had had some experience with this kind of problem, and when we asked them about the relationships involved, they found it natural to talk about a formula although they could not precisely express it in symbols. They knew that a parabola-like shape was reasonable for the function, and they noticed that the area of the rectangle can have the same value at two different values of the side length.

After explaining to them how to plot a graph (using Show Axes and Measurement Transfer) they were able to construct a ‘plot’, based on Locus, for the graph of the rectangle area against side length (Figure 6).
The final step was to introduce algebra into the problem: we asked them If $CD$ has length $x$ and the perimeter has length $P$ what is the area?

In response to this question, they articulately expressed the structure of the algebraic expression of the area of the rectangle. We pushed them towards using the quantities $x$ and $P$, and after some prompting to think about a specific numerical example, they eventually said:

A: ... oh, I know it’s $P$ take away $2x$ and then divide by 2, then that number times $x$.

However, they had great difficulties in writing the algebra, and were unable successfully to construct the expression for the area. The problem, we think, came from the students’ limited ability to think with ‘abstract’ symbols, compared with thinking about symbols as labels on a concrete geometrical figure. They held onto the idea that a quadratic function is associated with a parabolic shape, but arrived mistakenly at the expression for area $S = P - x^2$ (although wrong, we carried on the discussion with it in order to probe the students’ thinking). Surprisingly, Jackie thought this equation did not represent the graph that they plotted in Cabri, because she sketched $S$ as a $U$-shape, reasoning that by substituting numbers at a few positive values ($x = 1, 2, \ldots$) the value of $S$ is decreasing and must therefore reach a minimum at a later point — a reflection of how she was taught to plot graphs in the classroom by calculating a few points and then joining them up. Though there are no problems plotting a line from its equation using this approach, with higher degree equations it can be misleading. By contrast, the approach from geometry using loci gives students a sensible whole graph.

CONCLUDING REMARKS

In the experiments we have described, locus played a mediating role to afford an expression for generalising the relations between quantities. As one student put it:

Figure 6: A graph of rectangle area against side length in Cabri
"Oh, the Locus [is] where we can go! That's all the places they [the points or segments] can go"

This is a semi-abstract situation in advance of using algebraic expressions, in which quantities are ‘numericalised’ from the concrete geometric constructions. Given the tendency in the UK curriculum to substitute empirical experiment and measurement for the elaboration of structural relationships, we believe that we might have hit upon a way that students can be led naturally to algebraic representations and functional relationships. In our experiment, for example, from observing a geometric construction by dragging, the students elaborated their thinking about quadratic relationships, the symmetry of the situation and the existence of a maximum. More importantly they were able to express some of this knowledge geometrically. As another example, \( x = \text{constant} \) and \( y = \text{constant} \) graphs are among the most difficult equations to learn about algebraically (and these students struggled with pre-task questions we posed on this topic), but when the students ‘accidentally’ created an \( x = \text{constant} \) graph by plotting area against perimeter, they seemed to have no hesitation in reading off the vertical line graph in terms of its equation.

The exploratory studies we have undertaken so far have proved sufficiently interesting from cognitive and epistemological points of view, to provide grounds for cautious optimism. In future work, we intend to explore ways in which we can design didactical situations that afford students the opportunity to coordinate quantities by geometric construction in a DG environment, and further, to use this as a stepping stone towards the expression of functional relationships in algebraic terms.

TOWARDS UNDERSTANDING TEACHERS' PHILOSOPHICAL BELIEFS ABOUT MATHEMATICS

Charalambos Charalambous, George Philippou, & Leonidas Kyriakides
Department of Education, University of Cyprus

The aim of this study was to examine teachers' philosophical beliefs (PBs) about mathematics, the factors influencing the development of these beliefs, and their relation to teachers' beliefs and practices about teaching and learning mathematics. Data were collected through 229 questionnaires and five interviews. Analysis revealed a five-factor model, representing combinations of the three dimensions of a model proposed by Ernest (1991). Four homogeneous groups of teachers according to their perceived importance were identified. A relative consistency was also found between teachers' PBs and their beliefs regarding teaching and learning Mathematics. However, inconsistencies between PBs and teaching practices emerged, which could be partially attributed to the factors influencing the development of PBs. Implications for the development of teachers' training programs regarding the affective domain and suggestions for further research are drawn.

INTRODUCTION

Teachers' philosophical beliefs (PBs) are considered as the cornerstone of their teaching practices and their beliefs concerning teaching and learning. Thompson (1992) defines PBs as "teachers' conscious or subconscious beliefs, concepts, meanings, rules, mental images, and preferences concerning the discipline of mathematics" (p.132). Hersh (1998) asserts that these beliefs affect teachers' conception of how mathematics should be presented, since "the issue is not what is the best way to teach mathematics but what is mathematics really all about" (p.13). Ernest (1991) concludes that the research literature indicates that mathematics teaching depends fundamentally on the teacher's belief system and particularly on his/her conceptions of the nature and meaning of mathematics.

The review of the literature (Raymond, 1997; Thompson, 1992; Roulet, 2000) suggests that many factors influence the development of PBs, and particularly teachers' school experiences as mathematics students, that constitute their early systematic contact with mathematics. However, PBs can be considered as a dynamic body of beliefs influenced by many other factors, including, early family experiences, teachers' education programs, social and educational characteristics and school environment. The socio-cultural environment is also considered to exert influence on the development of PBs.

Teachers' beliefs may develop into a coherent philosophical system that directly influences their overall classroom behaviour. A teacher's own philosophy is thought to function as a filter influencing decisions and actions made before, during and after instruction (Philipou & Christou, 1997). Class organization, the choice of learning activities, the questions posed by teachers, and the homework that teachers assign to
students are likely to be influenced by teachers’ PBs (Stipek, Givvin, Salmon, & Mac Gyvers, 2001). Moreover, PBs were found to have impact on students’ achievement, teachers’ attitudes about the effectiveness of various teaching methods, innovations, curricula, textbooks and software material (Ernest, 1991; Philippou & Christou, 1997; Roulet, 2000). A number of researches, however, point out that there are inconsistencies between expressed PBs and actual teaching practices (Raymond, 1997; Thompson, 1992). The subconscious character of PBs and the influence of school environment on the development of these beliefs can justify these inconsistencies (Ernest, 1991). Evidently, teachers’ training programs should help prospective teachers develop and become aware of these beliefs.

Despite of the excessive research in this domain, no coherent way to measure PBs has been so far reported, due to the acknowledged complexity of PBs. The review of the relevant literature reveals a number of models that have been proposed in order to study these beliefs (e.g., Lerman’s two-dimensional model, Ernest’s three-dimensional model, Perry’s four-dimensional model, and Raymond’s five-dimensional model). We adopted Ernest’s model, since it is based on three philosophical ideas, derive from the history of mathematics evolution. First, the platonist view considers mathematics as an a priori static unified body of knowledge which exists out there and is discovered, neither invented nor created. Second, the instrumentalist view regards mathematics as a set of unrelated but utilitarian rules and facts; a viewpoint that can be linked with formalism in mathematics (Roulet, 2000). Thirdly, there is the experimental–constructivist view that attributes a prominent role in problem solving and regards mathematics as a dynamic, continually expanding field of human creation and invention. Teachers holding this point of view consider mathematics as a cultural product the results of which remain open to revision.

However, we are not aware of any systematic attempt to verify whether the three aforementioned viewpoints can satisfactorily describe teachers’ PBs. Thus, the main purpose of this study was to collect empirical data in order to examine the efficiency of Ernest’s model in describing teachers’ PBs. The study also aimed to provide evidence regarding the factors influencing the development of PBs and the consistency between these beliefs and teachers’ beliefs and practices related to teaching and learning mathematics.

**METHODS**

A three dimensional questionnaire was developed based on statements found in the literature (e.g. Ernest, 1991; Thompson, 1992). The first part included 17 five-point Likert-type items (1=Strongly disagree, 5=Strongly agree) reflecting teachers’ PBs along the three dimensions of Ernest’s model. The second part included four items regarding teachers’ beliefs about teaching and learning mathematics, namely it included questions related to the characteristics of a good teacher, a good student and indications of learning and learning goals in mathematics. For each item, teachers were provided with six statements, which corresponded to the three levels of Ernest’s
model and were instructed to put them into a hierarchical order that best described their own beliefs about mathematics. The third part of the questionnaire included open-ended questions related to teachers' practices. Of the 345 Cypriot teachers approached, 229 responded (192 primary and 37 secondary teachers), a response rate of 66.4%. The reliability of the scale, which measured teachers' PBs, was calculated using Cronbach's Alpha (α=.69).

Semi-structured interviews with four primary teachers and one secondary teacher were also conducted. The purposive sampling technique was used. More specifically, the primary teachers belonged to each of the four cluster groups that emerged from analysing teachers' responses to the questionnaire, while the secondary teacher belonged to the second cluster group. Teachers were asked to reply to open-ended questions, which could help us identify their conceptions about mathematics, such as "What is the first thought that comes to your mind when you think of mathematics?" "How would you define mathematics if you were asked to do so by one of your students". Furthermore, teachers were prompted to mention factors influencing the development of their PBs as well as domains that could be influenced by these beliefs. Specifically, teachers were urged to mention their school and university experiences in mathematics and their daily experiences with students, colleagues and headmasters. They were also requested to describe teaching goals, how they introduce a new concept, the structure and the context of their tests and their favourite activities. The constant comparative method (Denzin & Lincoln, 1998) was used to analyse the qualitative data emerged from the interviews.

FINDINGS

Since, a large number of significant correlations among teachers' responses concerning their PBs were identified, factor analysis was used to identify underlying "factors" that explain these correlations. Moreover, direct oblimin rotation was used, since the literature review underlines the correlations among clusters of beliefs and thereby relations between the expected factors. Table 1 illustrates the five-factor solution, which explains 56.3% of the variance and can be considered as the most appropriate solution in isolating teachers' PBs since all loadings are relatively large and statistically significant. The first factor F₁ can be seen as a combination of platonist-formalist views of mathematics and explains 20.6% of the variance, while the second factor F₂ explains 13.1% of the variance and reflects the instrumental-formalist views, which are close to the second dimension of Ernest's model. The third factor F₃ refers to the experimental-formalist belief of mathematics and explains 9.1% of the variance, the fourth factor F₄ combines experimental-instrumental views of mathematics and explains 7.2% of the total variance, while the fifth factor F₅ that explains 6.3% of the variance, is a rather pure platonist approach.

Since the five factors which emerged from our study represented combinations of the three dimensions proposed by Ernest, it was considered important to examine
teachers' philosophical profiles, that is groups of teachers according to their scores views in each of the above five factors.

Table 1: Factor Loadings of the Five Factors Related to Teachers' PBs as concerns Mathematics (M) Derived From a Direct Oblimin Rotation Procedure.

Though factor scores can be obtained in a number of ways, the calculation of the sum of variables which load most highly on each factor can be seen as an appropriate method of estimating factor scores (Kline, 1994) since it correlates highly, in most cases, with more elaborated procedures in which multiple regressions of all the variables on to the factors are computed. However, the relatively high values of the standard deviations, which emerged from calculating factor scores, revealed a variation among Cypriot teachers about the extent to which each factor is seen as representative of their PBs. Given that the 17 items can be classified into five broader
categories, teachers’ PBs were examined further by using Ward’s clustering method. Cluster analysis revealed four relatively homogeneous groups of teachers, representing four philosophical profiles. The four-cluster solution is justified since the Agglomeration schedule shows a fairly large increase in the value of the distance measure from a four-cluster to a three-cluster solution, and the standard deviations of the four groups are much smaller than those of the whole group of Cypriot teachers.

Table 2: Means and Standard Deviations of the Factor Scores of the Four Groups Produced by Cluster Analysis on the Five Factors of Teachers’ PBs.

Table 2 shows the means and the standard deviations of each group in each factor. It is clear that teachers of Group 1 (G₁) hold positive beliefs in four of the five factors. Taking into account the relatively high mean on F₄, and their negative attitudes on F₅, one can claim that G₁ teachers hold experimentalist-instrumentalist views. Group 2 (G₂) teachers were found to hold positive high views in all five factors and likewise the mean scores of Group 3 (G₃) in all factors were positive though less high. Thus, these two groups of teachers can be considered as holding a mixture of beliefs. Group 4 (G₄) teachers support the platonist-formalist views but disagree with the experimental-instrumentalist views. We can finally observe that the majority of teachers (166 out of 229) had complex PBs and only 63 can be positioned at the two ends of a spectrum describing PBs.

Kendall Coefficient of Concordance was calculated to examine the degree of consensus among teachers of each group in the ranking of the relative importance of the statements of the second part of the questionnaire. The analysis revealed a significant level of agreement (p<.05) amongst teachers of each group. Based on the mean ranks, a consistent pattern of responses was identified, in the sense that G₁ and G₃ teachers considered the statements reflecting experimental-constructivist ideas of teaching and learning mathematics as more important than platonist-formalist ideas. On the other hand G₂ and G₄ teachers responded on a reverse way, judging the platonist and formalist ideas as more important than the other ones. This pattern emerged for all the questions (i.e. characteristics of a good student and a good teacher of mathematics, evidence of learning and learning goals in mathematics).
The responses of these four groups on the third part of the questionnaire were found to be inconsistent to their PBs and teaching practices in three ways. First, a high percentage of teachers in all groups stated that they would like to teach every mathematical concept, to help students attend mathematics in the following years. They pointed out that parents, headteachers, inspectors and even colleagues exert pressure on teachers to cover all the prescribed content. Second, a high percentage of teachers, irrespective of the group, described a traditional approach in teaching mathematics (i.e., presenting the new concept on the blackboard and providing students with exercises for practice). However, there was a group of teachers who claimed that they use a dynamic investigative approach in teaching mathematics (experimentation, construction of meaning etc.) Though most of them belonged to G1, there were teachers of the three other groups who taught mathematics in that way. Thirdly, teachers in all groups complained that the new book series does not provide for enough practice in the four basic operations, and most of them did not seem to recognize the scope of the innovation introduced. Moreover, teachers considered that the books are appropriate for the most able students.

Analysis of the interviews

The interviews produced additional evidence on some features of teachers’ PBs, clarification of the factors influencing the development of PBs and how they can influence teaching beliefs and practices. First, it was clear that most teachers never took time to reflect on their PBs, as one of them put it “I never thought of issues related to the nature of mathematics, although I teach mathematics for many years”. Second, teachers’ answers revealed that their PBs were frequently inconsistent. For instance, while their responses concerning the nature of mathematics reflected the beliefs of the group they belonged to, their responses to questions regarding the evolution of the discipline and mathematical truth showed inconsistencies. Even though all the interviewees replied that mathematics derived of social-practical needs and it develops to serve social needs, almost all teachers, including those in G1, pointed out that mathematical ideas and procedures are regarded as valid only if there is an acceptable proof for their validity.

Teachers’ responses were also informative of the factors influencing their beliefs. All the participants mentioned the role played by their teachers and their school experiences on their mathematical beliefs. Some indicative extracts “my attitude towards mathematics can be attributed to my mathematics teacher, who tried to teach in a way that mathematics lessons were never boring” and another “my past positive school experiences formed the way I am perceiving mathematics and learning in mathematics”. On the other side, the university tutors did not seem to make any real difference, since “university lessons paid more attention to knowledge and ways of teaching mathematics than issues related to the affective domain”. The interviewees attributed a very restricted parental influence on their PBs, but they valued the interactions with colleagues. As one of them put it “I had a very good group of colleagues and we exchanged ideas about mathematics and ways of teaching specific
mathematical concepts”. These ideas and practices seemed to be more influential during their first years of employment.

The interviews seemed to reveal a marked inconsistency between teaching practices and PBs. All primary teachers, irrespective of their initial PBs, paid lip service to experimental approaches; they acknowledged the role of activities that offer students opportunities to construct knowledge. However, their favourite activities and their assessment practices echoed a rather traditional-formalist approach. Only the teacher of G₁ claimed that he developed activities that enable students to construct the meaning of mathematical ideas. On the other hand, the secondary teacher, although belonging to G₂, adopted a more formalistic approach in teaching mathematics; as she stated, “it is important to provide students with ample opportunities for practicing the algorithms presented by the teacher”. Proofs were a basic feature in her teaching, while learning theorems and definitions were considered as very important. Thus, the secondary teacher mentioned that her tests are based on exercises that require the presentation of definitions of mathematical concepts.

DISCUSSION

The results support previous studies, which refer to the complexity of teachers’ PBs and their subconscious character (Raymond, 1997; Stipek et al, 2001). The majority of the subjects in our study were classified into the two groups reflecting teachers with a mixture of PBs. The interviewees did not seem to have thought seriously about their conceptions about mathematics and its’ teaching; they were unaware of their own philosophy. The complexity of beliefs was indicated by teachers’ replies during the interviews concerning different issues related to the nature of mathematics and that is why the data failed to verify Ernest’s model of PBs. However, the model that emerged from this study can be considered as representative of teachers’ PBs, since it covers a wide spectrum of beliefs with teachers of G₁ and G₄ occupying the opposite poles of the scale. Teachers of G₁ can be considered as holding a more dynamic view of mathematics, also accepting its usefulness. On the other hand, teachers of G₄ regard mathematics as a static unified body of knowledge, consisting of facts, rules and skills that students have to acquire.

The interviews showed that that school experience plays the most prominent role in influencing the development of teachers’ PBs. Some previous teachers are seen as models and influence both beliefs and practices; this and the collegiate effect accounts for the appearance of traditional beliefs, even among younger teachers. University education did not seem to influence significantly teachers’ PBs. This finding is in alignment with Thompson (1992) claim that it is not possible to alter teachers’ PBs during two or three university courses.

The results of this study indicate that PBs might influence teachers’ beliefs about teaching and learning in mathematics as well as their teaching practices. Yet, the inconsistencies among beliefs and teaching practices found in this study show that the domain of beliefs is a complex one. Thus, it seems more appropriate to refer to
intercorellations between the two variables instead of domains influenced by beliefs, since we found evidence of the reverse direction of influence i.e., previous practices influence teachers’ PBs. Consequently, our study provides support to arguments about the dialectic relation between beliefs and teaching practices (Raymond, 1997; Thompson, 1992).

Finally, the present study underlines the importance of prompting teachers to reflect upon and examine their own beliefs systems. Since it is acknowledged that affective competencies can be learned and consequently be taught (Goldin, 1998), institutions that are responsible for teacher training, should also pay attention to the affective domain, providing teachers with opportunities to get aware of their own beliefs, the ways these beliefs are formed, and their dialectic relation to other domains e.g., their teaching practices. Further studies based on nonparticipant observations would be useful in shedding more light in the issues related to the inconsistencies witnessed between PBs and teaching practices.

THE EVOLUTION OF A STUDENT TEACHER'S PEDAGOGICAL VIEWS ABOUT TEACHING MATHEMATICS PROOF

Fou-Lai Lin
Taiwan Normal University

Ing-Er Chen
Foyin Institute of Technology

Abstract. This paper analyzed the change of a student teacher's pedagogical views about teaching mathematics proof during four years in a teacher education program. The changes identified in this study have shown a shift of her pedagogical views from convincing-formal to discursive explanatory. The changes of her related views about proof from formal to explanatory have been observed, too. Her change can be interpreted by Cooney's model of student teachers' belief change. A reason underlying her change is due to her participating in an action research in which she was becoming a reflective practitioner.

INTRODUCTION

Issues such as the role and function of proof (Villiers, 1987), the view about proof (Lerman et al., 1993), teaching approaches of proof (Hoyles & Healy, 1999; Sekiguchi, 2000) and learning theory of proof (Duval, in press) have been concerned and studied. Villiers (1987) found that about 60% of pre-service mathematics teachers realized the function of proof only in terms of verification/justification/conviction, and were not able to distinguish any other functions of proof. Studies of student teacher's views about teaching proof indicate that pre-service teachers' interpretations of mathematics proof differed from what the mathematics community would consider as mathematically acceptable (Knuth & Elliott, 1997). Their expectation of proving by their students was limited and they have a different notion of what is an acceptable mathematical proof outside of the formal setting of their university mathematics classes. Wittmann (1992; 1996) distinguished demonstration from proof, the former often having a very concrete nature, and argued for introducing demonstrative reasoning as soon as the first grade. He suggested that operative proofs should be included in primary mathematics.

Those studies could help us on understanding different pedagogical views about teaching mathematics proof. But how did the student teachers' pedagogical views about teaching proof evolve during the teacher education program is still unclear. The relationship between the view about proof and the pedagogical view about teaching proof and what is the mechanism to promote the evolution of student teachers' pedagogical views about teaching proof needed to be clarified. Those problems are what we are studied in this paper.
METHODOLOGY

This study was part of the research-based pre-service Mathematics Teacher Education Project, an inquiry into the development of pedagogical power of pre-service secondary mathematics teachers. One of two principles about mathematics teaching posed by the educator in the teacher education program is teaching for making sense of mathematics (Lin, 1999). The courses, mathematics learning, mathematics teaching and evaluation, mathematics content and method, and teaching practice, were included in this program.

The program could be divided into three stages: entering the program during the sophomore year (stage 1), practicing teaching during the junior year and senior year (stage 2) and being a beginning teacher for one year (stage 3). In the course of mathematics learning (stage 1), student teachers were required to investigate students’ understanding of some mathematics concepts and discuss strategies to help students’ learning. In the courses of mathematics teaching and evaluation, mathematics content and method, and teaching practice (stage 2), the main activities were creating student teachers’ experiences on different teaching approaches such as guided discovery, group discussion, and investigative teaching, via activities of analyzing mathematics materials and designing learning activities, and provided opportunities to reflect on expert teachers and peers teaching. The aim through the program is to develop student teachers’ pedagogical powers about teaching mathematics. At stage 3, the selected student teacher for the study taught mathematics in a secondary school and conducted an action research with us. There was a mentor in the school who should give suggestion to her but he did not do so.

The methods used in this study include questionnaire survey, classroom observations, and semi-structure interviews. A questionnaire designed to elicit student teacher’s views about proof and pedagogical views about teaching mathematics proof was administered to the student teacher Echor at stage 1, 2 and 3 (1998.03-1999.05-2000.08). The questionnaire had two tasks. The first task was modified from Lerman et al., ‘s (1993) study: “the sum of the interior angles of a triangle is equal to 180°”. The second task adopted Hanna’s (1983) three ways to prove \( 1 + 2 + 3 + \ldots + n = \frac{n(n + 1)}{2} \) and added four typical solutions collected from Taiwanese students. The student teacher, Echor, was asked to choose which way she preferred, give comment and to rate the quality of each solving method with scale of 1 to 5 for every item and choose which ways she preferred to use in her classroom.

Classroom observations and semi-structure interviews were conducted (stage 1--stage 3) and verbatim transcribed. In addition to those, we have collected her reflection notes and learning profiles during her pre-service education. All data were
confirmed by Echor later and used as a means of gleaning additional evidences of the questionnaire results.

Hanna’s (1990) and Hersh’s (1993) taxonomy of proof: formal proof and explanatory proof was adopted as an initial scheme to characterize student teachers’ views about proof. After the data of classroom teaching were analyzed, it was found that formal proof could be divided into two categories, formal view and convincing-formal view, and explanatory view could be divided into two categories, instructional explanatory and discursive explanatory, according to the teaching approach, that is teacher-centered or is student-centered respectively. Thus four pedagogical views about teaching proof are characterized as follows.

1. formal view (for convincing): teacher demonstrates well-organized deductive statement.
2. convincing-formal view (for convincing): teacher convinces students the truth by manipulation and special case, and follow with formal proof.
3. instructional explanatory view (for understanding): teacher demonstrates explanation.
4. discursive explanatory view (for understanding): the explanation is resulted from students’ discourse.

Those four views distinguish how teacher understand the functions of proof and what are the approaches of teacher’s teaching.

**ECHOR’S PEDAGOGICAL VIEWS ABOUT TEACHING PROOF**

This section reports the student teacher’s responds on which ways she would use in her teaching with reasons. The following table categorizes the ways Echor chose on each task at different stages.

![Fig.1 Categorizing the ways chosen at different stages](image)

**At stage 1**

Refer to Fig.1, Echor chose multiple methods to prove the tasks. Her comment on measuring method was that it is inaccurate. She preferred formal proofs and convinced students the statement is true by manipulation. She said:

"I must help students to make sense (1-2) first and then show them one
or two formal proofs (1-5, 1-3, 2-7). After these procedures, I will give more explanations (2-5, 2-6) to them finally."

Hence, her pedagogical view is toward to convincing- formal.

The above data was compared with her interview data at the beginning of this stage about teaching mathematics (Chin& Lin, 1998). It was found that she emphasized students' needs should be considered first, and teacher's instruction ought be accommodated to meet halfway with their students. She said that students' learning should be the priority but she described her teaching design with teacher-centered approach. She chose formal proofs to teach the two tasks, and added teacher-centered empirical verification for making sense before proving. Thus, we classified her pedagogical view about teaching proof as convincing- formal view at stage 1.

At stage 2

Echor chose Paper & Scissors way as empirical verification for making sense. Logo-style was in the unique Taiwanese textbook and was popularly used in Taiwan mathematics classrooms. Gauss’s method was the genetic method to prove task 2. The word “modified” means adding several numerical examples for testing. Her choice changed from multiple methods to a single one. All the methods of proving she chose were explanatory. Therefore, her pedagogical view was explanatory.

Data cited from our analysis of her teaching practice at stage 2 indicated that she taught proofs by lecturing without providing opportunities for her students to be engaged. She emphasized on making sense of mathematics for her students, and carried out her idea with teacher-centered way. For example, when she taught the theory of the sum of exterior angles in a triangle, she said everything by herself and just asked: “Do you understand?”. She tried to implement the ideas she have learned from the teacher education program to her classroom, but her ideas did not come true in her teaching practices. Her pedagogical view at stage 2 was classified as instructional explanatory.

At stage 3

Refer to Fig.1, Gauss’s method was used to explain Arithmetic formula. Her pedagogical view was explanatory. By contrasting her teaching at stage 3, we found that there were many activities for conjecturing, discussing, reporting, and interacting with the students. For example, when she taught polygonal pyramid, she said: "how do you feel about this polygonal pyramid?" “Please make a conjecture: how many vertex, edges, and faces does a polygonal pyramid with a regular polygon base have?” When her students make an error in constructing an identical line, she asked: “why do you know they are identical?” and “when are they identical?” Echor posed questions to guide students thinking and encouraged students to talk about their ideas. Her pedagogical view at stage 3 was classified as discursive explanatory.
THE CHANGE OF ECHOR’S PEDAGOGICAL VIEWS

From stage 1 to stage 2, the changes included that she changed her comment on induction, pointed out the function of the connection between algebra and geometry concretely, and was able to adopt strategies to fit individual difference. She agreed that using figural representation to explain identity has its positive meaning—it was intuitive and concrete. But she would choose numerical examples in her classroom teaching rather than the number-shape transformation under the consideration of its complexity and the rigorous of proof. Echor recognized mathematical induction was not easy for students to learn because of it was with little explanatory value. Mathematically, she was aware of the rigorous of mathematical induction, but she would not use it in her teaching. Her criterion was the simplest the best. The interview data about her change was as follows:

“I think my big change is that I try to do my best to help students getting a lot of knowledge before. So I use many ways to prove one thing. But I think one method is enough now. For beginning learner, one simple method is good enough.”

From stage 2 to stage 3, her change was unclear if we just analyzed data in Fig. 1. All the ways she chose were explanatory proofs like she did at stage 2. We analyzed her classroom teaching and found that she have realized the function of proof for explanation, testing, and justification (Yackel, 1998; 2001). She changed her view from instructional explanatory into discursive explanatory and adopted different criteria of rigorous for professional mathematics and classroom context respectively.

Two reasons are underlying her change. The feedback from students during her teaching practice in school for about four weeks at stage 2 have stimulated her to reflect that rigorous is not the first thing for student to learn at secondary level. She said:

“The experiences of teaching had an important influence on my view about teaching proof. When I responded on the questionnaire first time, I just considered which one had the most beautiful structure from my point of view. .... After I have taught, I knew that if I teach following the beautiful ways in the questionnaire, only very few students could understand.”

Another reason is her reflection on the processes of the action research. She said:

“After this experience, I knew that the platform should not be occupied by me. Students need platform, too. Teaching could be implemented in different way and students could learn actively. I think...I should wear their shoes to teach mathematics from their views....”
Her reflection on teaching in the action research at stage 3 helped her to be aware that student-teacher interaction may be a good approach for teaching and helped her to become a reflective practitioner.

**ECHOR’S VIEWS ABOUT PROOF AND VIEWS ABOUT TEACHING PROOF**

We analyzed Echor’s responses on the questionnaire about proof as Fig.2 shown. The change of her views about mathematics proof at different stage was from formal view, to formal view, and then to instructional explanatory view.

Fig.2-- Different ratings given for different ways of proving the tasks at different stages

Refer to Fig.2, Echor’s views about proof kept consistence from stage 1 to stage 2. She rated high scales to formal methods. Observing the flow of the scales from stage 1 to stage 3, it could be seen that the weight of explanatory proof was raised. The weight of formal proof became less and the weight of explanatory proof became higher. At the end of stage 3, Echor emphasized the function of explanation in a proof, understood the cognitive function of informal ways, considered the cognitive needs of the students and then gave up the formal way she preferred. We conjecture the change of her views about proof was resulted by the change of her pedagogical views about teaching proof.

**DISCUSSION**

Cooney et al., (1996) posit a scheme to conceptualize the professional development of pre-service secondary mathematics teacher. They regarded teacher’s development as a means for categorizing teachers, i.e. four positions: isolationist, naive idealist, naive connectionist, and reflective connectionist. Those four positions
reflect the extent to which teachers resisted or accommodated new teaching methods into their teaching schemes and exhibit a reflective orientation toward mathematics and teaching. Those four positions mentioned above could be used to describe Echor's development of pedagogical power in this study. At stage 1, she accepted the authority suggestion and wanted to use many ways to enhance students' understanding because she believed that every way of proof had its explanatory value and could contribute to students' learning. This showed she was a naive idealist. At stage 2, she just chose a simplest way for teaching proof. This decision was made pedagogically. She was aware that most of students in her class were confused with multiple methods for proving one statement. She can connect mathematics with her pedagogical mathematics. She also could identify the tensions resulted from the difference between her views of proof and about teaching proof. But she failed to see the significance of the connections and made no attempt to resolve the identified tensions. Thus she was a naive connectionist. At stage 3, she was becoming a reflective connectionist because she accommodated pedagogical ideas as her belief system that was restructured. The pedagogical view that was accommodated showed that she changed her view into explanatory, interactive, and discursive after her belief system was reconstructed. The change was not only the shift of her belief system about teaching mathematics proof but also the change of her belief about mathematics proof. The development of Echor's pedagogical power could be described as starting from a naive idealist, transferring to a naive connectionist, and finally growing to a reflective connectionist.

ACKNOWLEDGMENT

The paper is a partial result of a project funded by the National Science Council of Taiwan (NSC, 90-2521-S-003-016). We are grateful to NSC and the participating student teacher. The ideas and opinions expressed in this paper are the authors', not necessary reflect that of the NSC.

REFERENCE

Conference of the International Group for the Psychology of Mathematics Education, 1, 252-259. Tsukuba University, Japan.
Three groups of pre-service primary (elementary) teacher students responded to a questionnaire involving items on multiplication and division. Their responses to these items were analysed to compare the performance of the groups. In addition, students were asked to indicate the extent to which they felt that the items tested "numeracy" understanding. Students exhibited some difficulties on certain items, with ratio proving particularly difficult, but on average students indicated that each question was related to numeracy. The variations in perception may be due to the content of the item, the context, or the background of the students.

INTRODUCTION

In recent years many countries have made explicit a concern for "numeracy standards" in the general populace, among students, and among teachers of mathematics. The fact that "numeracy" is gaining currency as a word somehow parallel to "literacy" has, perhaps, influenced the efforts taken to recognise, test for, and remedy perceived problems. One difficulty with the term "numeracy", however, is that it has a number of definitions. In Australia, one definition states that "To be numerate is to use mathematics effectively to meet the general demands of life at home, in paid work, and for participation in community and civic life" (Australian Association of Mathematics Teachers, 1997, p.15), and numeracy is stated explicitly to include numerical, spatial, graphical, statistical, and algebraic skills. In the United Kingdom, in contrast, the definition of numeracy emphasises mainly numerical aspects of mathematics (Department for Education and Employment, 1998, p.11).

There is now a growing number of government programs being developed in Australia intended to improve the levels of students' numeracy (e.g., Department of Education, Employment and Training, 2001), and testing of numeracy performance now occurs in some states (e.g., at Grade 3, 5, and 7 levels in Victoria). Bearing in mind that it is known that teachers' beliefs affect their teaching practices (see, e.g., Thompson, 1992), there is a possibility that teachers' emphasis in mathematics may focus on things that they perceive to be more "numeracy related". It is thus of interest to determine how teachers perceive the numeracy content of different types of mathematical problems. It is presumed that they will make such judgements based on the mathematical content required and other aspects such as, perhaps, the context of the problem.

This study, therefore, reports on some pre-service teachers' assessment of the "numeracy value" of some questions involving multiplication and division, one of the key areas of subject matter knowledge for primary (elementary) teachers. There has been a long-standing concern about the levels of subject matter content
knowledge of pre-service teachers (see, e.g., Clarkson, 1998). It is well-known that multiplication and division questions cause difficulties for learners, including pre-service teachers. Rowland, Martyn, Barber and Heal (2001), for example, report on the low competence exhibited by prospective primary teachers on problems involving scale factors and percentage increase. Klemer and Peled (1998) also point out a difficulty with ratio and proportion. This report, therefore, will also examine pre-service primary teachers' actual performance on the items for which they assessed "numeracy".

At the university where this study was conducted, pre-service primary teachers gain their teaching qualifications by one of two routes: either through a four-year Bachelor of Education (BEd) degree or by first completing a degree in some non-education discipline before doing a two-year Bachelor of Teaching (BTeach) course. Students in the BEd program complete six semesters of mathematics (content, curriculum, and teaching methodology), and BTeach students complete three semesters. Suitably qualified BEd students may elect to do an advanced mathematics subject in each of their final three years, which involves additional tutorial time and content. This study investigates whether or not there are any differences between the groups of students in (a) performance on items requiring multiplication or division, and (b) the extent to which they perceive such items as concerned with "numeracy". Any differences may be due to the students' backgrounds and differences in content covered in their courses.

METHODOLOGY

Three groups of students participated in this study: two groups—from the advanced class (N=19), and from the mainstream class (N=51)—from the fourth year of the BEd course, and a group of students from the second year of the BTeach course (N=89). All students were thus in their final year of teacher training.

During a 45-minute tutorial, near the beginning of the year, students were given a "numeracy questionnaire", which comprised 23 questions, some with sub-parts, covering a range of basic mathematical topics. The content was chosen to correspond with that of the primary and early secondary years of schooling. In what follows, "item" means a question or part thereof. Students were required to answer the items and, for each item, indicate on a 5-point Likert scale the extent to which they agreed that the item was a "numeracy question". The questionnaire included the following definition of numeracy, adapted partly from the Australian Association of Mathematics Teachers (1997) definition, to use as a basis for this judgement: "Mathematical knowledge and understanding that adults need and should be able to use in everyday life without specific revision".

Six of the questions and their parts involved some aspect of multiplicative thinking, and students’ responses to these were analysed for this paper. Question 1 asked students to express $28 \div 3$ as (a) a whole number with remainder, (b) a mixed number (whole number with fraction), and (c) a decimal. Question 2 told of Amy
who worked from 8.45am to 5.30pm and asked (a) how long she worked, and (b) what she earns if she is paid $10 an hour. Question 3 asked which is the better deal: a 375g can of beans for $2 or an 810g can for $5. Question 4 asked how much flour will be left over if there are 11 cups of flour, each batch requires 3/4 of a cup, and as many batches as possible are made. Question 5 gave the exchange rate of $1 Australian for 50 kemmits and asked (a) how many kemmits will you get for $3.50, and (b) how much is 210 kemmits worth in Australian dollars. Finally, Question 6 asked how much concentrate is used to make 200ml of cordial, if cordial is made by mixing concentrate and water in the ratio 1:4. These questions corresponded to questions 1, 5, 9, 11, 14, and 23 on the questionnaire respectively.

Each item was marked right or wrong; if students answered Question 2a incorrectly but carried out a correct calculation in Question 2b based on their incorrect data, then Question 2b was marked right. The numeracy rating, ranging from strongly agree through neutral to strongly disagree, was assigned a number between 1 and 5, with 1 signifying “strongly disagree”, and 5 “strongly agree”, with “neutral” given the value 3. Students who did not respond to an item or who did not give a numeracy rating for an item were excluded from the data set when calculating overall success rates or numeracy judgements for that item. This inflates the percentage of correct answers for each item, but all items except Question 6—the last on the questionnaire—were attempted by 90% or more of the students. Question 6 was omitted by 21 of the 89 BTeach students and 3 of the 51 BEd students, perhaps because of its placement at the end.

RESULTS AND DISCUSSION

Students’ Performance on the Items

Figure 1 shows the percentage of students responding correctly to each of the items. As can be seen the most problematic item was Question 6, concerning the ratio 1:4, with only a quarter of those attempting it getting the correct answer of 40ml. Nearly half of the students (47%) responded with 50ml, presumably working with the fraction 1/4 instead of 1/5. A probability item on the questionnaire reported elsewhere (Chick & Hunt, 2001) also revealed that students often confuse ratios and fractions. An additional 20% of the students gave the answer 800mls to Question 6, perhaps because they misunderstood the difference between the cordial mixture and the concentrate.

Items 1b and 1c (requiring 28÷3 to be written as a mixed number and as a decimal respectively) also caused difficulty for students. A lack of understanding of how to treat the remainder when determining a fraction or decimal seemed to be the cause of most errors. In Question 1b, 12 of the 157 students wrote 9 1/28, confusing which of the divisor or dividend is the denominator of the fractional part. Of the 147 students who responded to Question 1c, 14 gave the answer 9.1, suggesting that the remainder of 1 obtained from the division was used as the number after the decimal point. A large number of students gave answers closer to the correct value but did
not show that the decimal expansion of 1/3 involves recurrence, with 21 giving the answer 9.3, 19 giving 9.33, and a further four giving 9.333 or 9.3333.

**Percent correct for each question**

![Bar chart showing percent correct for each question]

**Question**
1. 28 ÷ 3
2. Wage
3. Can of beans
4. Cups of flour
5. Currency
6. Cordial

Figure 1. Percentage of students in each group answering questions correctly.

In Question 2b (working out the wage based on the number of hours worked) a common difficulty came from dealing with 45 minutes as a decimal or fractional part of an hour, with at least eight students using 0.45 to give a final answer of $84.50. Just as Question 2b required students to operate on 8 hours and 45 minutes, Question 5b could also be answered by treating the number to be operated on as two parts. Many students treated the 210 kemmits as 200 and 10 more, and successfully converted the 200 kemmits to $4 Australian. They then had difficulty with the remaining 10 kemmits, leading eight students to give the answer $4.10 and another five to halve the 10 (rather than double it) to give $4.05. This part of Question 5 was not done as well as Question 5a, suggesting that students find one direction of currency conversion easier than the other, depending on the rates.

Looking at the overall results, the BEd advanced group performed significantly better than the other two groups, with a mean score of 8.2 for the ten items compared with 6.2 for the mainstream BEd class and 6.6 for the BTeach class (one way ANOVA, $p<0.0001$). When the results of the BEd advanced class are combined with the mainstream BEd class, however, there is no significant difference in overall performance compared with the BTeach group ($p=0.67$), suggesting that the path to a teaching qualification has no effect on performance. Question 1c (decimal evaluation of 28÷3) was the only question for which the differences between the groups on individual questions approached significance (a $\chi^2$ test with $df=2$ yielded $0.05<p<0.1$), with the BEd advanced class performing better than the other two groups. It would be expected that the advanced class perform better, as ability is the...
Students' Perception of "Numeracy"

The average numeracy ranking given to the questions by each group is shown in Figure 2. Overall, the average numeracy ranking for the questions ranged from 3.5 (for the BEd students on Question 1c) to 4.8 (for the advanced class on Question 2a), suggesting that the students felt that the items came in the purview of "numeracy" to some degree. It will be interesting to compare these values with those obtained for the remaining items on the questionnaire. To illustrate the potential for differences, the three probability items on the questionnaire—requiring students to place events in order of likelihood, and then assign a word and a numerical value for the likelihood of each event—were given much lower values for numeracy by the BTeach cohort. The BTeach students gave values of 3.5 to 3.7 as the numeracy ranking for the probability items (see Chick & Hunt, 2001), whereas their values on the multiplicative questions reported here ranged from 4.0 to 4.5.

Figure 2. Average numeracy rating of the questions for each group.

When the cohorts are all combined, the questions most regarded by students as being numeracy items were Questions 2a and 2b (time and wage calculation): for both items over 60% of all the students strongly agreed that the items were numeracy-related, with at most 3 students in all disagreeing or strongly disagreeing. The items with the lowest numeracy rankings were Questions 1b, 1c, and 4. Items 1b and 1c had the greatest number of students on the disagreeing side of neutral (17 and 16 respectively), but the modal (and median) responses were still agreement in both cases. Question 4 (fractional cups of flour) had nine students disagreeing and two strongly disagreeing that the item concerned numeracy; nevertheless nearly half
agreed and another 30% strongly agreed. It should be pointed out that of the 112 students who assigned numeracy rankings to all items, only 18 gave the same response for all questions. Six students did not give any numeracy evaluations at all.

Significantly different perceptions exist between the groups about the “numeracy content” on two of the questions. In Question 1c the BEd advanced class gave a higher numeracy ranking than the other groups (one-way ANOVA, $p<0.01$), with all but one student agreeing or strongly agreeing. All of the students who disagreed or strongly disagreed that the question concerned numeracy came from the other groups. It may be that the lack of context for this question (and also Question 1b) influenced the lower rankings, although the related and context-free Question 1a was more strongly regarded as numeracy. It is possible that students could more readily visualise a context for working out a remainder, than they could for determining fractions and decimals. In Question 2a (calculation of time difference) the BTeach class gave a lower numeracy ranking than the other groups (one-way ANOVA, $p<0.01$).

It was thought that there might be a relationship between students’ success rate on questions and the numeracy ranking, perhaps because students might assign higher numeracy rankings to questions they find easier. Figure 3 plots, for each question and group, the percentage of students in the group responding correctly against the average numeracy ranking given to the question by the group. There is the suggestion of a relationship; if all the data is combined the correlation coefficient is $r = 0.45$, with the BEd group marginally more scattered than the other two. This outcome may be a reflection of students’ confidence, given that other studies have established correlations between confidence and achievement (see, e.g., McLeod, 1992).

Figure 3. Relationship between numeracy rating and correctness for each of the groups.
Of interest, however, is the fact that at least one question—Question 6 about ratios of ingredients—was regarded as quite highly numeracy-related despite students’ poor performance. In contrast, students performed quite well on Question 1b—which required $28 \div 3$ to be expressed as a mixed number—but regarded it as less numeracy-related than most other questions. It may be that the issue of context comes into play here, with students able to do Question 1b but not seeing it as something they “should be able to use in everyday life”. Alternatively it may be the content, because Question 4 (which also involves fractions, with the cups of flour used to make batches of food) was given a reasonable context and yet students did not regard it highly as a numeracy question. The teaching and use of fractions has declined in Australia in recent years and this may have influenced students’ evaluations; certainly the students found Question 4 one of the more difficult items.

CONCLUSION

Not surprisingly, given the criteria for eligibility, the BEd advanced class performed better on the questions overall, although there were no significant differences on any individual items. It seems that students’ background prior to commencing a teaching degree and then the degree chosen makes little difference to the outcomes. While students do cover some mathematics content within their teacher training subjects, the content of questions used in this study was assumed to have been taught to students in their years of compulsory schooling. It would be interesting to confirm this by comparing an entering cohort with an exiting one, to determine whether or not students’ performance changes in the course of a teacher training degree. Similarly, it would also be informative to study the performance of primary and secondary school students: to see what, if any, changes take place in understanding of basic mathematics once basic education has been completed.

All items were regarded by the pre-service teachers as “numeracy related” to a greater or lesser degree. There were minor differences in perceptions of the numeracy value of items, perhaps as a consequence of the background or ability of the group of students, or the topic or context involved. It will be informative to examine other, less numerical, items from the questionnaire to compare numeracy rankings.

With teachers being called upon to explicitly teach numeracy and account for students’ numeracy performance, the question of what mathematical content is perceived by teachers as being numeracy is important. This is of particular concern where, as is happening already, education systems decree that a certain amount of teaching time be set aside for numeracy. With an overcrowded curriculum, it may be that some important aspects of mathematics and/or numeracy will be pushed aside if teachers do not perceive them as being strongly associated with numeracy. It is therefore of interest to continue investigating teachers’ perceptions in this area.

DEVELOPING STUDENT TEACHERS' PEDAGOGICAL VALUES: 
TWO INITIAL STATES AND A CO-LEARNING CYCLE

Chien Chin

Department of Mathematics, National Taiwan Normal University

To examine the possibility of introducing values to mathematics teachers, this paper describes the pedagogical values that a group of Taiwanese student teachers share, and the two competing states of, and the co-learning cycle for, values learning emerged from a study of three student teachers. Some reflections on the constraints, issues, and challenges of values education for mathematics teachers are discussed.

BACKGROUND TO THE RESEARCH

To resolve the questions of "How to help teachers become aware of and clarify their own values?" and "Through what process could teacher educators assist those teachers who are not aware of or not willing to modify their values?" concerning the issue of values education for mathematics teachers, raised in the PME 25 conference (Bishop, FitzSimon, Seah, & Clarkson, 2001; Chin & Lin, 2001a), this three-year follow-up PVIMTE (Pedagogical Values In Mathematics Teacher Education) project aimed to: examine the possibility of educating mathematics teachers about values; and develop the plausible curriculum of values education for mathematics teachers. This paper aims to describe the initial states of, and the co-learning cycle for, values learning emerged in the process of learning-to-teach from a case study of three student teachers.

Mathematics teachers may hold various beliefs that become values when enacted in their classroom teaching (Bishop et al., 2001; Chin & Lin, 2001a). For example, Rokeach (1973) suggests that values are prescriptive beliefs wherein some means or end of action is judged to be desirable or undesirable; and Allport (1961) contends that a value is a belief upon which a man acts by preference. For them, value is a preference, a desirable mode of conduct, or a desirable end-state of existence, concerning the conception of something that is importance and worthwhile of thinking and doing for the person. Thus, beliefs are more concerned with the nature of "propositions about phenomena", and values are more about the "key substances" underlying such propositions for people to think and act (Chin & Lin, 2001a). In this study, values were conceived as "teachers' pedagogical identities", referring to "their personal commitment to and action on a set of words, concerning the importance or worth of such words for thinking and practice of mathematics in the classrooms", for example the value of "individual thinking"; and beliefs as "their personal acceptance to a testable sentence, concerning the truthfulness or existence of such sentence", for instance the belief of "There is no learning if students do not think". This operational definition is in a way related to Seah and Bishop's (2000) contextualisation and de-contextualisation difference on beliefs and values, and it also echoes Aspin's (2000) distinction on the nature of beliefs and values for school contexts.
THEORETICAL CONSIDERATIONS OF THE RESEARCH

Two approaches seem to be helpful for developing teacher values (Chin, Leu, & Lin, 2001): (1) encouraging teachers to articulate the differences between one's intended and implemented, and the discrepancies between one's own and others, values; (2) developing values-related activities for teachers to model, justify, and reflect. Rokeach (1979) argues that social groups implicitly transmit, inculcate, and implement a certain cluster of specialized educational values among its members. This means that values are better developed in the process of group sharing and reflection. From a Socratic view (Ling & Stephenson, 1998), values education may involve such strategies as values clarification, critical thinking exercises and conversation in which individuals' values positions are articulated and critically examined. For Aristotle, the education of values includes debates and value examination activities; for Kant, moral reasoning within dilemma situations are useful for clarifying and developing values. Conceiving these philosophical ideas about values education, Raths' (1987) values clarification and Fraenkel's (1977) values analysis approaches were adopted in the study.

Findings in the literature of value change suggest that values may be re-considered by individuals through cognitive and affective incongruity or inconsistency of some kind. For instance, if persons are induced to behave in a manner incompatible with their values; or expected to new information, including evaluations, from significant others that is inconsistent with one or more central values; or exposed to information about inconsistencies already present among their values, then the persons' values are expected to be changed. It is the resulting conceptual and behavioural change from incompatibilities, dissonances, and incongruities that would enable individuals to re-assess, re-organize, and re-construct their values (Rokeach, 1973). There are in my views three major phases for developing pedagogical values with mathematics teachers (Bishop, 2001; Chin et al., 2001): (1) sensitising them to values issues through the analysis of and reflection on value-loaded teaching activities; (2) showing them examples of approaches to mathematics teaching at which differ markedly in the values aimed; (3) helping them clarify and modify their initial values, they might be in a better position to re-construct, re-organize, or re-assess a coherent values structure for their own classroom teaching. As a result, the provision of critical incidents and the creation of doubt; the clarification of one's own values positions; and the justification and criticism on value-related classroom teaching activities in a collaborative working-and-discussion team, were used to develop teachers' pedagogical values. The scheme addresses the socially shared and personally constructed nature of values development, in which the processes of values clarification, argumentation, identification, and action are central.

RESEARCH METHOD

The Teacher Participants

A questionnaire (Chin & Lin, 1998), concerning varying views of mathematics and mathematics teaching using 5-point Likert format, was used to select the participants
from two in and pre service teacher groups. 42 secondary school mathematics teachers, enrolled in the Master of Teaching program in the Department of Mathematics, National Taiwan Normal University, played as the sample for in-service side. A class of 24 student teachers at the third year of teacher education program, joined in the author's "methods of mathematics teaching" course, acted as the cohort for pre-service side. Two in-service and three pre-service teachers were selected according to the resulting factorial structures of the item responses. The case study and action research methods (McNiff, Lomax, & Whitehead, 1996; Yin, 1994) were used as the major approaches of enquiry to explore the values learning of the five teacher participants. The author played as a collaborator with two teachers and as a coach with three student teachers. The major purposes were to examine the possibility of introducing a set of selected pedagogical values and developing the curriculum for them to learn.

A Framework for Developing Teachers' Pedagogical Values

A two-level learning cycle, consisting of the resources of and scaffolding for learning values, was developed in terms of the first year data. The value-loaded activities, the teacher's reflective journals, and self-descriptive written interview data developed in the former study (Chin & Lin, 2000, 2001a, 2001b), including the topics of mathematical induction, permutations, trigonometric functions, and equation of circles, were used as the materials for value dialogues within a co-learning team. Before the participant teachers taught the topics, videos of that topic provided by Ming (see Chin et al., 2001) were playing back, discussed, and criticized within the team, and later the written self-descriptive interview data were provided for discussion and reflection. In addition, a topic-related values questionnaire was administrated for examining their value preferences. Therefore, we have four whole topics of audio-video records and written data prepared, accompanied with the topic-specific value preferences surveys for group discussion and reflection. The working-and-discussion team, including one teacher educator (the author), one mentor (Ming), two experienced (T1, T2), three student teachers (ST1, ST2, ST3), and one independent observer (O), was formed for the learning of values. Those ideas related to Schön's (1987) intelligent action, reflection-in-action and knowing-in-action, Vygotsky's (1978) social formation of individual concepts, and the three pillars - construction, narration, and reflection - suggested in Dutch Standards of mathematics teacher education (Goffree & Dolk, 1995), are all the alliances of this framework.

In the scaffolding, construction, reflection, narration, and diagnosis are the four major activities for learning-to-teach values. In reading, observing, and criticising the learning resources in such a co-learning team, the participants would be in a good position of using and constructing their own narratives about teaching. They could also re-consider the possibilities of rectifying their classroom values teaching. This self-and-collective regulation process, in which reflection and communication are two major activities of values clarification, and narration and metaphor are two indicators of a value communicator (Chin & Lin, 2001b), may create space for teachers to diagnose their values teaching. Two aspects about teacher intrinsic motives (awareness
and willingness) derived from a comparison between Taiwanese and Australian teacher values research (see Chang, 2000; Chin & Lin, 2001b; Leu & Wu, 2000; and Bishop et al., 2001) play as two affective requirements of learning-to-teach values. One is concerned with teacher awareness of values in classroom mathematics teaching and the other is about their willingness to teach that values. Moreover, thinking and action are two recursive levels of learning-to-teach values. It is very important to take the aspect of action into serious consideration, and to separate implicitly mental thinking from the enactive aspect of values practices. Thus, I used the procedure of values construction focusing strictly on the content of mathematics, from observation, simulation, micro teaching, to that of teaching practice and actual classroom teaching, to develop the three student teachers' content-specific pedagogical values.

The Research Instruments

Six questionnaires were developed for eliciting the participants' pedagogical values. One of the two general values surveys is to explore their degrees of agreement on the 25 propositions using 5-point Likert format. The second parts of the questionnaire ask teachers to select and rank 5 from the 25 statements according to the most/less importance for them, and describe reasons for the rankings. The second questionnaire asks teachers to rank the 14 values according to the degrees of importance for them in lesson planning and classroom teaching, for example the values of felt pleasure. The 4 remaining questionnaires address different values for each of the 4 teaching topics.

SOME PRELIMINARY RESULTS

An initial analysis of the questionnaire surveys, classroom observations, and interviews with the student teachers showed two initial states of, and a co-learning cycle for, values learning. The statistical procedure of factor analysis (SPSS, 1994) with principal components extraction and varimax rotation was used and tested on the item responses of the student teacher group. In comparison with the results produced by oblimin rotation, the factorial structure was almost identical. The resulting six-factor model, explaining 77.44% of total variance, was used to construe their shared beliefs. For example, the six items with highest loadings (>0.82) on the first factor suggest that the first belief proposition is "To teach mathematics, teachers should recognise beforehand student backgrounds/needs of learning". The remaining 5 beliefs can be found in Chin (2001).

Underlying pedagogical values nominated and taught by ST₁, ST₂, and ST₃

The values of mathematical forms and abstraction seemed to be the best stands for ST₁ and ST₂ to organise and teach mathematics. ST₁'s first two choices out of 14 values in the second questionnaire were mathematical forms and contents; and the last three options were about the affective aspects of learning mathematics, for example, felt pleasure, felt happiness, and willingness to learn mathematics. He said, "No matter students would be pleasant or not, as a teacher, I should teach them some mathematical forms and also try to force them to learn the forms" and "We should also make very good use of some typical
mathematical exemplars and to build student knowledge on that particular exemplars. ST2 ranked hardworking, intellectual growth, and creating mathematical abilities, higher than the values of practical knowledge and felt interest to the knowledge. For him, "Forms and exercises are more practical for classroom realities of mathematics teaching." and he felt that "Students will be very happy if they feel that their teachers teach them more mathematical content than other classes." and "The affective factors are the most difficult things for me to control in teaching, therefore, it is better to teach the mathematical contents more." In the microteaching, ST1 started with the example $\sum_{i=1}^{k} \frac{1}{k(k+1)} = \frac{n}{n+1}$ to introduce the mathematical induction. The reason to do so was "It is better for them to learn new concepts from a well known example, otherwise, classroom situations would not be able to under my control." For him, classroom orderliness and the understanding of mathematical forms are more important than just playing some artificial mathematical games. He said, "There are not much value to introduce mathematical concepts using games or pseudo-artificial activities, I would rather spend my time on demonstrating as clearer as possible the mathematical forms and rules." As a result, his teaching relied much on forms and exercises. If students couldn't get the sense he would "Give them five seconds to think, and then I will solve the problem and show them the solution. It is no way for me to stop and wait there." ST2 took over the lesson by introducing the formal proof of mathematical induction although this idea was criticized by T1 and T2, he still insisted to do so, because "It is absolutely necessary for students to understand logic necessity and existence within the system of mathematical knowledge." Therefore, the values of mathematical proofs, forms, and rules were addressed because "The concept is very rigorous and beauty in the sense of its structures." The values of pleasure and practical knowledge were central for ST3. ST3's first two choices out of 14 values in the second questionnaire were practical knowledge and felt interest to the knowledge; and the last two options were about the formal aspects of mathematics learning, for example, logic reasoning and orderliness. He hoped that "Students are the focus of my classroom teaching, and I will try very hard using daily life examples and student practices in which I can talk to students and to initiate their thinking." One central tenet of teaching for him was "increasing students' mathematical abilities using practical and realistic knowledge from daily life." In the microteaching, ST3 used a self-made teaching resource, a clock like plate, to introduce the definition of angle through visualisation. After that, he gave some questions for the students to solve. He said, "I really wanted to use some real staffs, helping students access to and make sense of the mathematical concepts. I hope that they can learn from the realistic aspects of mathematical knowledge through practices and reflections." Therefore, there are two sets of pedagogical values emerged from the questionnaire surveys and interviews. One set of values, as ST1 and ST2 exemplified, includes mathematical forms, rules, and proofs, and abstractness; the other set, as ST3 showed, consists of felt pleasure and practical knowledge.

Two competing states of values learning portrayed by ST1, ST2, and ST3

A shared understanding, emerged in the process of learning values, is the recognition of "felt easy to know but difficult to act". As they all hesitated to use felt pleasure in the
classroom, because “These ideas although are very important for teaching and learning, but, it seems very difficult for me to teach such a value, for example, feeling pleasure. Don't you think?” There are two initial states of learning-to-teach pedagogical values, in which one values the formal and logic-structural aspects of mathematics and the other values the practical aspects of mathematics and intrinsic motivation for learning. The most important tasks for ST1 and ST2 were to learn about “How to get more insight into the formal and abstractive nature of mathematical system and help them create approaches for teaching students understanding of such system?” They hoped that T1 and T2 could help them construct the strategies for introducing mathematical concepts. Their present states show a limited extension of visions about values, although they feel that it is useful to consider values in mathematics teaching. This suggests that they are in a "felt difficult to act however unwilling to act" state. What most important for ST3, was “How to collect more examples of designing mathematical activities for students to learn?” He expected that T1 and T2 could help him develop the situations to increase student pleasure in learning mathematics. Although these values positions were not observed in his classroom teaching practice, but he wanted to do so. In this case, his present state of values learning is in a position of creating value visions but with limited teaching experimentations. This suggests that he is in a "felt difficult to act and yet willing to act" state.

A co-learning cycle for learning-to-teach pedagogical values

To help them moving from the base of "felt easy to know but difficult to act", through the present states of "felt difficult to act however unwilling to act" and "felt difficult to act and yet willing to act", to "knowing is action", a co-learning cycle for learning-to-teach pedagogical values is developed as the following Figure 1 shows.

![Figure 1: A Co-learning Cycle for Learning-to-Teach Pedagogical Values](image)

In the values co-learning team, I was a participant observer and an action researcher; Ming acted as a values demonstrator; T1, T2, ST1, ST2, and ST3 were the practitioners of values; and O played as an observer. To monitor them transferring from values carriers to values communicators (Chin & Lin, 2001b), the recursive learning cycle including the activities of clarification, argumentation, identification, and action was developed for thinking and practising of pedagogical values. Two substantial layers are underlined in the cycle: the thinking aspect in the process of learning-to-teach, and the enactive aspect of the values learning process. These two layers are implicitly
connected and relatively informed each other in the co-learning process. Within the cycle, each member is a learner, learning about the concepts of values education and values teaching. The researcher learns "How to educate teachers about values teaching?", Ming learns "How to present his own values to outsiders?", the five participant teachers try to re-consider the values provided with their own. The levels within this cycle are in a way related to Jaworski's (2001) 3-level model of co-learning partnership for developing mathematics teaching for teachers, teacher-educators, and researchers. In the present study, the researcher and teacher-educator who develops one's recognition of values education within level 3a, level 3b, and level 2, focusing on the roles and activities that can be used to facilitate the participants' values learning. Ming and the five teacher participants are to enhance their abilities and recognitions about values teaching within level 2 and level 1. All the members were trying to understand other members' values and the differences that might be emerged in comparison of one's own and others' values during exchanges. To help student teachers reaching the goal of "knowing is action", all the members were trying to become value communicators through this developmental framework of values learning.

REFLECTION

To revisit the study aims, several aspects concerning the learning framework need to be re-considered. The group discussions seemed to be effective as there were different participants with different thoughts and backgrounds for student teachers to exchange, model, and reflect on their own thinking and action about values teaching. The value learning resources were effective and this might have contributed to the participants' value clarification processes. The co-learning cycle for values learning was also useful in the ways that it played in increasing participants' recognitions and awareness of thinking and practicing about values. Thus, the four main activities in the co-learning cycle seem to be useful for teacher educators to develop their student teachers' values. I would rather see it as a cyclic and recursive path for the teachers to reflect on and to learn about values, than as a static and single loop for them to go through.

The practices of educating mathematics teachers about pedagogical values that the present study describe, challenge much of our knowledge, beliefs, and values about mathematics teacher education from a very fundamental aspect, as the teachers are more seriously considered in their process of "becoming-a-teacher", related to his or her own processes of identities and values development. After all, classroom teachers are at the very hart of any curriculum reforms, not least of course in the recently launched Taiwanese New Mathematics Curriculum (ME, 2001) for the students under age of 15, in which the values of pleasure and practical knowledge are explicitly addressed. Is this a kind of "paradigm shift" for school mathematics curriculum and classroom teaching of mathematics? Or the challenge is more about the re-assessment and re-construction of teachers and educators' pedagogical beliefs and values?

Two issues concerning education of student teachers about values need to be further examined. One issue is about their willingness to teach those values in classrooms, and
the other concerns the ability to teach them. Although student interest and motivation to learn were important but they resisted doing so, as ST₁ and ST₂ showed. There were also problems related to the abilities of teaching the intended values as shown by ST₃. We have to create intrinsic motives for student teachers to teach their intended values, and to provide learning arenas to empower their abilities to implement them.

FACTORS AFFECTING THE IMPLEMENTATION OF REFORMS IN SCHOOL MATHEMATICS

Naomi Chissick
Ort Colleges and Schools for Advanced Technologies and Sciences

This paper describes on-going research that investigates the effects of an implementation project run in comprehensive schools in Israel. The research also examines teacher's self-esteem, and tries to discover its place in determining the teacher's willingness to adopt innovative practices. Results so far suggest that the implementation project is succeeding in promoting reforms in the schools' culture, but the complexity of the context in which teachers operate renders self-esteem nearly insignificant.

INTRODUCTION

The aim of the research reported in this paper is to examine the implementation of changes in mathematics teaching practices. It focuses on approaches to the implementation of new teaching-strategies for in-service high-school mathematics teachers, and on their feelings and reactions to this process. This topic has been high on the agenda of PME meetings for some time, and is still under scrutiny. My research also examines teacher's self-esteem, and tries to discover its place (amongst other factors like beliefs, norms, values and context) in determining the teacher's willingness to adopt innovative practices; at the same time, the effects of the reforms implementation on the teacher's self-esteem will be examined.

The research studies an implementation strategy operated by the author in 13 middle and high schools in Israel. The strategy is under constant review in order to improve the implementation methods, find ways to cope with resistance and promote renewal and regeneration of new ways in mathematics education.

THEORETICAL BACKGROUND

Change implementation processes have been widely examined in different contexts, including educational settings. This research looks at the problem from two perspectives: behavioural theories are used to examine beliefs, attitudes, norms and self-esteem; organisational/management theories are used to examine change implementation processes in organisations (schools) and teamwork (as part of the change); educational research literature ties them together.

Whitaker (1998) claims that "a key assumption upon which traditional orthodoxy in education has been built is that teaching in schools is concerned with the transmission of knowledge... that will remain valid throughout our lives." (p.15). This has been especially true for mathematics teaching (Weinzweig, 1999; Norton et al., 2000), and my observations in some 400 classrooms for this research suggest that this is still the case. Therefore, reform cannot occur without a change in the
mathematics teachers' system of beliefs and conception of the nature of mathematics and theories of teaching and learning. These, in turn, may affect the image and self-esteem of the mathematics teacher, who may undergo a change from the sole authority and source of knowledge, to a co-learner with the students (Clarke, 1997). The teacher needs to become a moderator, stimulating students to question the assertions of their colleagues (Ponte, 2001).

Clarke (1997) identified 12 factors that appear to influence the process of changing teacher roles, amongst them the in-service program. The social context is also a powerful influence. This is a result of the interactions between teachers and pupils, parents, peers and superiors, and their expectations from the teachers (Ernest, 1994). The common myths concerning mathematics and mathematics education also affect the expectations from the teachers, and as a result, affect their performance (Lim and Ernest, 1999). For example: "mathematics is made up of rules and procedures" (Amit and Hillman, 1999, p. 21); "the teacher is the source of knowledge, the pupils - passive receivers" (Weinzweig, 1999, p. 26).

It is therefore apparent that effective professional-development models will need to take these aspects into consideration. The elements that need to be considered when designing such models include:

- the designs should never stop evolving and changing (Loucks-Horsley, 1998). Constant reflection is an essential part of an effective program;
- institutional support is crucial (Ernest, 1994);
- the design should be done through collaborative work (Whitaker, 1998; Valero & Jess, 2000);
- the possibility of a loss of confidence and self-esteem should be taken into consideration (Whitaker, 1998).

Reforms in teaching demand both vision and courage. There are tensions, challenges, doubts, failures, guilt and frustration involved. As Koch (1998) puts it: "Nowhere is reform deeper, more personal, or more threatening than with teachers" (p. 118). And even more so, I find, with mathematics teachers, who are always under public scrutiny. Therefore, mathematics teachers who face a decision on implementation of changes in their practices have to confront the dilemma: how much of their professional persona can they risk? (Sakonidis et al., 2001). Or as House says:

"The personal costs of trying new innovations are often high ... they [innovations] require that one believes that they will ultimately bear fruit and be worth the personal investment. (quoted in Fullan, 2001, p. 36)."

Therefore, mathematics teachers' self-esteem seems closely connected to their willingness to attempt implementation of changes in their classroom practices. Many mathematics teachers display high self-esteem: they seem very confident both in their knowledge and in their didactics. Nevertheless, they might be reluctant to adopt new ideas and risk what they consider to be their 'achievements'. On the other hand,
Yackel (1994) gives an example of a teacher who was thought of as an exceptional mathematics teacher and was aware of it; presumably, his self-esteem was high. Nevertheless, Yackel describes his efforts to reform his practice as “remarkable”, and attributes this to his deep understanding of mathematics and his mathematical values.

Many psychologists believe that virtually all of human behaviour springs from two motives, the first of which is our desire for self-esteem (the second being our desire for sense pleasure) (Campbell, 1984). There is a wide range of books and articles on self-esteem and ways to measure it; the definitions and measurement of self-esteem are taken mainly from classical psychology (Rosenberg, 1965; Coopersmith, 1967). Blasovitch and Tomaka (1991) suggest an ‘integrated’ definition of self-esteem:

Self-esteem is the extent to which one prizes, values, approves or likes oneself (p. 115).

To date, the most popular measurement tool of self-esteem for adults is still the Rosenberg Scale (1967), with the Coopersmith Inventory (1967) not far behind (Blasovitch & Tomaka, 1991).

THE CONTEXT OF THE RESEARCH

Since April 1999 I have been running a project for the implementation of contemporary teaching practices in 13 middle and high schools in Israel. Its aim is to encourage the on-going professional development of the teachers, to help change the teaching practices, to encourage the use of technology and to promote teamwork in mathematics teaching.

On-going support is given to the mathematics teaching staff by assigning each school a ‘facilitator’ for one day a week for three years. The school’s head of mathematical studies (HoD) and the facilitator work together: they lead weekly workshops for the team, train them in up-to-date teaching methods, promote teamwork procedures, lead group learning sessions, and help to experiment with new teaching practices and with the use of technology in the classroom. The facilitators and department heads from the schools taking part in the project attend a monthly meeting in which there is an exchange of ideas, consultations, planning and evaluation of their work and progress (Chissick, 2000).

Regular feedback and reflections are exchanged between the project manager (who is also the researcher) and the facilitators and heads of department, and changes in the project’s activities are made accordingly.

METHODS AND ANALYSIS

The research examines two interrelated concepts:

- effective implementation of contemporary mathematics teaching practices (through the above mentioned project);
the self-esteem of the mathematics teacher, and its effect on his/her willingness to implement changes.

This is qualitative research using non-participant observational techniques (Glaser & Strauss, 1967), as well as questionnaires (both structured and semi-structured). The data accumulated from the project are analysed on a regular basis. As far as self-esteem and its effect on the adoption of reforms by teachers are concerned, the paradigm of grounded theory is adopted (Glaser & Strauss, 1967; Strauss & Corbin, 1998; Dey, 1999).

The analysis is inductive, based on a naturalistic paradigm as in Sanger (1996):

"The label 'naturalistic' in educational inquiry would signal that the research has been conducted in an educational milieu and seeks to characterise participant activity within programs, projects or other settings" (p.11)

The research questions, the choice of the research tools and the way to use them, as well as the research population, are determined during the process and can be changed during and as a result of analysis. (Gibton, 2001)

In addition to the study of the data accumulated from the schools, case studies will be carried out in two schools; one will be discussed in the next section. The participants are three mathematics teachers (one of them the head of department) in each school. They are observed in their classrooms (three lessons each) and interviewed three times each during the school year. The interviews are semi-structured and concentrate on four themes:

- the teacher's beliefs and attitudes towards mathematics and mathematics teaching;
- the teacher's beliefs and attitude towards the change process;
- the teacher's personal history as a student of mathematics;
- the teacher's self esteem.

Questionnaires about the implementation project have been issued to teachers (at the end of the two previous school years), HoDs and school heads. Microanalysis, as in Strauss & Corbin (1998) has been used to analyse the responses. The codes were entered into a spreadsheet, and sorted twice for analysis: once in the order of Code-School-Document for an overall analysis, and then in the order of School-Code-Document for case studies.

A basic set of codes was built, and changed as deemed necessary while the coding process was going on. The process was flexible and creative: codes were added, discarded or changed along the way.

Non-participant, semi-structured observations were made both at staff meetings and in classrooms. The observation reports included informal, descriptive, narrative accounts (Wragg, 1999) and event-coding tables (Bakeman & Gottman, 1986; Robson, 1993). These were scrutinised for behavioural patterns that may indicate
willingness or resistance to the implementation of reforms, and displays of high or low self-esteem.

In addition, regular weekly semi-structured reports from the project's facilitators, notes on informal conversation, and historical data accumulated in previous years are examined and analysed for indications of the main items mentioned above.

In the event, insufficient data has been collected on the teachers' self-esteem; its effect on the implementation of changes will be need to be studied more thoroughly in the future.

PRELIMINARY FINDINGS AND DISCUSSION - SCHOOL NO. 1

School No.1 is a comprehensive school (grades 7-12, pupils aged 12-18) situated in a development town, surrounded by affluent settlements. The town's population consists of 60% relatively new (residence 3-10 years) immigrants from the former USSR. This has an impact on the teachers (some of whom are new immigrants themselves) and on teaching methods, as the reigning learning paradigm amongst parents is a traditional one.

The implementation project is in its third and last year in the school. The team consists of 12 teachers and two HoDs: P. for grades 7-8, and A. for grades 9-12. They both co-operate willingly with the facilitator. Both are new to the task (first year for P., second year for A.) and are developing as leaders. The facilitator, D., has gained the teachers' trust and confidence by showing significant ability and knowledge, as well as empathy and understanding. This can be seen from the appreciation that the teachers express in the questionnaires and at meetings with the researcher; in addition, the relaxed and open relationship between D. and the teachers is notable.

In the analysis of the questionnaires (administered to the teachers, HoD and facilitator at the ends of the first two years of the project by the external assessor), open coding was used, with line-by-line analysis, as suggested by Strauss & Corbin (1998) and Dey (1999) for the first stages of the analytic process.

Some results can be seen in Table 1 below. In this table some of the codes were gathered into more general categories; for instance: use of technology, use of open-ended tasks, changes in assessment, and overall changes in classroom practices are all under 'changes in classroom practices'.

Further analysis of additional data (summaries of facilitators' meetings, notes from casual talks with D., A. and P.) shows that the facilitator was less convinced of the overall changes in classroom practices and the use of open-ended tasks than the teachers and the HoDs. As far as the use of technology is concerned, both the facilitator and the HoDs thought that some progress was made (although not as much as had been expected) while the teachers were divided on the issue: half of them did not see any progress, while the other half felt that some progress was made. This
might be explained by the fact that each teacher responded from her/his personal viewpoint, whereas D., P. and A. saw the whole picture and responded accordingly. At one of the facilitators-HoDs meetings that are held regularly, A. reported:

This year I was teaching the role of the parameters in the quadratic function on the shape and place of the graph, when I suddenly realised that this subject could be better taught with the graph-generator on the computer. I 'dared' it, and took the class to the computer lab. It was wonderful. They all understood and could generalise. (CT-371-2009: note on casual talk at a staff meeting, Sep. 2001)

It has to be noted that A. has attended quite a few courses on the use of computers in mathematics teaching in the past, and the benefits of using a computer had been well known to her for some time. It seems that the support and encouragement that D. and her peers gave her, as well as the realisation that she should set an example, gave her the strength to 'take the risk' and brave it. Her report (above) on her experience to the team, and her frankness about her doubts and fears served as a catalysing agent for her peers.

Except for one teacher, everybody felt that they have been going through a process of personal development. It remains to be seen whether this will result in the initiation of further studies or similar processes in the future.

As can be seen in Table 1, teamwork culture, which is one of the main aims of the project as an instrument for progress and reforms implementation, seems to be having an impact on the teachers. Most teachers reported active participation and peer-support.

Table 1: Results of questionnaires' analysis - School No. 1
The effects of the implementation project on teaching practices and on teamwork can already be seen. The atmosphere in the department has changed: teachers consult each other, work in groups on subjects of common interest, produce open-ended assignments and worksheets and discuss assessment policies.

**DISCUSSION**

Analysis of the results from all the schools taking part in the research so far shows a significant change in teamwork culture in all the schools; some changes of classroom practices (excluding the use of technology) which includes the use of open-ended tasks and more pupil-centered teaching; and a general feeling amongst the teachers that they are undergoing a process of professional development. School No. I seems to represent the general results fairly accurately. These results may imply that the implementation project is successful in promoting the adoption of reform practices. Nevertheless, it remains to be seen if the effects of the project remain, and if the teams can carry on the momentum on their own.

Not enough data has yet been collected about the teachers' self-esteem; therefore, it is too early to come to conclusions about its effect on reform implementation. Although it is widely believed that self-esteem is a major factor that affects human behaviour (Campbell, 1984), it may be that the complexity of the context in which teachers operate renders this factor nearly ineffective. From close acquaintance with some of the teachers, it seems that there is no immediate connection between self-esteem and readiness for change; self-esteem may turn out to be just one of the many varied factors (for example: external exams, peer support, content knowledge, school environment, time limit and more) that affect the willingness of mathematics teachers to implement new teaching practices. It is expected that in-depth interviews, and the use of the self-esteem measurement scales (mentioned above) will give more insight on the counter-effects of self-esteem and reform implementation.

THE EFFECT OF EFFICACY ON TEACHERS' CONCERNS WITH REGARD TO THE IMPLEMENTATION OF A NEW MATHEMATICS CURRICULUM

Christou, C., Philippou, G., Pitta-Pantazi, D., Menon-Eliophotou, M.
University of Cyprus

The present study aims to examine the concerns of primary school teachers in Cyprus in relation to the recent implementation of a new mathematics curriculum. An adaptation of the Stages of Concern Questionnaire (SoCQ) based on the Concerns-Based Adoption Model (CBAM) and a teachers' efficacy questionnaire were administered to a representative sample of teachers. The findings suggest that teachers' concerns are largely affected by their efficacy beliefs. Furthermore, there were significant differences in teachers' self-concerns across years of involvement with the implementation. However, no significant differences were found in task and impact concerns across teachers in the initiation, implementation and refinement stages.

INTRODUCTION

Research results suggest that the perception of those involved in innovations are of major importance for the successful implementation of an innovation (Richardson, 1990; Sztajn, 1997). The significance attributed to the innovation by those involved in it is often considered as one of the most crucial factors for its successful implementation. However, the literature examining the relationships among the factors that contribute to the successful implementation of reforms, such as the experiences, concerns, and skills of the teachers involved in the process, appears to be inconclusive. This study aims to provide the framework of a model that may explain the relationships between teachers' concerns and their teaching efficacy. Our work focused on the application of the CBAM model in Cyprus with teachers attempting to implement a new mathematics curriculum through the adoption of a new series of mathematics textbooks.

One of the main purposes of the new Cypriot mathematics textbooks is to engage students in thought-provoking, original problems that involve challenging themes. Students are expected to investigate a series of carefully sequenced activities aimed at hands-on discovery of mathematical concepts, with mathematics often integrated with other content areas. The textbooks also aim at supporting teachers' efforts in identifying and addressing students' prior knowledge and connecting it with new ideas at linking conceptual and procedural knowledge, and at relating mathematics to other fields of human endeavor. The adoption of the new textbooks and the subsequent changes in the teaching of mathematics is considered one of the most important innovations in primary education in the last ten years.
The new series of textbooks has been introduced gradually in all public primary schools in Cyprus since 1995: Grade 1 teachers were called to use the new series of textbooks in 1995, grade 2 teachers in 1996, and so on until 2000, at which point all teachers became involved in the adoption of the innovation. At present, there are teachers at different stages in the implementation of the reform. Given the importance of the innovation, it was considered necessary to investigate the degree to which Cypriot teachers had accepted the new curriculum suggested through the new mathematics textbooks and followed it in the classroom.

The proposed efficacy and concerns model (ECM) is an attempt to examine teachers’ concerns about the implementation of the new mathematics textbooks and explain how teachers’ efficacy influences their concerns.

THE PROPOSED MODEL AND THEORETICAL BACKGROUND

The ECM model integrates two basic ideas about the implementation of educational reforms - the concerns based stages and teachers’ efficacy beliefs. Drawing upon relevant literature from each of the two domains, we have attempted to explain the proposed model, which is depicted on Figure 1.

Concerns-based Stages

Concerns refer to the feelings, thoughts, and reactions individuals have about an innovation that is relevant to their daily job (Hord, Rutherford, Huling-Austin & Hall, 1998). The adoption of an innovation requires a change that involves people, thus making it necessary to form an understanding of human concerns in order to help individuals move in the process of change. Concerns exert a powerful influence on the implementation of reforms and determine the assistance that teachers may need in the adoption process.

The CBAM helps educational leaders to this effect by showing them how the individuals most affected by change react to the implementation of innovations (Hord et al., 1998). The model can identify the special needs of individuals and enable administrators to provide the appropriate assistance. The CBAM includes three key tools used to collect relevant data: Stages of Concerns (SoC), Levels of Use (LoU), and Innovation Configurations (IC). The most important of the three tools is the SoC questionnaire, which is used to measure teachers’ concerns about an innovation they are expected to implement (Hall & Loucks, 1978). The SoC questionnaire is structured around three dimensions of concerns: self, task, and impact, as depicted in the right side of Figure 1. In the self-concern dimension teachers are trying to learn about the innovation and understand what the innovation means to them. In the task-concern dimension, teachers express their concerns about how to cover objectives, provide and organize instruction. The third dimension, impact, focuses on teachers’ concerns about the effectiveness of the innovation on students’ performance and abilities.
Earlier research by McKinney, Sexton, & Meyerson (1999) indicated that implementation of innovations occurs in a sequential manner — initiation, implementation and refinement (Figure 1). The initiation phase is closely related to the development of self-concepts, the implementation phase with the task-concerns and the refinement with the impact-concerns of teachers.

**Teachers’ Efficacy**

The conceptualization of teacher efficacy is based on the theoretical framework of self-efficacy developed by Bandura (1997). Bandura (1997) defined perceived self-efficacy as “beliefs in one’s capabilities to organize and execute the courses of action required to produce given attainments” (p. 3). In the same sense, teaching efficacy, which is a form of self-efficacy beliefs, can be defined as teachers' beliefs in their abilities to organize effective teaching-learning environments and have positive effects on student learning.

Self-efficacy influences several aspects of behavior that are important to teaching and learning (Woolfolk & Hoy, 1990). Among these are the choices of activities that a teacher makes, the effort put forth and persistence in accomplishing a task (Bandura, 1997). Teachers’ efficacy beliefs have also been related to student achievement, student motivation, teachers’ adoption of innovations, and teachers’ management strategies (Woolfolk & Hoy, 1990).

![Diagram](image)

**Figure 1: The proposed ECM model**

Dempo and Gibson (1985) identified two dimensions of the construct. The “general teaching efficacy” which refers to the belief that teachers in general are able to influence students’ learning, and the “personal teaching efficacy” that measures the individual’s conviction in his/her own power to control students’ motivation and achievement. More recently, Soodak and Podell (1996) supported a third dimension of teacher efficacy and proposed a different interpretation. They suggested that
teacher efficacy is comprised of three factors: Personal Efficacy (PE), Outcome Efficacy (OE), and Teaching Efficacy (TE). More specifically, PE refers to teachers' beliefs that they have the skills to bring changes in students' behavior and performance, while OE refers to the belief that, when teachers implement those skills, they can achieve desirable outcomes. The TE factor refers to teachers' beliefs that teaching in general can lead to students' successful performance overcoming influences outside the classroom which affect learning, including children's home environment.

In this study we adopt Soodak and Podell's interpretation of teacher efficacy since it incorporates previous research results (Woolfolk & Hoy, 1990) and it is consistent with Bandura's (1997) differentiation between efficacy expectation and outcome expectations. However, in the present study we only use the PE dimension of teaching efficacy due to space constraints.

AIMS OF THE STUDY

The first aim of the present study was the validation of the ECM as a theoretical model of explaining the effect of teaching efficacy on the development of teachers concerns towards the implementation of mathematics reforms. The second aim is closely related to the first and it refers to the examination of how efficacy beliefs influence the concerns of teachers as they move through stages of implementation. Specifically, the model suggests that as teachers are involved in the teaching with the new mathematics textbooks, they move through the initiation to implementation and refinement stages. In the present study, we assumed that teachers who were involved with the innovation for 0-1 years belong to the initiation stage and thus they merely express self-concerns. Teachers involved with the innovation for 2-3 years belong to the implementation stage, which is related to the task-concerns. Finally, teachers with 4-6 years of involvement belong to the refinement stage and thus they are expected to express impact-concerns.

During the process of innovation, teachers express different concerns, which are influenced by their efficacy beliefs. To date, no other model has incorporated efficacy and teachers' concerns in a comprehensive manner involving causal relationships. The following two hypotheses reflect what we would expect if efficacy affects teachers' concerns about the implementation of new mathematics textbooks:

(a) The fitting of the ECM showing causal effect of efficacy on teachers' concerns to be acceptable, and

(b) A decrease in self-concerns with increases in task and impact-concerns when teachers' scores at the initiation stage are compared with those at implementation and refinement stages. Similarly, we would expect a decrease in task-concerns with increases in impact-concerns when teachers' scores at the implementation stage are compared with those at the refinement stage.
METHOD

Participants and Instrumentation

The participants in this study were 655 teachers (155 male and 500 female teachers) from 100 elementary schools in Cyprus. Schools were selected on the basis of size, location and demographic characteristics. The sample included three groups of teachers covering the initiation, implementation and refinement stages.

Two instruments were used as data sources. Both instruments were administered at the same time to all participants. The first instrument was an adaptation of the SoCQ as described by van den Berg & Ros (1999). The SoCQ questionnaire, which included 36 items, was used to measure the self, task and impact concerns. For the purposes of the present study teachers' rating to the 36 items of the questionnaire were made on a 9-point scale ranging form 1 (strongly disagree) to 9 (strongly agree): all responses were recoded so that higher numbers indicated greater agreement.

The measures of teaching efficacy were obtained through a questionnaire which was used in previous studies in Cyprus (see Christou, Philippou, & Dionysiou, 2001). Respondents used a six point agree/disagree scale to respond to 13 statements which measured TE, 11 which measured PE, and 10 which measured OE. The coding of the negatively stated items was inverted to ensure that high scores meant high efficacy on all items of the scale.

Data Analysis

The assessment of the proposed model was based on a multi-sample mean and covariance structures analysis, which is part of a more general class of approaches called structural equation modelling. One of the most widely used structural equation modelling computer programs, EQS 6.0, was used to test for model fitting in this study. In order to evaluate model fit, three fit indices were computed; the chi-square to its degree of freedom ratio (χ²/df), the comparative fit index (CFI), and the root mean square error approximation (RMSEA). These three indices recognized that observed values for χ²/df <2, values for CFI>.9, and RMSEA values close to 0 are needed to support model fit (Marcoulides & Hershberger, 1997).

RESULTS

To test the first hypothesis we posited a model with three factors (self, task and impact concerns), which are causally related to teaching efficacy (see Figure 1). Factor loadings, factor regressions and variable intercepts were constrained to equal across the three groups of teachers (teachers at the initiation, implementation and refinement stages). We tested the ability of a solution based on this structure to fit the data. As reflected by the iterative summary, the solution converged smoothly,
and the goodness-of-fit statistics showed that the model had a very good fit to the three-group data ($\chi^2 = 364.174$, $df=236$, $\chi^2/df=1.54$, CFI=.96, RMSEA=.02). All items loaded strongly and distinctly on each of the factors shown in Figure 1. The standardized loadings of all measures were above .5, and were statistically significant in all groups. The regressions of efficacy on the self (.297), task (.880) and impact concerns (.461) were significant and equal in all groups, indicating that efficacy exerts an important effect on teachers’ concerns (see Table 1).

To examine the second hypothesis of the study of whether the latent construct means of self, task, and impact concerns are significantly different in the three groups of teachers, we turned to the construct equations, which are presented in Table 1. The parameters of interest in this case were the factor intercepts that represent the latent mean values. Because the initiation teachers had their parameters fixed to zero for comparison purposes, we concentrated on estimates for the teachers in the implementation and refinement stages. The lower part of Table 1 shows the comparison between teachers in the implementation and refinement stages. To compare these two groups of teachers we fixed the factor means of the implementation group to zero.

Table 1: Construct equations of teachers’ concerns

Table 1 shows that self-concerns are increased significantly in teachers in the implementation (.172) and refinement stages (.254). This increment means that teachers have less self-concerns when their involvement in the innovation increases. On the contrary, teachers’ task and impact concerns seem to increase as they proceed to higher stages of implementation. This is denoted by the negative sign of the latent
factor means (-.143, -.169 for task, and -.066 and -.085 for the impact concerns). However, the latter effects were not significant by z-tests. These results replicate partially the results reached by van den Berg and Ross (1989).

DISCUSSION

The purpose of this study was twofold. First, to explore the effect of teaching efficacy on teachers' concerns regarding the implementation of a new mathematics curriculum and the use of new mathematics textbooks; second, to address the extent to which teachers at different stages in the implementation process of the innovation had different concerns in relation to the innovation.

Earlier research indicated that teachers' efficacy beliefs were related to student achievement, student motivation, teachers' adoption of innovations, and teachers' management strategies (Woolfolk, Rossoff, & Hoy, 1990). The data of the present study reinforced previous studies by validating a model in which the relationship between efficacy and concerns is a causal one. The model also showed that teachers' efficacy beliefs affect more the task concerns of teachers than the self or impact concerns (see Table 1).

The differences in concerns across different groups of teachers was the main topic of investigation under the second research question of the present study. In general, research evidence on the development of teaching concerns has yielded mixed results (Ghaith & Shaaban, 1999). The study provided evidence that years of teachers' involvement with the new mathematics curricula and mathematics textbooks explained to an extent the developmental nature of teaching concerns. Teachers' concerns in the initiation stage appeared to be self-oriented, reaffirming van den Berg, & Ros (1999) conclusion that teachers during the early years of an innovation are absorbed with day-to-day difficulties and pay little attention to the newly encounter problems of the students. Teachers at the initiation stage in this study seemed to focus on the implications of the new mathematics curriculum and textbooks for themselves; they were largely interested in the changes that could occur in their personal work situations, and in the manner in which they could be required to prepare their daily work. In contrast, teachers at the implementation and refinement stages reported less interest in the consequences of the innovation for themselves but they did not report greatest interest in their students and did no have more ideas with regard to the adoption of the innovation in comparison to teachers in the innovation stage. Although this result seems to contradict the conclusions of other research studies (van den Berg & Ros, 1999), it can be explained by the fact that concerns in the present study were analysed in the light of the teaching efficacy effect.

The results highlight the importance of attending to the concerns and experiences of teachers with respect to the new mathematics curricula and textbooks. It is important for policy makers and school leaders to acknowledge and identify the concerns of
teachers in order to increase the prospects of success for educational innovations. The differences found in this study between experienced and beginning teachers can be used to inform the planning and implementation of intervention program.

UPPER ELEMENTARY TEACHERS' MATHEMATICS RELATED ANXIETIES AND THEIR EFFECTS ON THEIR TEACHING*

Rina Cohen and Karen Green
Department of Curriculum, Teaching and Learning, OISE/UT

This paper is related to a study of grade 5-8 teachers' math-related anxieties and attitudes, their impact on their teaching practices, and how these teachers can be helped in dealing with their anxieties and improving their teaching. Following initial teacher interviews, the teachers will participate in a series of "Math Empowerment" workshops that will utilize a holistic approach, including a lot of math work along with activities for emotional, psychological and social support. This paper reports the findings of the first phase of the study, consisting of initial teacher interviews. Teachers' various types of anxiety are described and illustrated, along with their own schooling experiences that gave rise to these anxieties, as well as their current teaching challenges and coping strategies in dealing with these challenges.

Introduction

It has been established that pre-service, and in-service elementary teachers frequently exhibit math dislike and/or anxiety (Bush, 1990; Hembree, 1990; Trice, A. D., & Ogden, E. D. (1986-1987). Furthermore, there have been numerous claims that these teachers inadvertently pass on their negative attitudes towards math to their students (e.g. Bulham & Young, 1982; Karp, 1991, Martinez, 1987, Widmer & Chavez, 1978) although these claims have not been supported by all studies (Bush, 1991; Swetman, 1994). Recent math reforms have added new dimensions in teachers' math-related fears: the need to teach a new curriculum, including new educational philosophies and approaches to learning and teaching math that teachers may have never been exposed to (Battista, 1992). Province-wide testing has been recently introduced in Ontario, and the threat of teacher testing is looming.

This paper deals with an ongoing project consisting of a qualitative study of a group of 12 upper elementary (grade 5-8) Ontario teachers who experience significant math-related anxieties and feelings of inadequacy. The purpose of the study is twofold: (a) to gain a better understanding of these teachers' math-related anxieties, attitudes and beliefs, and their effects on their math teaching, (b) through conducting a series of workshops for these teachers, to explore a holistic approach to helping these teachers in dealing with their anxieties and improving their math teaching.

This paper reports on some initial findings of the study based on teacher interviews conducted so far. Teachers' math-related anxieties and attitudes, classroom teaching challenges and coping strategies will be described. Since the data collection and initial analysis for the whole study will be completed by the early summer, some findings from the later stages of the project will also be included in the conference presentation.

*This research was supported in part by a grant from the Imperial Oil Centre for Studies in Science, Mathematics and Technology Education, The Ontario Institute for Studies in Education of the University of Toronto (OISE/UT), Toronto.
Theoretical and Empirical Background
The problem of "math anxiety" came to the fore in the early 1970's (e.g., Fennema, 1974; Tobias, 1976; 1978). Earlier research on gender issues indicated that females are more likely to develop math anxiety than males (e.g., Fennema & Sherman, 1976; Tobias, 1976; Zaslavsky, 1994). Moreover, math anxiety was shown to relate inversely to math performance and bound directly to avoidance of the subject (Hembree, 1990; Ho, et al., 2000). It was also shown that students who were exposed to traditional math instruction reported more math anxiety than those who were exposed to alternative emphasizing problem solving and discussion of students' own informal strategies (Newstead, 1995; 1998). Math anxiety was often considered as a subject-specific manifestation of the test anxiety construct. Since math anxiety lacked its own theoretical construct, researchers applied models of test anxiety theory to math anxiety (Hembree, 1990; Bandalos, Yates & Thorndike-Christ, 1995; Ho & al. 2000). More recently, however, researchers identified other components of math anxiety besides test anxiety, such as problem solving anxiety, abstraction anxiety, or fear of the public aspects of doing math in the classroom (Newstead, 1998; McLeod, 1992; Hembrees, 1990; Brown & Gray, 1992).

There has also been much research on other aspects of affect, such as attitudes toward, and beliefs about math (e.g., Thompson, 1992; Battista, 1994; Ma and Kishor, 1997; a Gierl & Bisanz, 1994; Hannula, 1998; McLeod, 1992). A number of researchers have been exploring the whole array of affect in mathematics, including attitudes, beliefs and emotions (DeBellis & Goldin, 1997; McLeod, 1989). Particularly, in recent years there has been discussion of the unstable nature of some of these constructs and their dependence on the context in which they are observed. For instance, Tirosh (1993) uses the term: "specific affects" to describe students' emotions, attitudes and beliefs as they react to specific mathematical situations, activities or topics. With regards to attitudes, it has been suggested that they are unstable and unreliable and are strongly influenced by the specific conditions in which they are observed or perceived (Gellert, 2001, Martino & Zan, 2001; Ruffell, Mason & Allen, 1998). The approach used in this study is based on the above distinctions and we will also deal with particular manifestations of affect as they arise in specific situations.

Methodology
This is a qualitative case study of the group of teachers that will participate in the workshop series. We also hope to conduct individual case studies with two of the teacher participants. Data collection has already started with the teacher interviews, and will continue throughout the duration of the workshops and in the final teacher interviews following the workshops. Participants consist of 12 grade 5-8 classroom teachers who have self-identified as having math related anxieties.

Following the initial interviews (half which have already taken place), these teachers will participate in a series of seven "math empowerment" workshops during February and March of 2002. The workshops will utilize a holistic approach, including a focus
on math learning and teaching approaches, combined with activities for emotional, psychological and social support. Constructivist principles (Confrey, 1990) and the NCTM Principles and Standards (2000) will guide the math learning component. Workshops will include small group work on various math tasks and problems, sharing and discussion, along with group reflection, journal writing, guided visualization and relaxation activities (Tobias, 1978; 1989; Eisenberg, 1992; Martinez, 1987; Zaslavsky, 1994). The workshops will provide a safe and supportive environment to help participants feel secure and free to take risks. Participants will be also able to interact via email or phone with each other and with the researcher at any time in-between workshops, so they can feel fully supported in-between workshops.

Data Collection: Besides the initial and final interviews, data will also be collected during the workshops and will include:(i) Samples of participants’ work on math tasks during the workshops;(ii) Samples of participants’ reflections written during the workshops; (iii) Transcripts of 5-6 recorded discussions involving participants working in small groups; (iv) Questionnaires to be administered three times during the workshop series; and (v) Field notes taken by the researcher and research assistant during workshops and interviews.

Initial Findings and Discussion
The findings reported here are based on transcripts of the interviews with six of the teachers. The interviews were semi-structured and lasted 40-65 minutes. The findings will be discussed according to the main themes that arose in the interviews.

Participants' Difficulties During Their Own Schooling: In one of the interview questions participants were asked to recall their elementary and secondary school experiences in math. Four of them experienced problems with math in elementary school, and all of them had problems in high-school. When asked about how she felt about math in elementary school, Sarah, a young grade 6 teacher, talked about the many tears she had shed about math during that period, and described her difficulties and how she came to hate math:

- Do you remember if you had any specific difficulties when learning math?
- Um, Yeah, multiplication especially. It was really difficult for me, all through public school and even into high school.
- When would that have started?
- Grade 4! [big laugh from Sarah]. And I, I really remember it. And it wasn’t until actually I started teaching multiplication when somebody told me it was repeated addition, I never understood what I was doing.
- Sarah!
- And, all the way through public school I remember I hated it. And I have memories of doing “mental math.” I always hated that. And when teachers go around, and they ask you, you do it in order?
- Yes.
- And I would sit going, “Oh, please, what question?” and I would there and count backwards to see which one I was going to get.
- Oh my!
- And I remember I finally got one right one day, and my teacher went, "Look everybody, Sarah FINALLY got one right!" And it was that comment that threw me off for the rest of my life. I hated it since then.

For Sarah, the above incident has made a lasting impact and set the stage for the development of her math anxiety.

**Participants' Math Teachers' Teaching Styles:** When asked about the teaching styles of their teachers in both elementary and secondary school, participants described them as very traditional and textbook-based. One participant talked about her frustration when she wanted to know why things were to be done in a certain way, but nobody could tell her:

> I remember them placing more emphasis on skills and procedures. That's what I remember. If they did something other, you know, I don't want to take credit away from them because they may have, but I remember the procedures and the skills being very specific, our homework being very specific in that way – you have to do this and this in order to get that answer. And the problem that I had at the time when I had homework, I would often ask my brother to help me, I have an older brother, and the thing that I always asked was "Why?" I remember this very clearly, as I was asking him, "Well why do you do that?" And he would say "This then this, make this." "Why?" And nobody answered why and it bothered me. I wanted to know why because it made no sense to me. That this and this would equal, that.

Another young participant stated that the teachers' 'drill and kill' approach made math a boring and meaningless subject for her. This is how she kept herself busy during math lessons:

- ...But, especially Gr. 11 I wasn't with it at all. Gr. 10, I spaced out in class. I actually, I used to write songs about math. [laughter]
- Do you have any of them still?
- I do.
- You'll have to bring them to the workshops.
- I have this whole series – The Pythagorean Song Series.
- Really?
- Oh yeah, about like, "Pythagorus, I love your root hypotonous..." I made like whole songs and poems and stuff. [laughter] That's what I did in math.

Not surprisingly, research has shown that teachers who identify their own math teachers as having stressed computation and drill are more likely to be math anxious than teachers whose math teachers had stressed understanding (Carroll, Widmer and Chavez, 1979; Hembree, 1990).

**Participants' Teaching Styles and Classroom Challenges**
The teachers had a lot to say about how their limited math knowledge impaired their teaching and expressed concern about not giving their students the right skills they would need later. A grade 7 teacher who is also a music specialist said:
- I just teach from the textbook and I don't do that in any other subject... but I just feel like. I don't know it so I guess I just decided to do it, exactly following the prescription...
- That's quite common.
- Yeah... It's just like playing a musical instrument, I understand that you need to read the notes, you need your fingering, you need the sound of it in your head, so you need all these different components so then I can break it down and teach each of these components... With the math, I just don't know what to teach first, I don't know what the smallest stuff is... so I just follow the book.

Another participant reflects on the impact of her negative school experiences on her teaching:

- After having described your math history, can you sort of pinpoint where your anxiety comes from?
- Yes, I almost think it's lack of support during my whole math career... because... I think it's not being able to extend my knowledge of math.... I have the basics but I can't extend it...
- Do you feel you are stunted somehow?
- In some ways, yeah, .. I mean, .. you know, even in my own classroom in teaching math I find it difficult to bring them beyond the basics..... how do you extend that knowledge .... and some of these kids have some pretty interesting questions that I'm stuck because I have the basic knowledge but find it difficult to extend it...

As is typical for math anxious people, the two teachers cited above are unable to experience any creativity when it comes to math. They seem to lack the relational (or conceptual) understanding required in order to be creative. (Skemp, 1978)

Teachers' Coping Strategies:

The same teacher cited above then went on to describe her ways of coping with her teaching challenges:

- ... I now have to do a lot of extra work for myself; in order to walk into the math class prepared I practically do the homework myself in order to make sure I know exactly...
- How much time you spend preparing for a math class?
- Probably around a good hour for each math class, plus marking, ... so that I make sure that I can answer even their basic questions... and you know, I have some pretty bright students in my class... but you know, I also depend on a lot of the bright students in my class because they often see, ... and are able to explain things sometimes better than I can... or in a different way, at the kids level...

Interestingly, over-preparing for lessons and doing all the exercises ahead of time has been mentioned in the literature as a strategy that helped teachers compensate for their anxieties (Martinez, 1987).
All of the interviewees discussed their worries about being asked difficult questions in class that they were unable to answer, or being asked to solve a new problem unlike the ones in the text. In the excerpt above the teacher describes a common coping strategy for dealing with such situations: asking for help from the bright students in the class. A couple of other participants reported using similar strategies and were able to ask for help from their brightest students. But some of the participants had a problem with admitting to their class they did not know how to solve a problem. One of the teachers stated that "I am the teacher, so I am expected to know the answer". He would not admit to his grade 8 class that he did not know the solution to a problem and found other ways of getting by. Sometimes he would pretend he knew the solution but asked one or two of the bright students to solve the problem on the blackboard. At other times he would shift to another activity and seek help from his colleagues after class.

Various Types of Math-Related Anxiety:

As seen above, these teachers reported a number of different types of math-related anxieties, from the "classical" math anxiety (or "mathophobia" defined by the early researchers (Lazarus, 1974; Tobias, 1978) to more specific anxieties in relation to specific topics, activities or teaching situations. By far the most dreaded teaching situation for all participants was being asked a difficult question in class that they could not answer. Teachers devised a variety of coping strategies for dealing with such occurrences, as was discussed above.

When asked which math strands or topics they felt the most apprehensive about, the teachers varied quite a bit in their responses. Some mentioned geometry as a difficult topic, while others were pleased to report they found geometry easy because they could "see it". Measurement was considered "manageable" by most of them. Yet nearly all of the teachers mentioned algebra as a topic they were most apprehensive about, obviously because of its abstract nature, and had difficulty explaining it to their students. Abstraction anxiety has been a focus of some research (e.g. Brown & Gray, 1992).

Problem solving anxiety (McLeod & Adams, 1989) was by far the most dominant within this group and manifested in participants' fear of being asked to solve an unfamiliar problem in front of their class. It was also the reason why some participants reported solving all the relevant textbook problems prior to class. The last question in the interview was aimed at assessing teachers' degree of problem solving anxiety and whether they would exhibit resourcefulness and optimism, or feel helpless and hopeless, when faced with a non-routine math problem. The question asked:

- Suppose I were to give you an open-ended, non-traditional math problem to solve right now. What would be your immediate reaction? How would you feel about being given this problem to solve? – (Probe as necessary: identify emotion, identify bodily reactions) - Would you attempt to solve the problem?
Here is a grade 7 teacher's response to this question:

- Suppose I were to give you an open-ended, non-routine math problem... (teacher tightens up in her chair, looking very nervous).... Just SUPPOSE I were to give you a math problem, I am NOT actually giving you one! - How would you react? - What would you do?
- Just you saying that is making my stomach go in a big knot... Oh, I just hope she's not going to ask me a math problem...
- Would you try to solve it?
- No way! (appears to be frightened)

This response demonstrates this teacher's learned helplessness when it comes to math problem solving. Learned helplessness happens when a person has experienced repeated failures in the past and believes that whatever their effort in the future, the outcome for them will not change. It's a feeling of loss of control. (Gentile and Monaco, 1986).

There was one more participant who exhibited learned helplessness when answering this question. The other four participants replied that they might feel somewhat uneasy but would go ahead and try to solve the problem. It could very well be that some of the more severe cases of math anxiety are indeed related to learned helplessness. This phenomenon deserves further study.

In conclusion, this was an initial report on some of the early findings in our project. We are looking forward to starting the workshop series where we hope to gain a much deeper and richer understanding of the participants' cognitive and affective responses to doing math tasks and their progress in trying to deal with their math anxieties.

References

We explore how college students understand ideas of functions, and which representations are productive for them in promoting their ability to work flexibly across representations. We use pre- and post-test scores, and triangulations via student self evaluations, to generate a hypothesis related to flexible thinking and success in algebra. We use confidence intervals to provide evidence for a highly significant change in student flexibility in algebraic thinking, and to assist in generating a plausible model of how the use of function machines in a developmental algebra course is instrumental in stimulating that flexibility.

INTRODUCTION

Students who present in developmental algebra, in universities and two-year colleges, commonly see mathematics as consisting solely of procedures and formulas. Unfortunately this vision of mathematics does not generally assist them in carrying out the procedures accurately, efficiently or appropriately, or in getting the formulas right in context. The unifying idea of a function is generally not something with which developmental algebra students are familiar or comfortable. Further their mathematical thinking, focussed principally on procedures and “correct” formulas, is largely inflexible and highly context specific. We relate the ideas of functions as a unifying concept in algebra, and flexibility of algebraic thought, through the use of function machines as a generic representation of functions with power to assist students in becoming more flexible and competent in their algebraic thinking.

Functions and function machines

Students often rely on intuitive and unreflective ideas of functional relationships. The subtlety of the function concept with its process-object duality and various representations proves to be highly complex. It is a concept, with wide-ranging powers and with widespread misunderstandings, that has been studied extensively in recent years (see, for example, Markovits, Eylon & Bruckheimer, 1986; Vinner & Dreyfus, 1989; Leinhardt, Zaslavsky, & Stein, 1990; Harel & Dubinsky, 1992; Cooney & Wilson, 1993; Even, 1993; Cuoco, 1994; Thompson, 1994; Wilson & Krapfl, 1994; DeMarois & Tall, 1999; Lloyd & Wilson, 1998). Both teachers’ and students’ conceptions of functions are of enduring interest in mathematics education, because of the fundamental organizing and analytic role in mathematics played by modern reflective notions of functions. Various representations of function (table, graph, algebraic, for example) may be seen as ways of representing calculation of an input-output relationship. Functions viewed as input-output machines were studied in mathematics education as far back as 1965 by Peter Braunfeld. Tall, McGowen & DeMarois (2000) proposed the function machine box as a generic image that can act...
as a cognitive root, embodying the salient features of the idea of function, including process (input-output) and object, with various representations seen as methods of controlling input-output. The function machine embodies both an object-like status and the process aspect from input to output. Recent studies (McGowen, DeMarois & Tall, 2000; McGowen & Tall, 1999) indicate that the introduction of the function machine as an input-output box enables students to have a mental image of a box that can be used to describe and name various processes. This can take place often without the necessity of having an explicit process defined. Other forms of representation may be seen as mechanisms that allow an assignment to be made - by a table, by reading a graph, by using a formula, or by some other assignment procedure.

**Flexibility**

Krutetskii characterized flexible thinking as reversibility: the establishment of two-way relationships indicated by an ability to “make the transition from a ‘direct’ association to its corresponding ‘reverse’ association” (Krutetskii, 1969, p. 50). Gray and Tall (1994) characterize flexible thinking in terms of an ability to move between interpreting notation as a process to do something (procedural) and as an object to think with and about (conceptual), depending upon the context. In this article, flexibility of thought encompasses both Krutetskii’s and Gray & Tall’s ideas as facets of a broader notion of flexibility. In addition to reversible associations, and proceptual thinking, we are interested in connections between various representations of functions, including tables, graphs and algebraic syntax, which we refer to as conceptual. The proceptual divide (Gray & Tall, 1994) is, in a broader sense, part of a conceptual divide in which flexibility is compounded by student difficulties in using and translating among various representational forms.

The theoretical background on flexibility suggested we pair questions so that a student scoring correct on both of a pair was evidence of flexible thinking for that student. For example, for a simple function f we might ask: (a) what is f(5) ? and also ask (b) for what value or values of x is f(x) = 0? Essentially this is the difference between evaluating a function and solving for a value. 12 of a total of 31 questions were organized in pairs - 6 pairs in all. Question pairs addressed differing representations of functions: syntactic formulas, tables, graphs, and function machines. Success in both questions of a given pair was regarded as an indication of flexibility of algebraic thinking with respect to the representation for that question pair. Question pair 8 & 9 (Q8. Given f(x) = x² - 5x + 3, find f(-3); Q9. Given f(x) = x² - 5x + 3, find f(t-2)) relates to flexibility in that a student who can answer both questions correctly can substitute a number for a variable in an algebraic expression, and can also generalize the substitution from numbers to the situation of another algebraic expression in a different variable. Question pairs 10 & 11, 12 & 13, 14 & 15, and 16 & 17 are all concerned with evaluation versus solving. Success on both questions for any one of these question pairs indicates flexible algebraic thinking in the sense of Krutetskii. Details of question pairs 14 & 15 and 16 & 17 are given below in the results.
METHOD
Data were collected from a cohort of students taking a common 16 week course in developmental algebra at a two-year college. Data were of two sorts: pre-test and post-test scores (weeks 1 and 16 respectively; identical questions), and student written self-evaluations, turned in by week 16. Of the 135 students initially enrolled in the course, 87 students completed the course and were taught in 6 sections by 4 different instructors. The text for the course (DeMarois et al, 2001) emphasized the use of function machines, as well as syntactic algebraic formulas, tables, graphs and finite differences. However, function machines are not mentioned explicitly after chapter 3. Instructions given to students for their self-evaluations included: “What mathematics have you learned during this time? Write a summary of what you have learned.” Students were asked to cite specific examples of mathematical growth, and to place their mathematical understanding, knowledge and skills competencies, in the context of Clarke, Helme & Kessel’s (1996) criteria for meaningful learning in mathematics. They were not explicitly or specifically asked to address function machine or other representations for functions.

RESULTS AND ANALYSIS
Students’ pre- and post-test responses were significantly different. We present results for the set of linked pairs of questions: 6 pairs, comprising 12 questions of the complete set of 31. The inter-item reliability (Cronbach’s alpha) of the linked pairs of questions on the pre-test was 0.43 and on the post-test 0.88 (identical questions on the pre- and post-test). Since the questions did not change from pre-test to post-test, we conclude that this cohort of students saw the questions as having greater internal consistency at the end of the course than at the beginning. The correlation between pre-test and post-test scores for the linked pairs of questions was small and statistically significant ($r^2 = 0.04, p < 0.05$). This indicates no linear relationship between pre-test and post-test scores on the paired questions: students did not increase uniformly and proportionately from pre-test to post-test.

A confidence interval analysis for the paired two-sample difference in proportions, between the pre- and post-tests, of students who correctly answered both of a linked pair of questions yielded the results shown in table 1, below. Note that for the first linked pair (questions 8 & 9) one section comprising 12 students was not available for analysis, so the data there comes from 75, rather than 87, students.

The differences in proportions are all significant at the 99% level: no 99% confidence interval for the difference in means contains 0. In the context of the other question pairs, the least significant difference in proportions correct on both of a linked question pair is that for questions 14 & 15:

Questions 14 & 15: A function table copied from a TI-82 graphics calculator is shown:

Question 14: What are the output(s) if the input is -2?
Question 15: What are the input(s) if the output is -3?

The most significant difference in proportions correct on both of a linked question pair is that for the linked pair of questions 16 and 17, which are as follows:

Questions 16 & 17: Consider the equation \( y = 3x - 7 \).

Question 16. What are the output(s) if the input is 5?

Question 17. What are the input(s) if the output is 0?

Table 1: 95% & 99% confidence intervals for differences in proportions pre- to post-test, of students getting both question pairs correct. Note that none of the confidence intervals contains the value 0 and that the confidence intervals show effect size.

The confidence intervals, at varying confidence levels, and the relative effect sizes can be seen in a visually striking way via confidence bands. These consist of a plot of the confidence interval, for the difference in proportions, versus the specified confidence level. In Figure 1, below, we illustrate these confidence bands, for confidence levels between 0.95 and 0.99, for the question pairs 14 & 15 and 16 & 17.

Figure 1. Confidence bands: confidence intervals for a difference in proportions, pre-test to post-test (vertical axes) versus confidence level (horizontal axes). The straight horizontal lines show the difference in proportions for the sample of 87 students
Student written self-evaluations

Student written self-evaluations indicated that many feel a function machine model assists them to make sense of notation, to organize their thinking, and to produce equations to describe data. References to input and output occurred in the work and interviews throughout the semester of students who were successful. They used the function machine notion to organize their thinking as they worked problems and interpreted notation. In contrast to the more successful students, the least successful students made very few references to function machines in their work or in the vocabulary they used. The least successful students demonstrated little or no improvement in their ability to think flexibly. Students were deemed "least successful" by a combination of post-test, final examination, and final portfolio grades - all of which form the components of a student's final grade for the course. Usually the top 15% and the bottom 15% of the class, after final course grades are determined, are examined to identify the most and least successful students, given the 15% criteria. Given class sizes, this is generally the top 3 to 4 and bottom 3 to 4 students in any given class.

Excerpts from self-evaluations for some of the more successful students are provided below.

Student A: I know that function machines are good models for mathematical relationships when one wants to clearly identify and separate the input, output and process. I also can look at function notation, f(x), and understand what it is stating: That f is a function of x. I see the input (x), the output f(x), and the process, when in a relationship form like f(x) = 3x + 10. I know now that 'solving' can refer to many different things including: 1) solving for an unknown variable; 2) solving a system of equations (where the given functions share the same input and output values); and 3) solving an equation (finding the input value(s) that produce an output of 0).

Student B: Function machines are a great way to visualize the process of inputting, finding # processing, and finding the output. Before I never knew there was a difference between evaluating, simplifying, and solving an equation. We EVALUATE the function to find the output of a function when the input is given. After we evaluate, we simplify using various mathematical properties such as associative, distributive, and identify. We use order of operations to obtain the output or the answer. We SOLVE to find the input, given the output. Numerically, a linear relationship is the change between two outputs divided by the change between corresponding inputs that always produce a constant slope.

Student C: I now have the skills to interpret and use mathematical notations appropriately, reflected in my work and ability to interpret a function machine; convert from one type of mathematical notation to another, convert a function machine to an equation/equation to function machine. I have identified inputs and outputs, which was the key to answering the questions, appropriately and accurately in my tests on questions involving: recognizing the given slope to make a table, showing input/output;
identification of a given notation and breaking it down by input/output; naming input/output from a given function machine or equation; finding output if given input/finding input if given output.... I am knowledgeable in understanding the difference between evaluating and solving: solving for $X$; evaluating for $Y$. I have learned more about equations and functions during the past 4 months than I have ever learned in my lifetime.

Student D: I had no idea what function is and what a relation is, but now I do. Relation is mathematical notation with at least two variables. Independent one is input. Dependent is output. I know that relation, which has only one output for each given input is a function. If I see $f(8) = x + 7$, I know I am given an input. $f(x) = 8$ gives me output. I can work with ordered pairs. In case $(8, 45)$, I see 8 as input and 45 as output.

CONCLUSION

The major lesson to be learned from our analysis of the data collected on the pre- and post-tests and student self-evaluations is that some factor (or factors) across 6 classes, with 87 students and 4 instructors, is associated with a dramatic change in flexibility of algebraic thinking at the whole class level. An emphasis on functions as machines is the novel element that is likely to assist students to form mental images to assist them in the interpretation and use of syntactic algebra. How far and wide, and how strong across ability ranges, this effect might be we do not yet know. The evidence we have presented suggests that the representation of functions as function machines assists students' understanding of or development in algebra, and provides them with models that will require no significant re-shaping and modification in further mathematical studies.

The average increase in syntactic skills over the 16 week course was very significant. The linked question pair showing the highest gain consisted of syntactic algebra questions 16 & 17, asking about input and output for the function $f(x) = 3x - 7$. The mean gain, across the cohort of 87 students, for the average number of correct answers to both these questions, from pre-test to post-test, was a very high 0.82 (ref. Hake, 1998). This is very strong evidence that students were flexible, in the sense of Krutetskii, in interpreting this type of syntactic algebra question by the end of the course, compared with a general inflexibility at the beginning.

A function machine representation was used throughout the text (DeMarois et al, 2001) and the course as a means of helping students make sense of notation and to understand processes of “solving an equation” versus “evaluating a function”. The pre-post tests show a statistically highly significant increase in students’ ability to use algebraic notation. This, taken together with student self-evaluations, suggests strongly, but does not prove, that a function machine representation provides students with a way of organizing their thinking and with a more process-oriented view of mathematics.

This approach may not be appropriate for all students at all levels. However, for students who have had algebra previously and place into a developmental algebra courses, starting with a process notion of function and a function machine.
representation seems to help them make sense of notation. Such students believe they need to be able to manipulate symbols successfully and, as a consequence of this belief, focus on being able to "do algebra": that is, manipulate syntactic expressions. A function machine representation provides them with a potential means to organize their thinking so they can be more successful in dealing with notation than in their past experiences with algebra.

Student work and writings are replete with references to "input" and "output" in their concept maps, their explanations, and in their self-evaluations - indications that introduction and use of function machines impacted their thinking and provided an organizing tool or principle throughout the semester.

We hypothesize that use of a function machine representation of functions correlates with a student’s ability to work flexibly across syntactic, graphical, and tabular representations. More specifically, we hypothesize that:

1. a student’s ability to form mental images of functions as machines;
2. use of a graphing calculator as a concrete manifestation of a function machine; and
3. use of finite differences and finite ratios to make sense of parameters and to help students have some understanding of where equations come from, given data;

are jointly highly and significantly correlated with their ability to utilize syntactic algebraic representations of functions and, to some extent, correlated with an ability to utilize graphical and tabular representations of functions. The pre- and post-test data we have presented, together with student self-evaluations, provides a strong foundation for this hypothesis. The class of students we studied dramatically increased syntactic algebraic skills over a period of 16 weeks. Many of the students stated explicitly this was due to understanding functions as processes, through a representation as function machines, particularly the ability to form images of function machines, and through the use of finite differences in conjunction with function machine representations.

Implication is omnipresent as a tool in mathematics. However, this concept is neither clear nor easy. In this paper, we present a didactic analysis of implication under three points of view: sets, formal logic, deduction reasoning. For this study, our hypothesis is that most of the difficulties and mistakes, as well in the use of implication as in its understanding, are due to the lack of links in education between those three points of view. Then, we will show, thanks to the analysis of a problem from our experimentations, how the sets point of view can be implied in geometry, even with few knowledge.

INTRODUCTION

The implication seems to be a transverse mathematical object. Although it is in the heart of any mathematical activity, since it is essential for the formulation of proof, it does not have a definite place in French teaching, and is hardly ever taught.

Moreover, the existence of the implication as an object of natural logic, leads to confuse it with the mathematical object. As a result, the implication seems to be a clear object. Yet, students have difficulties related to this concept until the end of university, especially with regard to necessary conditions and sufficient conditions.

Our theoretical framework is placed in the theory of French didactics, in particular, we use the tools of Vergnaud's conceptual fields theory and those of Brousseau's didactical situations theory. Our study is based on the work of V. Durand-Guerrier [Durand-Guerrier, 1999] on the one hand and of J. Rolland [Rolland, 1998] on the other hand. V. Durand-Guerrier shows, in particular, the importance of the contingent statements for the comprehension of the implication. J. Rolland, as for him, was interested in the distinction between sufficient condition and necessary condition.

We will present three points of view on the implication and their place in French teaching. Then we will show, on some examples, the effects of a causal conception of the implication. Lastly, we will study a problem of geometry taken from an activity tested on beginner teachers of mathematics during year 2001.

THREE POINTS OF VIEW ON THE IMPLICATION

The notion of implication does exist in natural logic as it is necessary to our everyday life. The mathematical implication then seems a model of the natural logic implication. Like any model, this mathematical concept is faithful from certain angles to that of natural logic but not from others. This distance between the
mathematical concept and the object of our everyday life leads to obstacles in the use of the mathematical concept. An epistemological analysis [Deloustal, 2000] enabled us to distinguish three points of view on the implication: formal logic point of view, deductive reasoning point of view, sets point of view.

Of course, these three points of view are linked and their intersections are not empty. We will not develop here the formal logic point of view (for example truth tables or formal writing of the implication).

We call "deductive reasoning" the structure of an inference step: "A is true; A implies B is true; Thus B is true". Its ternary structure includes a premise "A is true", the reference to an established knowledge "A \implies B" and a conclusion "B is true" [Duval, 1993, p 44]. The reference statement may be a theorem, a property, a definition, etc. One thus builds a chain of inference steps: the proposition obtained as the conclusion of a given step is "recycled" as the entrance proposition of the following step. Therefore, in the deductive reasoning, the implication object is used only as a tool. However, in French secondary education, where this point of view is the only one, it often acts as a definition for the implication.

Generally speaking, having a sets point of view, means to consider that properties define sets of objects: to each property corresponds a set, the set of the objects which satisfy this property.

The sets point of view on the implication can then be expressed as follows: in the set $E$, if $A$ and $B$ are respectively the set of objects satisfying the property $A$ and the set of objects satisfying the property $B$. Then, the implication of $B$ by $A$ (i.e. $A \implies B$) is

```
\begin{array}{c}
\text{A true} \\
\text{A implies B} \\
\text{Thus B true}
\end{array}
```
satisfied by all the objects of the set $E$ excluded those which are in $A$ without being in $B$, i.e. by all the objects located in the area shaded below.

![Venn diagram](image)

**OBSERVATIONS IN FRENCH TEACHING**

The definitions of the implication or of the associated terms are hardly ever found in school textbooks. They appear in some first years of university textbooks and in some new highschool textbooks (syllabus 2000).

There is a compartmentalization of these points of view in French school textbooks, no link is established. Whereas the ensemblist point of view is completely missing (only the sentence "$A$ included in $B$ if for every $X$, $X \in A \Rightarrow X \in B$" can be found in some university textbooks), and whereas the logical point of view appears only in some university textbooks, the deductive reasoning is dominating particularly in the secondary school where it acts as a definition.

Secondary school textbooks do not assume the definition of the implication, which is identified with the natural logic object.

If... then: "standard" expression which tends to explain that if a property is satisfied, one can deduce from it that a second one is also. [in Mathématiques seconde, collection Pyramide, éd. Hachette éducation, 2000]

An implication is a mathematical sentence indicating that a data (1) involves or implies a conclusion (2) [in Mathématiques seconde, Déclic, éd. Hachette, 2000]

Many definitions of the implication, within the register of the deductive reasoning, connote an idea of causality and even temporality: "One has $Q$ as soon as one has $P$"; "If $P$ is true then $Q$ is true". This causal aspect is strengthened by the definition of the demonstration in school textbooks. Indeed, this one is presented like a succession of sentences, connected by theorems, properties or definitions, leading from the hypothesis to the conclusion.

To prove that the statement "$P$ implies $Q$" is true, is to prove that, on the basis of the hypothesis $P$ is true, one reaches, by observing rules of calculation, theorems, definitions, the conclusion $Q$ is true. [in Mathématiques seconde, IREM de Poitiers, éd. Bréal, 2000]

**CAUSAL CONCEPTION OF THE IMPLICATION**

A conception is "a set of rules, practices, knowledge which make it possible to solve a class of situations and problems in a satisfactory way, whereas there is another class of situations where this conception fails, either that it suggests false answers, or that the
results are obtained with difficulty and under adverse conditions." [according to Brousseau, 1997]

We understand by "causal conception of the implication" all the rules, practices and knowledges related to the interpretation of the sentence "A implies B" by "A is the cause of B". This conception of the implication is obviously very close to natural logic and its validity field is wide, it includes, in particular, all usual problems requiring a deductive reasoning. As we showed in the preceding paragraph, this conception is strengthened by teaching practices, but leads to inconsistencies in the use of the mathematical concept. Indeed, from this interpretation, one can easily derive the interpretation "A is the cause of B and only A" then the interpretation "A is the cause of B, A thus precedes B" which we will call "temporal conception of the implication". This last interpretation is reasonable within natural logic since in the physical universe, the cause precedes the effect! However, it leads to a paradox in the use of the mathematical implication: if $A \Rightarrow B$ is translated by "A is the cause of B and thus A is before B", how to accept that B is a necessary condition for A?

Here are some examples from our experimentations which illustrate errors that one can explain by the causal conception. They are Sarah’s answers, Sarah who studies for the competitive examination to be a teacher in secondary education.

- Give the negation of $P \Rightarrow Q$.
  
  Sarah: Q can exist without P existing.

- Are there implications between these expressions "M is a necessary condition for T" and "T is a sufficient condition for M"?
  
  Sarah: There are no implications between those expressions because T requires M and having T is sufficient for having M. [...] For me "M necessary condition for T", that means that necessarily one must have M to have T. Thus M implies T. In the second one, having T is sufficient for having M, therefore T implies M.

The "causal conception of the implication" model may explain many errors, in particular those due to the implication "which is not in the right way". Experimentations at university showed that, contrary to a widespread idea, a logic lecture is not enough to get rid of this conception and of the errors which result from it.

**RESEARCH HYPOTHESIS**

The experiments carried out for three years, within the framework of our research, have shown that the implication was not a clear object even for beginner teachers and that the difficulties were primarily due to a causal conception of the implication. Yet this causal conception is not only present in natural logic, but it is also strengthened by French teaching practices. Lastly, this conception may "live" in spite of a logic lecture. Following these comments, we formulate the research hypothesis:
it is necessary to know and establish links between these three points of view on the implication for a good apprehension and a correct use of it.

In the following paragraph we show that a problem of geometry, using only easy properties, may question the reasoning in a non obvious way and allow a work on the implication under the sets point of view.

STUDY OF A QUESTION OF THE GEOMETRY-PROBLEM

Let ABCD be a quadrilateral with two opposite sides with the same length. What conditions must diagonals satisfy to have: two other parallel sides (P1)?

In an usual French secondary education problem, the implication is generally in the way "A ⇒ B" where A and B are known. To solve the problem, one makes then use of a deductive reasoning in which A is considered as true. This implication usually takes place in a specific class of objects, for example quadrilaterals, triangles or parallelograms... One considers, in fact, the implication: "in H, A ⇒ B", but H is implicit when the corresponding class is "institutionalized", that is to say very well known and used, like in teaching. Indeed, if the implication is in the parallelograms class, to solve the problem one uses properties of the parallelograms implicitly (for example, convexity), without expliciting this restriction.

The search for sufficient conditions follows the model "in H, (A?) ⇒ B", i.e. what is the property A that is enough for the objects of the class H to satisfy, if they are to satisfy the property B as well. This is hardly ever practised in French teaching.

Our problem suggests yet another approach. The hypothesis "to have two same-lengthed opposite sides" does not, here, represent a class of "institutionalized" objects. This hypothesis must thus remain explicitly present during the resolution. Since the class H does not exist as such in teaching, it is necessary to come back to the associated property. There is thus, on the one hand, H which one knows and A that one does not know and, on the other hand, B that one knows. Between them, there is an implication whose direction is not given since we did not specify if the requested conditions were necessary or sufficient.

Let us present, now, three approaches which may induce different solving strategies.

The first approach raises the question of sufficient conditions. One may list conditions on diagonals (same length, perpendicular) and then check if these conditions, added with the hypothesis H, imply the conclusion B. This approach puts back the problem within the deductive point of view. Then, the found conditions are known as sufficient, but this strategy is "expensive".

The second approach refers to known objects. Some quadrilaterals which satisfy both H and B are well known, for example squares, rectangles, parallelograms. Besides, the properties of their diagonals are also well known, and then one can work directly with equivalences. However, if some conditions may be cheaply found, this strategy
does not give the exhaustiveness of the results, all the configurations are not a priori reached.

Lastly, the third approach raises the question of necessary conditions. Which objects satisfy both H and B? Then, what properties have their diagonals? This approach is basically related to sets point of view. Since the set $A$, such as the set $B$ contains the intersection of $A$ with $H$ is sought (in terms of properties: $A$ such as $(H$ and $A) \Rightarrow B$), seeking first the intersection of $H$ with $B$ (i.e. the objects satisfying both the properties H and B) seems natural. Then, there are two ways to study those objects which satisfy H and B, either to be in $H$ and add the property $B$, or to be in $B$ and add the property $H$. The first strategy is closer to the text of the problem but the second one looks easier. It seems, indeed, easier to draw two parallel sides than two same-lengthed opposite sides.

First sets point of view strategy: $H$ then $B$ ($H$: two equal opposite sides)

Once the points A and B placed in the plane, the hypothesis (H), $AD=BC$, means that the points C and D belong to two same-rayed circles respectively, one centred on B, the other centred on A. Once D placed, the property (B) "two other sides parallel", means that C is the intersection of the straight line parallel with $AB$ containing D with the centred on B circle. There are two intersection points $C_1$ and $C_2$.

Two configurations are thus obtained: isosceles trapezium ($ABC_1D$) and parallelogram ($ABC_2D$) [fig.1]. But one must not forget that, once A fixed, one may still change the distance $AB$, the ray of the circles and the position of D (linked to that of C) on its circle. So, when the two circles intersect, there is a new configuration: a cross quadrilateral called $CQ_1$ ($ABC_1D$) [fig.2]

So there is the implication: $(H$ and $B) \Rightarrow \text{parallelogram or isosceles trapezium or cross quadrilateral } CQ_1)$. We thus know the configurations which satisfy both H and B, it remains then to find the conditions on the diagonals.

However, for a quadrilateral, being a parallelogram is equivalent, to having diagonals which cross in their middle. This property is well-known by French pupils. Isosceles trapeziums and cross quadrilaterals $CQ_1$ have same-lengthed diagonals. Now remains to see whether "to have same-lengthed diagonals" ($A_1$) is a sufficient
condition, i.e. if the implication, within the quadrilaterals, (H) and (A1) ⇒ (isosceles trapezium or cross quadrilateral (CQ1)) is true.

For that, the sets point of view is necessary again, we have to study the quadrilaterals which satisfy (H) and (A1). We will not detail the rest of the solving, but let us say that these two conditions bring obviously the isosceles trapezium and the cross quadrilateral CQ1 but also a cross quadrilateral CQ2 (cross quadrilateral linked to parallelogram) which does not satisfy the conclusion (B). The condition "having same-lengthed diagonals " is thus not sufficient and will have to be restricted to exclude CQ2. The final solving of this exercise is not the subject of this article, but we wanted to show how this problem, with easy objects, can question the implication.

Second sets point of view strategy : B then H (B: two parallel opposite sides)

To express (B), one draws two parallel straight lines, one including A and B, the other including C and D. A, B, D being fixed, there are two points C so that AD=BC (ie so that (H) is satisfied) : C1 and C2. Two configurations are then obtained : parallelogram (ABC1D) and isosceles trapezium (ABC2D) [fig.3]. But, again, A being fixed, B and D can move on their line. Thus, when [BC] crosses [AD], a new configuration is obtained : a cross quadrilateral CQ1 (ABC2D) [fig.4]. The rest of the solving is the same as in the previous strategy.

Fig.3................................................................. Fig.4

This second strategy, also based on the sets point of view, is not as far-reaching as the preceding one. Indeed, proving that the conditions are sufficient needs to come back to the hypothesis (H) and thus needs to use the previous strategy.

CONCLUSION

The analysis of the students' answers of the whole geometry problem is still in progress. However, we can already say that, although students first found this exercise very easy, its solving required a very long research in groups. The answers are incomplete and, in the end, the students declared this exercise complicated.

Robert: "It is an exercise which as a teacher, I would not give before university"

The exercise fulfilled its role, as for the work on the implication, since discussions about necessary and sufficient conditions took place in the groups in an explicit or implicit way. In addition, the exercise also fulfilled its role, at least partly, as for the work on the sets point of view. In particular, to have the exhaustiveness of the results, the groups, which had drawn apart the cross quadrilaterals, had to take them again into account.
These results are to be placed among others. Indeed, this problem of geometry forms part of a six hour experimentation including other stages of work, in particular, studies, in groups, of written proofs and of a problem of discrete mathematics. Moreover, this experimentation takes sense when one knows that it was preceded by two others, carried out in 1999 and 2000. This problem of geometry is, thus, to consider as part of a broader context. Now, remains to finish the analysis of these results and to connect them together, this is our goal for next year.

1 We take into account the following expressions: P implies Q ; P brings to Q ; P thus Q ; Q is a consequence of P ; if P then Q ; P → Q ; P is a sufficient condition for Q ; Q is a necessary condition for P.

2 This will be detailed in the following paragraph.

3 We call validity domain of a conception the group of the situations which may be correctly solved with the practicities associated to this conception.

4 These experimentations were carried out in June 1999 with four mathematics students, [Deloustal, 2000].

5 This expression is equivalent, in mathematics, to the expression "P and Non Q".

6 These two expressions are equivalent, in mathematics, to the expression : "T implies M"

7 There were two other questions : two 90 degrees angle (P2) ; two other same lengthed sides (P3) ?

Teacher Behaviours that Influence Young Children's Reasoning

Carmel M Diezmann, James J Watters, Lyn D English

Queensland University of Technology, Australia

Abstract: Children are expected to develop the habit of reasoning from their earliest years at school. However, there has been limited emphasis on strategies that teachers can use to support young children's reasoning. We report on a case study of four teachers who implemented mathematical investigations that provided reasoning opportunities for their classes of seven-to-eight year olds. An analysis of teacher behaviours and their students' responses suggests that reasoning is influenced by (1) teachers' expectations of reasoned actions and responses, (2) instruction in reasoning as systematised thinking, and (3) authentic opportunities for reasoning. These influences are discussed together with examples of how these teacher behaviours support or inhibit reasoning.

Reasoning is central to mathematics as a discipline (Steen, 1999) and underpins mathematical learning (Russell, 1999). As the National Council of Teachers of Mathematics (2000) emphasizes, the ability to reason is essential to mathematical understanding, and should be a primary goal in mathematics education: "By developing ideas, exploring phenomena, justifying results, and using mathematical conjectures in all content areas and — with different expectations of sophistication — at all grade levels, students should see and expect that mathematics makes sense (p. 56). While the NCTM recommends that students from their earliest years at school should engage in reasoning activities, there are conflicting viewpoints about young children's capacity to reason. Some have proposed (e.g., Piaget & Inhelder, 1969) that there are developmental constraints to young children's reasoning. However these assumptions have been strongly challenged. For example, Tang and Ginsburg (1999) have argued that poor mathematical performance is a consequence of educational failure rather than children's inability to reason. Two alternative constraints to young children's reasoning have been proposed. First, young children's ability to reason is limited by their knowledge (Brown & Campione, 1994; Metz, 1997). Thus, reasoning is adversely affected by a weak knowledge base. Second, young children's reasoning can be inhibited by teacher competence (Brown & Campione, 1994). Metz (1997) argues persuasively that if the constraints to young children's knowledge and skill could be overcome then with judicious scaffolding, they should be able to engage in abstract reasoning. This hypothesis was supported in a study of young children's reasoning in mathematics and science that involved conjecture, argumentation, and evaluation of evidence (Watters & Diezmann, 1998).

Given that teacher competence can be a constraint to reasoning and the NCTM recommendations, the purpose of this paper is to identify the teacher behaviours that influence young children's reasoning. Teachers' competence in supporting young children's reasoning appears to be related to the nature of the instructional tasks, and the classroom culture.
Challenging Instructional Tasks
The teacher plays a crucial role in supporting the development of students' reasoning through the selection and implementation of cognitively challenging mathematics tasks (Henningsen & Stein, 1997). Hiebert et al. (1996) explain that the cognitive value of a task resides in the opportunity that it provides for students to explore and solve a problem. Teachers need to maintain the cognitive challenge in a task by proactively supporting students' cognitive activity without unnecessarily reducing the complexity of the task (Henningsen & Stein, 1997). While some tasks provide limited opportunities for reasoning, mathematical investigations are ideal tasks due to their scope for cognitive challenge (Boldt & Levine, 1999; Diezmann, Watters, & English, 2001). Investigations involve solving open-ended problems in which students make and test conjectures, engage in logical thinking, seek patterns and relationships, and explain and convince others of their viewpoints (e.g., Greenes, 1996).

Reasoning in the Classroom
Reasoning in the classroom is affected by teacher expectations, the classroom discourse, opportunities to make sense of mathematics through different types of reasoning and more general conditions such as a supportive climate. Gravemeijer, Cobb, Bowers, and Whitenack (2000) argue that in supportive classrooms: “(1) The students would explain and justify their thinking when contributing to whole-class discussions; (2) The students would listen to the contributions made by their classmates; (and) (3) The students would indicate when they did not understand a classmate’s explanation or contribution and ask clarifying questions” (p. 251). These expectations encourage student participation, and a quest for understanding. They also highlight the importance of productive discourse in mathematics whereby students explain their ideas, build on others' ideas, and generalize beyond a specific example (Sherin, Mendez, & Louis, 2000). Mathematical investigations involve the exploration of a particular line of thinking in which students use resources to test conjectures, and hence, engage in transformational reasoning. According to Simon (1996) transformational reasoning is a dynamic process in which the conclusion is reached by running physical or thought experiments. Investigations also provide opportunities for inductive and deductive reasoning when students generalize from their experiments or explain the chain of thinking that led them to particular conclusions.

While sound reasoning is ultimately the goal, instances of flawed reasoning are inevitable in classrooms where students are novice reasoners. Russell (1999) argues that flawed reasoning plays a dual role in the classroom. First, students need to practice the various components of reasoning (e.g. conjecturing). They also need opportunities to justify and critique their own and others’ reasoning, and respond to challenges to their reasoning. Second, flawed reasoning may also highlight mathematical issues that are relevant to the whole class and need to be addressed. For example, flawed reasoning may reveal that students hold the erroneous view that
it is acceptable to reach different solutions in a convergent problem if different solution processes have been used. Thus, teachers should be alert to flawed reasoning and capitalise on the learning opportunities they it presents.

**Design and Methods**

This research adopts a case study design (Yin, 1994) in which a teaching experiment was conducted with the goal of supporting the development of investigatory abilities in young children. The study was implemented in four Year 3 classes with a total of 95 children (ages 7-8 years) in a parochial school in a relatively affluent outer suburb of a major city. Three of the teachers had in excess of ten years teaching experience while the fourth was a first-year, albeit mature age, teacher. Class sizes ranged from 18 to 26 students with the smallest class containing two special needs students. Students engaged in a 90-minute session each week for 10 weeks focussing on mathematical investigations (Diezmann et al., 2001) that was taught by their classroom teachers. The teachers were provided with ongoing professional development about investigatory approaches and reasoning, and teachers and researchers met regularly during the ten-week period to debrief, plan, and evaluate the program. The case study database comprised achievement tests, teacher and student interviews, student work samples, teacher and researcher notes, and photographs of teachers’ and students’ classroom work. Additionally, two researchers (CMD, JJW), who were non-participant observers, captured salient events on video. An assistant videoed the whole class. Data were analysed using constant comparative strategies (Glaser & Strauss, 1967) to identify emerging patterns, themes, and issues related to young children’s reasoning and investigatory abilities while being sensitive to the existence of conflicting data to disconfirm the analysis. In this paper, we report on those data that inform us about how teachers can facilitate or inhibit reasoning behaviour in young children.

**Results**

Analysis of teacher behaviours revealed three patterns of interaction that influenced students’ reasoning. First, by providing modelling and timely intervention, teachers developed the perception that reasoning involves justifiable actions. Second, teachers built on this perception by encouraging students to engage in systematic thinking using the language, and strategies associated with reasoning. Third, teachers capitalised on situations and conversation to create opportunities for reasoning.

1. **Reasoned Actions and Responses**

Teachers developed an expectation of sense making in mathematics through their patterns of discourse with students and by modelling sense making. These behaviours included asking students to justify their responses and actions; encouraging students to use “because” in sharing information; pressing students to explain unclear or incomplete responses; rephrasing students’ words to enhance clarity; explicitly connecting ideas from different students; drawing students’ attention to critical aspects of tasks; negotiating step-by-step guidelines for accomplishing challenging tasks; and by justifying their own actions — as if thinking
aloud. The following examples illustrate how teachers influenced reasoned actions and responses from the students. In the first example, the teacher set up a clear expectation of reasoning to which the students responded. In contrast, in the second example, the teacher’s failure to address flawed reasoning inhibited reasoning.

**Smartie Can Example:** Students were working in small groups to predict how many Smarties (sweets) were in small opaque sealed canisters. In one group, Melissa predicted that there were 27 Smarties. She reached this prediction by establishing that the canister had a length and circumference of three Smarties and nine Smarties respectively and computing the product of these figures. After the teacher instructed the class to justify their conclusions, Melissa repeatedly resorted to demonstration and explanation to convince her group that 27 was a sound prediction. While the group readily accepted the plausibility of Melissa’s approach, they did not accept her prediction immediately. Melissa’s persuasive argumentation and use of evidence led to a vigorous group discussion, which culminated in unanimous support for her conclusion. Thus, the teacher’s clear expectation of reasoning resulted in this group striving to make sense of the task and each other’s responses.

**Card Game Example:** During a place value card game, the teacher generally prompted students to justify their actions and encouraged them to monitor and challenge each other’s actions. However, not all students’ reasoning was subject to the same level of scrutiny. Michael, a mathematically gifted student, twice engaged in flawed reasoning, which went unchallenged by either teacher or peers. For example, small groups of students were dealt three cards to represent a three-digit number (e.g., 2 4 3). They then took it in turns to draw a card from the pack (e.g., 8) and used it to make the highest possible number by replacing an existing card in the hundred’s, ten’s or one’s position (e.g., 8 4 3). When all cards had been used the person with the highest three-digit number was declared the winner. Michael had seven turns during this game and demonstrated flawed reasoning on his second and sixth turns. The teacher queried his reasoning on the second turn but did not press Michael for an explanation: “Why? Why didn’t you put it (the 1) on the one’s”? Michael shrugged and the teacher commented: “Now you have made it 30 smaller not just four smaller.” Michael again made an error on his sixth turn but his peers did not query his placement of cards, though they queried each other’s actions during the game.

![Card Game Example](image)

Michael’s exemption from justifying his actions is a concern. His flawed reasoning could be explained by disinterest if the game was insufficiently challenging. However, given that he was a keen participant in this game, was highly competitive, was playing with another capable student, and was observed to engage in flawed reasoning at other times, it seems more likely that Michael was either impulsive or did not fully understand the game. Thus, while the learning environment provided support for other students to account for their reasoning,
Michael was not afforded this same opportunity. Other students’ reasoning can also be inhibited if they unquestioningly accept responses from students, such as Michael, whom they somehow regard as infallible. Teachers also inhibited reasoned actions and responses through their use of recall-oriented questioning, limited wait time, and through inadequate responses to requests for assistance.

2. Reasoning as Systematised Thinking

These students were generally unfamiliar with the culture of reasoning. Teachers supported their enculturation into the practices of reasoning by developing relevant vocabulary; scaffolding students to make and test conjectures; challenging students’ assumptions; focusing students’ attention on the available evidence; promoting logical thinking; encouraging students to present their ideas as a chain of reasoning; and highlighting argumentation as a tool for evaluating alternative conclusions. The following examples illustrate the importance of discourse in developing students’ understanding that reasoning is systematised thinking. In the first example, the teacher’s interaction and use of mathematical language supported the students to think about the unanticipated result. In the second example, the teacher failed to adequately address the student’s incorrect use of everyday language, thus limiting the development of his knowledge that reasoning is systematised thinking.

**Speed Investigation:** During a class sharing session, one group reported on an investigation in which they explored whether the speed at which a Smartie rolls down a slope is affected by its colour. The group had predicted that colour would have no effect on speed. However, after completing their investigation, this group recorded that “coulor efex speed. We though it would’nt efet but it did [Sic]”. The class reaction to the group’s conclusion about colour being a critical variable for speed was mixed. The teacher worked from the students’ comments to draw attention to the ways in which the Smarties might have differed from each other apart from colour, thereby challenging the conclusion that colour alone affected speed. She also proposed how disagreements could be resolved through further investigation.

| Mark       | It might just be their weight or something. |
| Teacher    | So you think actually that probably some of the (differently coloured) Smarties were a little bigger than some of the other Smarties. And you think that is a better reason (than colour alone) for them sliding faster? |
| Andrew     | It could have been the way they were made. |
| Teacher    | Yes. You think they had different sizes and shapes? |
| Andrew     | We do think colour affected it as well. |
| Amanda     | I don’t think colour (alone) would affect it. |
| Teacher    | Why don’t you think colour would affect it? |
| Amanda     | Because, it doesn’t matter what colour it is. Colour is just to make it look better (on the surface). |
| Teacher    | Look different? ...So that is a very interesting point isn’t it. **We probably would have to investigate that a bit more before we come to some opinion that we all shared.** |
Colour Example: The class had been investigating the frequency of particular colours in boxes of Smarties. Michael’s report on his Smartie box was marked by idiosyncratic use of the terms “all” and “except”.

<table>
<thead>
<tr>
<th>Michael</th>
<th>We had all of them (colours) except green</th>
</tr>
</thead>
<tbody>
<tr>
<td>Teacher</td>
<td>You had every colour except green? Where there any white ones?</td>
</tr>
<tr>
<td>Michael</td>
<td>No.</td>
</tr>
<tr>
<td>Teacher</td>
<td>Were there any black ones?</td>
</tr>
<tr>
<td>Michael</td>
<td>No.</td>
</tr>
<tr>
<td>Teacher</td>
<td>Oh, any browns?</td>
</tr>
<tr>
<td>Michael</td>
<td>Yes.</td>
</tr>
</tbody>
</table>

Though the teacher challenged Michael’s statement twice, this was insufficient to prompt him to revise his statement that “We had all of them except green”. Thus, there was a need for the teacher to pursue this inconsistency and encourage Michael to reflect on his reasoning. This example illustrates the need to emphasise the correct use of everyday words that indicate class inclusion and exclusion, such as “all”, “every”, “any”, and “except”. The student in this example, Michael, was the gifted student also featured in the card game example. Thus, although Michael had a heightened capacity for reasoning, there were shortcomings in his reasoning, which needed to be addressed.

3. Authentic Opportunities for Reasoning
The use of intrinsically interesting situations can enhance young children’s motivation and commitment to reasoning. The following two examples illustrated how teachers promoted and limited opportunities for reasoning in these situations.

Story Example: One teacher promoted reasoning about quantity through her implementation of the story, “The Doorbell Rang” (Hutchins, 1986). This story involves the repeated occurrence of children sharing out a batch of 12 cookies but before they can eat the cookies the doorbell rings and they also have to share their cookies with the new arrivals. Thus, over time, each child receives fewer and fewer cookies. The teacher capitalised on the reasoning opportunities in this story through her organisation of and interaction with the students. She seated the class around a batch of cookies and assigned students to be the story characters. After the actors depicted the arrival of each new group of children in the story and shared the cookies out, the teacher asked questions, such as “Have they got the same amount of cookies? How do we know? How else could we know?” Through the enactment of the story and the teacher’s encouragement to reflect on what was happening, the class developed a clear understanding of the inverse relationship between the number of children who were to share the cookies and the quantity they would receive. Later in the story, the students were also able to ascertain the number of cookies each child would receive after Grandma arrived at the door with another batch of 12 cookies. Some students continued to use this experience as a referent. For example, over 12 weeks later, Alice reasoned from cookies when the outcome of a division was not a
whole number: “And if we had an odd number of cookies we had to do something ... like break them in half.” Hence, the implementation of the story provided a memorable referent from which the students could reason about quantity.

* Dissolving Smarties: Students were using Smarties to explore an aspect of mathematics. One group decided to explore what happened to Smarties after they had been dropped into hot water. This investigation provided opportunities for reasoning, about time, temperature, volume, and quantity. However during the investigation and in the subsequent sharing session, the teacher emphasised the “fun” element of the activity to the extent that the mathematical opportunities were overlooked. Thus, while it can be motivating for students to engage in interesting activities, the teacher needs to preserve and foster the mathematical value of the activities, and support students’ reasoning within the particular context.

**Conclusion**

Young children’s reasoning can be enhanced or inhibited by teachers’ behaviour through their discourse, the type of support they provide for their class, and how they implement mathematical tasks. Reasoning was promoted when teachers clearly valued reasoning, modelled reasoned actions and responses, and held high expectations of the class. The children responded to high expectations with continual attempts to engage in sense making in their actions and discourse, and challenges for their peers to do likewise. While these children were generally unfamiliar with reasoning as a systematic way of thinking, with ongoing teacher guidance and scaffolding, most children began to utilise at least some of the language, rules, and strategies associated with reasoning. Learning experiences that provided rich opportunities for students to develop and practice this more “formal” reasoning were those where the teacher focussed strongly on the mathematics in the situation and used the task to create a forum for reasoning about topics of interest.

These insights provide the base for us to extend our studies in developing more comprehensive documentation of the teacher behaviours that support and inhibit reasoning. If reasoning mathematically is to become “a habit of mind” (NCTM, 2000, p. 56) from the earliest years of schooling, action needs to be taken at preservice and inservice levels to develop the appropriate pedagogical content knowledge.

**References**

Watters, J. J., & Diezmann, C. M. (1998). “This is nothing like school”: Discourse and the social environment as key components in learning science. Early Childhood Development and Care, 140, 73-84.

This paper elaborates on the hypothesis (taken from psycholinguistics research) that the development of argumentative skills depends on contextual factors. With reference to Mathematics Education, the potential inherent in context complexity is investigated, distinguishing between different kinds of complexity. Some educational implications concerning the teacher's didactical choices are sketched.

The importance of argumentation [1] in Mathematics Education has been increasingly recognised in the last decade. In spite of the development of research concerning the 'why' of argumentation, a relatively small number of papers dealt with the 'how', in particular with the conditions suitable for the development of argumentative skills; only few dealt with the mathematical and extra-mathematical content of the problem situations as a relevant factor. However, there are good reasons to think about the relevance of these 'context' factors (for a discussion about the meaning of 'context' see the next Section). In psycholinguistics the hypothesis of context-dependence of argumentative skills was an object of widespread investigation during the 70s and the 80s (for surveys, see French, 1985; Sell, 1991). The aim of this paper is to investigate the potential of context complexity in the development of students' argumentative skills related to mathematics at primary school level. I will also draw attention to some conditions (as regards the teacher's choices) for the potential of context complexity to be exploited. The orientation of this paper is theoretical. However two teaching experiments, performed in the past with different purposes, will be shortly presented; they will provide the reader with some examples to ground the analysis.

THEORETICAL FRAMEWORK

The general hypothesis underlying the research reported in this paper is that the quality of students' argumentation strongly depends on the nature of the objects and situations which argumentation refers to, provided that suitable didactical choices (concerning the tasks and the educational environment) are performed by the teacher. This hypothesis draws on the context-dependence of peculiar forms of argumentation. Considering the contributions brought by "several major developmental theorists" (Brown, Donaldson, Gelman, and others) to research concerning contextual factors in cognitive development, L. French wrote: "They are in basic agreement about the importance of contextual factors in both the acquisition and display of cognitive abilities. Their essential premise is that cognitive competence initially arises within, is embedded within, and is practiced within particular contexts" (French, 1985, p. 321). Referring to specific psycholinguistic research concerning the acquisition and display of cognitive competencies related to the comprehension and use of relational terms ('because', 'if', 'but', 'or', etc.) she stressed the importance of "the content of sentences in which relational terms are embedded" (ibidem, p. 322).

As regards the meaning of the word 'context' in this paper, we can observe that, in Mathematics Education as well as in common language, the word 'context' may take
different meanings (for a survey see Wedege, 1999, pp 206-207). It can refer to constraints, signs, situations that must be considered by the student in accomplishing a given task ('reference context'); to the formulation of the task (context as 'text'-Freudenthal, 1991); and to the environment – in particular, the educational environment - where the activity takes place (the 'situation context' - see Wedege, 1999). In our hypothesis all the different meanings of the word 'context' intervene, and 'reference context'-dependence is not seen as isolated from 'situation context'-dependence. In the next Section we will consider some aspects of the 'reference context' (simply named 'context'), while some educational implications concerning the 'text' and the 'situation context' factors will be sketched in the last Section.

As concerns the argumentative skills considered in this paper, we will refer to the mastery of relational terms as well as more complex skills that intervene when contradictions are detected and made explicit, when coherence is questioned, etc. Tasks and argumentative skills will be considered in the perspective of mathematics education at primary school level, with an eye to more advanced mathematics.

In this paper, the potential of context complexity will be considered as regards both the number of elements to be co-ordinated in a problem situation (or in a set of tasks dealing with the same subject) and the quality of the links to be established (from simple juxtaposition to comparison, up to a comprehensive and coherent systematisation) (cf. Sell, 1991). This paper will elaborate on the specific educational hypothesis that primary school students’ argumentative skills can be enhanced by exploiting context complexity in two ways: for some students, as an opportunity of exercising specific argumentative skills; for other students, as an opportunity of approaching these skills through the interaction with more competent peers and/or the direct mediation of the teacher, who suggests the appropriate linguistic forms to express complexity (cf 'Zone of Proximal Development': Vygotsky, 1978, Chapt. VI).

**EXAMPLES**

Concrete examples illustrating the ideas developed in Section 4 will be taken from two teaching experiments performed by the Genoa Group Project in the years 1997 and 1999. The first experiment was carried out in a grade-II class and concerned the task of measuring the height of wheat plants growing in a pot with a ruler having a one-centimetre distance between the edge and the beginning of the scale: "How can we measure the height of the plants in our pot with our ruler, in order to account for their growth over time?". From the educational point of view, the task was aimed at constructing some operational invariants (Vergnaud, 1990) of the concept of measure, e.g. the translation invariance and the additivity of lengths. From the research point of view, the aim of the teaching experiment was to study the argumentative roots of the construction and refinement of those operational invariants up to an explicit and conscious mastery of them. The research was reported in Douek and Scali (2000).

The second experiment concerned the ‘Stefano’s problem’ in a IVth-grade class:

"At the beginning of classwork on sun shadows, Stefano (a VI grade student) thinks that shadows are longer when the sun is higher and stronger. Other students think the contrary. In order to explain his hypothesis, Stefano produces the following drawing:
and writes: "As we can see in the drawing, the sun makes a longer shadow when it is higher, that is at noon, when it is also stronger."

We know very well that shadows are longer when the sun is lower (early in the morning and late in the afternoon). So, in Stefano's reasoning there is something that does not work. What is wrong with Stefano's reasoning, and particularly with his drawing? Try to explain yourself clearly, so that Stefano can understand."

From the educational point of view, the aim of the task was to refine the model of the Sun shadows phenomenon (the 'shadow schema') already used by students in many activities. The task put into question the meaning of the word 'high' when referred to the 'height' of the Sun in the sky. A link with the concept of angle was implicit in the task. From the research point of view, the aim was to study the process of conceptualisation and the role of argumentation in it (see Douek, 1998 and 1999a).

In both experiments individual tasks were alternated with classroom discussions about individual productions, managed by the teacher. The experiments were performed in an educational context where verbal reporting of thinking processes (with no worry about their correctness) was an important element of the didactic contract.

SOME KINDS OF CONTEXT COMPLEXITY, AND ARGUMENTATION

Different kinds of context complexity will be considered in relation to their specific potential in the development of argumentative skills. We will move from complexity depending on the characteristics of the content of the problem situation, to complexity inherent in the tools needed to tackle the problem.

Time and Space Complexity

In mathematical modelling activities, objects and situations to be dealt with can belong to different space scales (micro-space, meso-space, macro-space: see Berthelot & Salin, 1992). They can also be involved with different time scales. We can observe that the passage from one space (or time) scale to the others entails relevant changes in cognitive processes. Complexity depends on the need for a comprehensive consideration of phenomena, which are to be analysed under different time and space scopes. The specific forms of argumentation which intervene in managing time and space complexity concern comparing arguments related to different space or time environments, or checking the validity of a statement according to different space or time scales, (etc.), particularly under the form of hypothetical reasoning.
In the specific case of 'Stefano's problem', space complexity intervenes when students must create links between the drawings (made in the micro-space of the sheet of paper), the observed phenomenon (happening in the meso-space of the courtyard experiment) and the phenomenon occurring in the macro-space of the sun system. During a classroom discussion concerning the problem of the 'command variables' of the geometric model of shadows, the teacher asked what would happen to his own shadow if he moved one step forward. He meant to put into question the relation between the virtual observation of his shadow if he moved forward and the schema drawn on the blackboard. A 'good' student, Federico, transferred to the macro-space what he could imagine in coherence with the schema on the blackboard, where the sun was drawn near the obstacle that cast the shadow. He said: "If you move, then your shadow becomes longer, because the Sun stays there and you go farther". The conception of the relative positions of sun, earth and obstacle in the macro space that had been developed during the experimental work in the meso-space of the courtyard, was replaced by the direct observation of the micro-space schema. As a consequence, it was then necessary to rebuild coherence between the previous conception and the schema. The evident contradiction of Federico’s statement with what many students knew (the invariance of the length of the shadows of a moving object) provoked high quality argumentation in the classroom. Some excerpts are reported below:

Simone: "I agree that the shadow will become longer; if you move in that drawing, the Sun does not move and you can see that the shadow becomes longer and longer"

Andrea: "I do not agree with Simone and Federico, I can give you an example: if you are in a car and move... for instance, from Turin to... to Pinerolo... you see the sun...always with the same height in the sky... and the shadow does not change. The position of the sun changes only if a long time elapses! So there is something that does not work in this drawing."

Mariella: "In the real world, near to the Earth, sun rays are parallel, while in this drawing... using this drawing... they are convergent".

Anna: "Yes, the sun is not there... it is very, very far"

Coherence was gradually reconstructed through argumentation by relying on different sources of arguments, as described in details in the next Section.

**Complexity of Sources of Arguments**

Arguments may originate from the classroom history, from empirical or theoretical evidence, from shared principles, etc. Complexity depends on the need for integrating different sources and making them coherent, when for example one source is not sufficient to get a satisfactory solution, or when some contradictions emerge. This need for integration and coherence requires specific forms of argumentation; the "A, while B", "A, but B" and "if A then B so C" clauses intervene as necessary tools.

Let us go back to Federico's confusion. A contradiction appeared between his statement, based on the 'shadow schema' drawn on the blackboard, and other references shared by his schoolmates. First, it clashed with another geometrical model previously elaborated in order to solve the specific problem of the effect of changing the position
At that moment she lacked arguments to choose another variable (the slope of the sunrays) and produce schemas coherent with her past experiences. The slope of the sunrays appeared as crucial during the following discussion, and various connected arguments were considered. In particular, the students recalled a past experience; with the help of the pictures taken in that occasion they represented the slope as the inclination of the arm pointing at the sun "moving in the sky" in different imagined positions. So a link with the static representation of the 'sun shadow schema' was established. Some excerpts are reported below:

Static-Dynamic Complexity

In applied mathematical problem solving, dynamic situations must be represented in a static way in order to elaborate the relations that connect relevant variables. For instance, in the case of Stefano's problem the dynamic evolution of the sun shadow phenomenon is usually represented (in the students' individual solving processes) through two or more drawings concerning specific states of the phenomenon itself. Complexity derives from the need for relating static representations to one another and to the evolution of the phenomenon in a coherent way. The argumentative skills involved concern the discussion of the coherence between representations and reality.

In particular, in the case of 'Stefano's problem', one student, Ambra, drew a pair of schemas in which the position of the sun and the inclination of the sunrays remained unchanged; instead she changed the height of the obstacle casting the shadow in order to obtain a shorter shadow at noon (this was a shared knowledge in the classroom). Ambra did not relate consciously the different hours of the day to the different positions of the sun in the sky. At that moment she lacked arguments to choose another variable (the slope of the sunrays) and produce schemas coherent with her past experiences. The slope of the sunrays appeared as crucial during the following discussion, and various connected arguments were considered. In particular, the students recalled a past experience; with the help of the pictures taken in that occasion they represented the slope as the inclination of the arm pointing at the sun "moving in the sky" in different imagined positions. So a link with the static representation of the 'sun shadow schema' was established. Some excerpts are reported below:

Fig. 2
"Amor's drawings do no work together, because the heights of the child are different, while in the real world the height does not change."

"It is the slope of our arms when we imagine ourselves pointing at the sun moving in the sky that changes."

"It is the slope of our arms in the pictures that changes, and so it is the slope of the rays in the sun shadow triangle that must change."

**Complexity Inherent in the Change of Frames**

A problem situation can be considered within different frames (for ‘frames’ in Mathematics Education, see Arzarello et al., 1995). For instance, some difficult Euclidean geometry problems can easily be solved within the frame of analytic geometry. Complexity depends on the need for comparing different frames and moving through argumentation from one to the other.

In the case of the 'Wheat plants measuring problem' this kind of complexity intervened during the individual solution phase, in which the students interacted with the teacher. The first thing most students wanted to do was pushing the ruler down into the pot, or breaking the bit before the zero (a concrete, physical solution). Then the teacher argued against such solutions (because they would damage either the roots or the ruler), so the students gradually switched to imagining to push the ruler (or to break it). The teacher drew their attention to the number they could read when the ruler was just beside the plant and the one they would read if the ruler was pushed down (or broken). The students had to consider both what they read and what they would read. Many of them developed solutions: either they imagined the numbers were all sliding, one after the other ('translation solution'), or they imagined to stick the little broken piece at the top of the plant ('additive solution'). They arrived to a solution within a material physical frame, consisting of virtual actions on real objects. When they came to writing their solutions or giving examples, in order to explain their solutions, they often moved to the numerical frame, and said "It is the following number" or "I add one to the number I can read". The physical solution was a necessary step to gradually get to a 'translation' or an 'additive' solution within the numerical frame. Afterwards, the solutions were shared in the classroom (see next Section) and a discussion followed. At the end, the students developed complex argumentation in order to account for the validity of each solution and compare the two solutions:

"In our case Rita's reasoning works, because 1 on the scale goes to 0 on the ground, and then 2 goes to 1, 3 goes to 2, and finally I can read the exact measure. But this shows that it works well because the initial piece of the ruler is 1 cm long. Alessia's reasoning always works because it is as if I broke it and add the initial piece, and I perform the same thing with numbers. And I can always do the same and add the number accounting for the measure of the initial piece, whatever it is."

**Complexity of External Representations**

A plurality of systems of signs (verbal, iconic or geometric, symbolic) may intervene in many mathematical activities (such as modelling). Complexity depends on the necessity of co-ordinating such signs and dealing with them in a functional way (cf Duval, 1995):
for instance, language as a command and reflective tool, geometric signs as models (as in Stefano’s problem), algebraic symbolism as computational devices, etc. In collective discussions this kind of complexity involves different games of interpretation and related argumentative skills, especially concerning the control of solution strategies.

In the ‘Wheat plant measuring’ activity, after the individual problem solving (in interaction with the teacher) and presentation of the ‘additive’ and ‘translation’ solutions, the students were provided with two drawings (to stick in their copy books) representing a wheat plant in its pot, and two paper rulers. They were first asked to express clearly (in written words) the ‘translation’ solution, and they all did it within the physical frame. Then they had to represent the translation of the numbers on the ruler with a sequence of arrows; and then to write the calculations that represented symbolically in the numerical frame what they got in the physical frame. They repeated this kind of representation for the ‘additive solution’. This activity allowed intensive argumentation in interaction with the teacher, because the teacher systematically asked to justify the arrows and the calculations with reference to the imagined virtual solutions within the physical frame. These solutions played the role of justifying the choice of the calculations that solved the problem. Here is an example of an individual text (after the interaction with the teacher):

"In words I can say that I move the ruler, so each number slides, it is as if each number vanished and became the following one: 0 becomes 1, and 1 becomes 2, and so on. If I have to show it I must draw arrows from 0 to 1, from 1 to 2. But to get the measure only the last step is important: I read 22 on the ruler, then 22+1 is the measure".

The same complexity in dealing with various representations can be found in the discussion about Ambra’s drawing in the ‘Stefano’s problem’.

**SOME REMARKS ABOUT THE ROLE OF THE TEACHER**

The exploitation of the potential inherent in the contextual elements described in the previous section relies on appropriate didactical choices made by the teacher.

First of all, we must consider the importance of the choice and formulation of tasks, and the choice of the right moment to perform them in the classroom, in order to avoid that complexity is reduced. Concerning the choice of tasks: A problem like the ‘Stefano’s problem’ involves different kinds of complexity, with an increased potential for argumentation. Concerning the text: In some experiments performed within the Genoa Group Project we have seen that the ‘Wheat plants measuring’ activity looses most of its potential if the following text is given to the students: “Keeping into account that plants cannot be extracted from the ground, that the ruler cannot be put into the ground and that the ruler has a one-centimeter distance between the edge and the scale, establish how to measure the height of wheat plants in the pot”. We saw that the percentage of good solutions decreased and the quality of the classroom discussion was lower. Probably, the formulation of the task guided the solution process and prevented students from detecting and managing the constraints of the problem situation. Moreover it is obvious that the argumentative potential of the problem situation cannot be exploited if the task is proposed too late.
Second, we must consider the management of classroom situations. As regards Stefano's problem, another teacher tried to exploit the same problem in her class. As a reaction to students' initial difficulties, she decided (before the classroom discussion about students' individual productions) to suggest the use of the concept of angle, saying that "the mistake of Stefano was to consider the height of the sun as a distance from the ground, not as the angle formed by the sunray with the ground". The consequence was that no real debate was developed during the following discussion and the students simply wrote (after the discussion) a more or less precise paraphrase of what the teacher had said.

NOTES
[1] In this paper, the word argumentation indicates two things. First, it denotes the individual or collective process that produces a logically connected, but not necessarily deductive, discourse about a given subject. This agrees with the first definition for 'Argumentation' provided by the Webster Dictionary: "1. The act of forming reasons, making induction, drawing conclusions, and applying them to the case under discussion". Second, it points at the text produced through that process, in accordance with the meaning the Webster dictionary presents: "3. Writing or speaking that argues". The linguistic context will allow the reader to select the appropriate meaning, whenever this word is used. In this paper, the word 'argument' is used with the meaning of "A reason or reasons offered for or against a proposition, opinion or measure" (Webster). So, an 'argumentation' consists of one or more logically connected 'arguments'.

REFERENCES
Duval, R.: Sémiosis et pensée humaine, Peter Lang, Berne
This paper considers students whose undergraduate study was characterised for them by either natural or alien learning and examines the ways they evolve or change their style of learning when they encounter independent graduate study in mathematics. We explore the changes they undergo and, towards the end of the paper, fit those movements into a developing theory grounded in the data from interviews with all the PhD students at one medium sized mathematics department in the UK.

Introduction

What happens when you find yourself learning on your own? While the notion of a transition is fundamental to many areas of mathematics education, the transition we examine in this paper is perhaps the one that we might genuinely call ‘becoming a mathematician’: the transition to independent graduate study.

The transitions in understanding concepts, social transitions that accompany changes between schooling levels and transitions between levels of abstraction/generalisation have all been the subject of significant research programmes within the mathematics education community. Often these transitions may co-occur: new concepts or different levels of abstract thinking can come just as students move to a new level of schooling. In each case, the new situation requires the learner to develop both new mathematical ideas and new ideas about the learning of mathematics and the didactic contract which must be negotiated between student and teacher. In this paper, we consider the situation in which, while there may still be a teacher (in the form of a supervisor), the relationship between the learner, the knowledge and this teacher is radically different from all those at previous levels.

We consider some of these aspects in relation to the transition between undergraduate study and independent graduate study (which, in the UK context, we take to be a substantial doctoral study leading to an original thesis in some field of mathematics). This paper examines the form this transition took for 13 PhD mathematics students – the entire available PhD population, who were at various stages in their work – at one
UK university and, in particular, the ways in which the students’ learning styles appeared to change in response to the new learning situation.

**Background and research method**

The existing literature on learning styles is quite extensive, but has been built predominately from studies at school or undergraduate level. The theories which have been developed have been useful in analysing the difficulties students have in learning new knowledge they encounter. Many of these are built around a basic dichotomy between students who seek to connect new knowledge with old and those who do not. Relational and instrumental understanding (Skemp, 1976), deep and surface learning (Marton & Saljo, 1976), procedural and conceptual knowledge (Hiebert & Lefevre, 1986) etc. all place this split at the centre of their theory.

In our own work (Duffin and Simpson, 1993), we have developed a theory of the ways in which learners might respond to new knowledge by absorbing it into existing structures (a *natural* response), limiting or modifying existing structures to deal with it (a *conflicting* response) or by building a new, initially separate structure to house the new knowledge (an *alien* response).

Following Pinto’s work with our theory (Pinto, 1998) we have extended this theory about responses to learning encounters to develop a split between learners. On the one hand we have those who attempt to make analogical connections between new knowledge and existing ideas and are loathe to accept knowledge which does not fit easily into existing structures (who we call *natural* learners). On the other we have those who are happy to develop a separate schema to cope with new experiences, perhaps only later using conflicts to connect pieces of knowledge together (who we call *alien* learners).

While student responses to the new learning environment they face in independent graduate study have been the subject of some research, it tends to be general, focussing across a large number of subject boundaries. The large, ESRC-funded projects reported in Burgess et al (1995), Pole et al (1997) while focussing significantly on the relationship between students and supervisors, suggested a split between students as ‘technicians’ (focussing on the skills required for research) and students as ‘scholars’ (focussing on the substantive knowledge uncovered). Similarly, Ford (1985) examined a split between holist and serialist graduate learners, albeit with students at masters, rather than independent doctoral level.

However, in this paper, we will see that when we focus more tightly on the specific topic of mathematics, the straightforward dichotomies of natural/alien, scholar/technician and holist/serialist need to be expanded.

We draw upon a larger paper based on semi-structured interviews focussing on two main areas of interest. We asked students about their personal learning histories from primary school onwards, but focussing more often on recent, accessible memories from their undergraduate study. We also asked them to consider their current learning
style, specifically about how they would respond to being asked to learn a new area
of mathematics. In addition, all of the students had some contact with undergraduates,
normally through tutorial teaching and we gained some insight into their
understanding of their own learning from their discussions of their perceptions of
others.

The interviews were conducted in the style of a ‘conversation with a purpose’
(Burgess, 1988), they were independently coded and initially analysed by each author
and, while we inevitably had the existing learning style dichotomies in mind, we were
careful about imposing the theory on the new situation so that any theory concerning
how students respond to independent graduate study was grounded in the data. As we
will show, we were right to take such care as this investigation caused us to expand
and refine the theory in unexpected ways.

While we did not intend to gather data representative of a postgraduate mathematics
population, the sample consisted of all the available doctoral students from a medium
sized mathematics department in the UK and may be seen to provide access to the
key themes which shape students’ renegotiations of their learning style in response to
independent graduate study. The number of issues raised by the data from this sample
suggests the validity of this transition as an area of study that we plan to investigate
across a much larger group.

Movements

Clearly, the interviews were rich in issues to be investigated. In particular we
encountered on student who showed flexibility in his learning, able to choose a style
depending on both context and the value he placed on the knowledge to be gained.
Another retained a strongly alien mode of learning, becoming an arch-formalist. Yet
another defied expectation by appearing to move from a natural to an alien learning
style.

However, in a paper of this length, we will concentrate on only the general sense of
movement (in terms of the change of learning style) which the sample as a whole
students revealed to us as the students described how they came to terms with their
own changed circumstances as postgraduates.

Our independent coding clearly split the students on their undergraduate (and school)
style of learning into natural and alien learners as described above. What we
discovered, however, was that while the natural learners evolved their learning style
to cope well with independent study, the alien learners had to adopt new styles – in
two quite different ways.

Natural Learners

Six of the students were classified as showing aspects of natural learning in their
undergraduate style. The movement to graduate study seemed to be quite smooth for
them and we get little sense of change of learning style. A typical example is Brian, who described his attempts to learn new mathematics as a graduate student in exactly the same ways as he had as an undergraduate:

When I do try to look at the definitions of a new subject, I do try to think how it relates to different things I’ve done before, that does make me feel a lot more sure about it. For instance, like if you first look and it said the inner product on a Hilbert Space, I see that as a generalisation in multiplication and then it becomes more sort of meaningful.

(Brian)

However one notable aspect of the movement to graduate study for natural learners was that they viewed it with some relief: it gave validity to their way of working, in contrast to their undergraduate experience where they appeared to feel that they achieved less well than did those students who saw the mathematics as ‘just something to be learned by rote’.

Thus Oliver, thinking of himself when he was an undergraduate observing fellow students, spoke of how he would tussle with a problem: ‘I would interrogate it to death … it took a long time for me to get it into my thick skull' while others ‘just seemed to recite the mantra and see it as something to be learned’. His perception was that these students often appeared to achieve better than he did: there was, to him, a clear disadvantage to his learning style:

… for exams yes, which in some sense is a little silly and is perhaps reflected by the fact I didn’t get a first. With some subjects analysis for example standard questions prove whatever theorem, and so there are some people who will just develop short term memory tricks just rather like an actor learning lines. … I suppose in some sense I emerged with a greater understanding for having done so. But the downfall of that I suppose is that I would spend too long on learning certain proofs and therefore not learn enough proofs and would then invariably be left in the dark on certain questions.

(Oliver)

In graduate study, however, the “downfall” is less obvious as the sense of a frenetic pace of learning is replaced by a sense of confidence:

… it's just a question of, well occasionally talking to different people in the coffee room assimilating different examples, examples are important. Very, very, very slowly absorbing principally I guess through osmosis

(Oliver)

Not all the natural learners had completely left the frustration behind. Christos described his own learning as being “like a big building where I start all the way from the ground until the top of it”. Although he felt he had been a natural learner throughout most of his school and undergraduate learning, he did undergo some changes on becoming a postgraduate student. He said that before graduating he limited himself largely to learning from his lecture notes and contrasted this with his
postgraduate work because he used books more at that level. However, he found that there still wasn't really time to do as he liked to do 'to get to understand every detail' saying "I know we don't have all the time in the world and life is short so I just try to understand as much as possible".

So natural learners seem to take their encounters with independent graduate study in their stride. The frustrations of the speed of undergraduate learning (or appearing to be surrounded by those who learn faster – if only by rote) are much lessened. Their fundamental learning style is rewarded by the freedoms of graduate study.

**Alien Learners**

In contrast, alien learners, accustomed to the comparative safety of undergraduate learning where they had a set text to follow and procedural methods to use to achieve success, found that their accustomed way of working was no longer adequate to their new circumstances. It required them to be able to work independently and some tended to feel less secure and confident than hitherto. Lucy, for example, says

> There's no set syllabus. I find that a lot harder … It's a bit difficult if you are trying to muddle through by yourself. I like to be told. Once I've been told I can then understand. I don't really like finding things out for myself very much.

*(Lucy)*

Lucy was more articulate about her position than some of the others but her words sum up the general position for these students.

Our study found that these students who clearly showed that they were alien learners at the undergraduate level and before, tended to move in one of two directions. Some moved towards a more natural learning style, but others seemed to respond by developing a learning style which did not fit into our existing natural/alien split (or indeed, the general connected/disconnected learning styles of other theories outlined earlier).

While natural learners, or those who had been alien learners as undergraduates who moved towards natural learners as postgraduates, were interested in making analogical links between new mathematics and existing knowledge, some of the alien learners subverted their learning style to a new one (which we came to call 'coherence' learning). In response to independent graduate study, these previously alien learners appeared to search for a structure within the new mathematics, while still basically keeping it initially separate from their existing knowledge.

**Alien → Natural Learning**

Alan spoke about his own way of learning as an undergraduate and earlier, indicating that he had merely tried to be a good student learning what he was being taught without giving much thought to whether he understood it or not though at the time he had thought he did understand it because he did quite well. 'I learned a lot of proofs
just by learning them and regurgitating them'. But now he thinks much more about what the mathematics is about:

I prefer it if he [his supervisor] first talks with me about it to give me an intuitive idea ......just on an intuitive level and then I try to make the mathematics fit to what my intuitive ideas are ... some proofs are intuitive ....but if the proofs are not intuitive ..... [I like] to work through it and think about how I worked through it ... I've matured a lot as a mathematician; I'm better as a mathematician but not as good as I thought I was before'.

(Alan)

This reflection, intimating the confidence and security engendered by competent alien learning, shows a growing recognition that understanding is not merely about successful reproduction of techniques and proofs. Instead, he is beginning to see the need for a 'fit' between the mathematics and 'what my intuitive ideas are' — a sentiment which sets him clearly on the path to a natural learning style.

Lucy, who so clearly enunciated the difficulties faced by alien learners in encountering graduate study, when asked how she viewed her current way of learning said

... instead of learning things by rote I'm having to go much more into the background and start with things I already know and learn by analogy or build them up; I found that a lot harder.

(Lucy)

Lucy and Alan both seem to be in the early stages of the transition but appear to be moving towards a new perception of what 'to understand' means in which they seek analogies and a fit between the new mathematics they are learning and their existing knowledge. They are in the process of moving more towards a natural way of learning.

**Alien → Coherence Learning**

Not every alien student moved towards natural learning in response to the new learning environment. Indeed, some students were causing us some difficulty since their descriptions of their current, postgraduate learning styles did not appear to fit the basic natural/alien dichotomy (nor the relational/instrumental, deep/surface, conceptual/procedural theories discussed earlier). Instead they seemed to develop in a different direction. Yes, they were seeking structure, but not the structure _around_ the mathematics which the natural learners and natural converts appeared to seek, but structure _within_ the new mathematics they were learning

Rebecca came across as our archetypal coherence convert. She was highly articulate and had reflected on both her own learning and that of the undergraduates she taught as a Graduate Assistant.
I always want to know where it’s going so the first thing would be to see where it’s going to and to get there I’ve got to do each of the steps one after the other.

(Rebecca)

There remains a sense of the procedural, and no sense of the need for the support of an analogy, but while for her younger self, understanding lay in “getting it finished” and “I wasn’t bothered about why I was doing it”, now understanding comes gradually:

So I think I’m probably … looking at each of the steps on their own to start with, to work out this bit and then the next bit, and then the next bit, until I’ve got that, and then eventually it all comes together

(Rebecca)

Sudeep, also a strongly alien learner as an undergraduate, really saw himself as a physicist rather than a mathematician but he too had come to have a strong sense of the internal structure of what he was learning as he came to his postgraduate work. He still saw himself as one who liked to become proficient in techniques and felt that understanding for him came through that proficiency, a characteristic of many alien learners, but this is increasingly mixed with this sense of structure within the mathematics:

I would to start with, I would try to find a certain structure in the piece of mathematics that I'm looking at, try to find some logical procedure that's involved and try to understand how and why the result is obtained.

(Sudeep)

So, for these learners, the encounter with independent graduate study has led them to adapt their learning style to accommodate to the new learning environment. Separate pieces of knowledge will no longer suffice. However these students do not move to the wholly cohesive sense of natural learning (as Alan and Lucy were beginning to do), instead they develop a learning style in which they need to sense the coherence of the new mathematics as a structure.

Summary

Encountering independent graduate study is, then, a quite different experience for natural and alien learners. For the former, it is met with open arms, a vindication of a learning style which has been a struggle to maintain in other pedagogical environments with fellow students appearing to succeed with seemingly easier learning styles. For the alien learners, however, there is a need to change – the independence which the natural learners see as liberating is bewildering and even threatening to the alien learners. The procedures which could be followed and the pre-digested ideas which could be readily absorbed are missing and they must face the prospect of developing new knowledge for themselves. Some are able to do this
by adopting a more natural-like learning style — looking for analogies which help them make sense of new ideas. However, most excitingly for us in developing our theory of learning, some developed a different way of learning: seeking not analogies, but internal structure, which allows them to retain some aspects of alien learning (the initial separateness of the new knowledge) while enabling them to progress by building new knowledge into frameworks.

LEARNING MATHEMATICS COLLABORATIVELY - LEARNING THE SKILLS

Julie-Ann Edwards

Centre for Research in Mathematics Education, University of Southampton

The research in this study explores the learning of mathematics through collaborative activity in two pedagogically identical environments but with distinct and different skill-learning agendas. Evidence is provided through analysis of small group discussion in the naturalistic emancipatory and socioconstructivist setting of both classes. Audio tapes are used as evidence for both qualitative and quantitative analysis. Findings indicate that groups which explored mathematical problems collaboratively sought solutions which reflected the input of the whole group. A greater degree of 'helping' activity was exhibited amongst groups of students who were overtly taught collaborative skills. Results suggest that a coconstructed group environment is more conducive to learning mathematics than an imposed structure.

TALK IN THE CLASSROOM

The study of talk in the classroom involves three disciplines: linguistics, psychology, and sociology. Whilst overlaps in interests are represented by, for example, psycholinguistics and sociolinguistics, each discipline contributes a component to the overall picture. Educationists have, more recently, tended to a sociological interpretation of talk and its relation to learning in classrooms, though the psycholinguistic analysis of classroom talk has done much to move thinking forward and validate the use of peer talk in the classroom. In a review of small group talk, Good, Mulryan and McCaslin (1992) describe “clear and compelling evidence that small group work can facilitate student achievement as well as more favourable attitudes towards peers and subject matter” (p167). This evidence validates further research into small group talk in the classroom.

Research in the area of psychology has offered a relation between talk amongst peers and metacognitive activity. Peterson and Swing (1985) investigated students’ cognitions as mediators of the effectiveness of small group work. They use the quality of explanations as a measure of metacognitive activity and relate achievement by outcome to the level of these explanations, both given and received. Their study found that small groups which engaged in high order explanations achieved higher scores in individual work.

Similarly, Larson et al (1985) use metacognition as a focus for their study. Their stance is that knowledge about one’s own cognition leads to effective self-monitoring activity and thus to more purposive cooperative learning with effective transfer of this learning to the individual. They conclude that metacognitive activity facilitates cooperative learning and that elaborative activity facilitates transfer to individual learning. They summarise a need to “tailor cooperative learning strategies to instructional goals”. This involves the use of “cooperative learning with a focus on
metacognitive activity” and “elaborative activity within cooperative learning emphasised”.

There are difficulties inherent in attempting to assimilate findings such as those above into a study which is essentially naturalistic, though comparative. Firstly, very few studies have undertaken similar psychological research using small group work in mathematics classrooms. The control of variables is such that there are serious implications for the validity of these research findings in naturalistic settings. Furthermore, these studies were especially designed research situations and undertaken in a matter of hours. One of the factors implicit in effective small groups is the time involved in working together (Laborde 1994). This is not accounted for in psychological studies because it is a social factor, though Peterson and Swing acknowledge the possible impact of the nature of the group on cognition.

COLLABORATIVE AND COOPERATIVE SMALL GROUPS

Cooperative and collaborative learning is perhaps the greatest change to be seen in mathematics education in recent years. Classroom discussion, often involving cooperative or collaborative group work, has become an increasing focus for research. Debate still rages about whether discussion per se is effective in the mathematics classroom (see, for example, Sfard, Nesher, Streefland, Cobb and Mason, 1998). The consensus is that there are positive effects but questions remain about the nature of discussion which actually generates a positive outcome on mathematical learning.

A good deal is known about cooperative small group learning (for reviews, see Good et al ibid, or Cohen 1994). Discussion of cooperative learning in these reviews begins from the assumption that research has already established it as a legitimate means of teaching and learning. For example, peer collaboration is effective for mathematical tasks which require reasoning but not for tasks which require rote learning. Both the above reviews advocate a future focus for research on the socially situated learning which occurs in small groups. They argue that research on small groups has gone beyond a need to justify its benefits through improved learning outcomes. They emphasise the need for work on the factors which affect discourse processes rather than factors which affect achievement outcomes. There is suggestion of a paucity of process data because of a lack of classroom observations and student interviews which would help to describe what happens during small group interactions and provide information about these processes. There is also a perceived need for cooperative group participants to develop interpersonal skills relevant to group work. Team-building activities conducive to prosocial behaviours are recommended before cooperative group work takes place.

Much less is known about collaborative small group work than cooperative small group work (Lyle 1996). This may be due to the divide between US and UK approaches to both cooperative and collaborative learning. The US work tends to test hypotheses in experimental situations whereas the UK work tends to be more
ethnographic. As a result, little has been reported about a range of issues such as how the composition and dynamics of collaborative groups affect their ability to function effectively (for a recent report, see Barnes 1998), or whether the students themselves find it an effective way of working. One study which does address this issue is reported by Edwards and Jones (1999). The research discussed above suggests a need for more research to be undertaken on small group work in mathematics classrooms relating to the influence of the task, processes of group interaction, the status of group participants and the need to overtly teach skills for cooperation, the focus of the study described here.

COLLABORATIVE AND COOPERATIVE LEARNING

In an overview of cooperative learning research by Davidson and Kroll (1991) one definition of cooperative learning is “learning that takes place in an environment where students in small groups share ideas and work collaboratively to complete academic tasks” (p362). However, they recognise that this definition encompasses a broad range of practices and meanings applied to the same terms. Most definitions of cooperative learning do not encompass the essence of collaborative learning. This demonstrates the need for a careful definition of terms.

Damon and Phelps (1989) consider it imperative that distinctions are made between types of peer interaction. They describe cooperative learning as utilising distinct principles and practices such as specific role assignments in a group, division of tasks and goal-related accountability of both individuals and the group. It is defined by Damon and Phelps as high on equality and variable on mutuality. Peer collaboration, in contrast, involves groups of novices working together to solve challenging problems which none of the participants could do prior to the collaboration. Relationships in peer collaboration are described as high on equality and high on mutuality.

Much of the research into cooperative learning has not made the necessary distinction between cooperative and collaborative; indeed many studies interchange the terms. Most such studies have centred on outcome objectives as a measure of success. Few have studied the internal dynamics of small group work and the relation of this aspect to cognition. More recent studies that do so include those reported by Webb (1991) and Cobb and Bauersfeld (1995).

For the purposes of this study, I define collaborative learning as that which is constructed amongst student peers working together in self-selected groups (defined in this study as coconstruction). The process involved in mathematical endeavour is as important a focus to the group as the end outcome. Though the aim is to provide a solution to the activity, the lack of an outcome is not seen as failure, as the process is an end in itself because it is viewed as valid mathematical activity.

Some studies of small group work explore ways of supporting such mathematical reasoning by students through problem-solving (for example, Gravemeijer, McClain
In a response to Gravemeijer et al, Groves (1998 p210) outlines three critical aspects in developing students’ powerful problem-solving: “the role of the teacher, the ‘design and enactment’ of sequences of instructional tasks, and the development of a classroom culture which supports students in explaining and justifying their thinking”.

Jaworski (1994 p56), furthermore, describes four aspects of mathematics learning which characterise an investigative approach to learning. These descriptions by Groves and by Jaworski point to the need to develop an environment (or culture or ethos) conducive to the processes of mathematical activity.

**THE PEDAGOGIC APPROACH**

The pedagogic approach in the study reported here can be described as an emancipatory socioconstructivist model in which a variety of open-ended situations are used as learning contexts. It is emancipatory, firstly, because the teacher is constantly involved in reflective action research (Jaworski, 1992). Secondly, the direction of classroom mathematical activity is directed by students within small groups and assessment outcomes are negotiated between the class and the teacher. The role of the teacher is that of a facilitator of ideas, challenger of decisions, and scaffolder for content learning. The influence of direct teaching is minimal, carefully timed, and designed so as not to affect the power relations established in the classroom.

The classroom approach is socioconstructivist, based on the teacher’s underlying belief that mathematics learning cannot occur in isolation of the learner’s culture, gender, politics, environment and social history and that these influences will affect the way in which learners construct learning and how they interpret learning situations (see, for example, Ernest 1991). The use of collaborative classroom activity amongst students supports the belief in such an approach.

Research has suggested that the direct teaching of cooperative or collaborative skills may be beneficial to learning (see, for example, Sharan 1990). Some studies in cooperative mathematics learning in small groups call for the direct teaching of collaborative skills or team-building skills to enable groups to work effectively (see Good et al ibid, Cohen ibid). The study described in this report addresses this call within collaborative groups.

**DATA COLLECTION AND ANALYSIS**

Students in this study attend an inner-city comprehensive secondary (11-16) school. A Year 8 group (12-13 year olds) whom the teacher had taught for the previous two terms received the ‘normal’ pedagogy. Any references to collaboration were made within the context of the mathematics or mathematics learning. A Year 7 group (11-12 year olds) provided the comparative group. This class received direct instruction (after Mercer et al 1999) on collaborative learning skills as a means of learning.
mathematics. Reference to collaborative organisation was made during lessons where necessary to reinforce this initial introduction to collaboration.

The whole class session for Year 7 was audio-recorded during the ‘teaching’ of collaborative skills which took the form of a class discussion to establish shared meanings for collaboration. No recording was made for Year 8 at this time as a parallel session did not take place. Throughout the ensuing 10 teaching weeks, pilot sessions of single groups were audio-recorded to accustom students to being recorded. These tapes were not considered as data for this study because of their possible contamination of outcomes in an experimental situation. After 10 weeks all small groups were audio-recorded in each class for three parallel lessons during one week.

To fit with the sociolinguistic approach to the analysis, two methods of analysis are used: constant comparative analysis and categorisation/typology. Data from audi-tapes and field notes was categorised in sections of various lengths, to reflect the nature of the talk. Such sections were defined as ‘episodes’. Results were recorded as numerical data to indicate frequency of occurrence with a proviso that each occurrence may not be equivalent to another in terms of representative time. This is a task for further analysis of the data. One aspect of group work that is intimately related to talk which is not exposed by the use of audio tapes is the skill of listening to others. While there may be some evidence in the form of responses to each other that group members are listening to each other, it is a feature which is not directly measurable.

FINDINGS

There were 30 categories of talk identified, some of which were common to both classes, some of which were particular to Year 7 and some to Year 8. These categories are summarised in Appendix 1 with a brief description of each.

There are distinct trends in the results which suggest that the Year 8 class tends to focus on the mathematical skills involved in group work, rather than the organisational skills. Categories 1 and 2 (the organisational categories) are negligible in Year 8. For year 8, category 5 (talking aloud) is a feature which may function also as category 6 (checking with each other). It may serve as a means of keeping members jointly informed of the direction of thinking within the group. This is borne out in a decrease in necessity for category 6 as the amount of talking aloud increases. It is also reflected in a decrease in the number of periods of silence indicating individual work.

Helping behaviours, prevalent in cooperative groups, (categories 7, 8 and 9) were only evident in the Year 7 class. The degree to which assertions were made (category 18) was much lower in Year 8. This is juxtaposed against the tendency for this class to use more questioning, explaining and challenging modes of communication (categories 10, 11 and 12). Categories involving more sophisticated group talk, such
as justifying decisions, accepting another's reasoning, confirming behaviours, argumentation and making collective decisions (categories 13, 14, 15, 19 and 22) were also only represented amongst the Year 8 class. Predicting or hypothesising about the work (category 21) and demonstrating some pleasure in the work (categories 23 and 24) were almost equally represented between the classes. However, of 50 instances of ‘negative’ behaviours (categories 27, 28, 29 and 30) only 4 were exhibited by Year 8.

SUMMARY

The Year 8 class whose learning is implicit through mathematics exhibited many more features of positive mathematical activity. Results therefore indicate that the coconstructed group environment is more conducive to learning mathematics together than an imposed structure. Previous discussion has suggested that the direct teaching of group skills is a lengthy process. A mathematics teacher needs to consider the most efficient mathematical use of time in the classroom. The findings from this research suggest that a more efficient use of mathematics lesson time is a focus on the nature of mathematical processes, mathematical actions and the building of mathematical knowledge as a means of promoting effective group skills rather than on the group skills themselves. This is evident in the extent to which the Year 7 class, taught directly, exhibited negative and ‘off task’ behaviours compared with the Year 8 class.

There is evidence that when group skills are taught directly, it is these skills that remain overt in group practice. The social activity is emphasised more than the mathematical activity in this situation. The directly taught groups referred to group processes during the mathematical activity. Similarly, this class were able to give specific examples of instructions to encourage group activity. In contrast, the class who learned group skills through their mathematical practices, could not think of explicit examples, though indicated that they were aware of these skills being part of their mathematical activity. This suggests a greater focus on the mathematical activity.

Appendix 1

Categories of talk

1: Organising (non-work): of equipment, paper and other requirements
2: Organising (work): administrative activity related to the functioning of the group;
3: Comparing data: occurred when students were generating initial data for analysis;
4: Assigning tasks: allocation of specific areas of the activity to each of the members;
5: Talking aloud: a ‘stream of consciousness’ activity by one or more members;
6: Checking with each other: ensuring the group were working in the same direction;
7: Requesting help: indicated a request for a peer tutoring arrangement;
8: Receiving help: a member of the group responded positively to a request for help;
9: Receiving no help: a member of the group asking for help was ignored;
10: Questioning to compare: assertive roles sometimes requiring explanations;
11: Explaining: involved the information directly available to group members;
12: Challenging: involved a request to explain or justify findings or decisions;
13: Justifying: use of information beyond that worked with at the time;
14: Accepting reasons; verbal indication of understanding and/or acceptance;
15: Confirming: an offer of a finding with an explanation and a request for agreement;
16: Agreeing: a verbal indication that a result or decision was agreed upon;
17: Seeking agreement without explanation: an offering made without justification;
18: Asserting: a statement made which was not responded to by any other member;
19: Argumentation: an argument with a positive direction and a positive outcome in the form of agreement, though not structured as a challenging argument;
20: Collective act: two or more members of the group are in verbal unison about evidence or decisions;
21: Predicting/Hypothesising: the group is working towards a solution for the activity
22: Making decisions: related to outcomes of the mathematical activity and involved agreement amongst members of the group;
23: Excitement: reflected by an indication of joy in a finding or decision;
24: Enjoyment: reflected by an overt statement to this effect;
25: Silence: a period of time when members of the group were working individually;
26: Comment on group work: awareness of whether the group was collaborating;
27: Arguing: negative interactions, often about assertions about results;
28: Boasting: about achieving a result that others in the group had not;
29: Correcting: another group member’s suggestion without offering an explanation;
30: Off task work: chatter about anything other than the task in hand;
UNDERGRADUATE STUDENTS’ VERIFICATION STRATEGIES OF SOLUTIONS TO COMBINATORIAL PROBLEMS

Michal Mashiach Eizenberg* and Orit Zaslavsky**
*Emek Yezreel College, Israel; **Technion – Israel Institute of Technology

This study is part of a larger study focusing on one of the difficulties in solving combinatorial problems, namely, on the verification of a solution. Our study aimed at identifying verification strategies students employ when solving combinatorial problems, and at evaluating their level of efficiency in terms of contribution to reaching a correct solution. Fourteen undergraduate students participated in this part of the study, of which 8 were interviewed individually and 6 in pairs. During the interviews the participants were asked to solve 10 combinatorial problems, thinking aloud, and to try to verify their solutions. Five verification strategies were identified, two of which were rather frequent and more helpful than others. The most frequently used strategy was the least helpful.

BACKGROUND

Combinatorics is one of the important areas of discrete mathematics, which is “an active branch of contemporary mathematics that is widely used in business and industry” (NCTM, 2000, p. 31). It is significant to people’s everyday experience as well as their professional practice, and is connected to various strands of mathematics and other disciplines, (e.g., computer science, communication, genetics, and statistics).

Combinatorics is a topic that can, and furthermore should, be an integral part of the mathematics curriculum, from early elementary grades through senior high school (English, 1993; NCTM, 2000). First, because the fundamental principles of Combinatorics are rather easy to comprehend, and rest on very little factual knowledge and memorization. Secondly, many combinatorial problems can be solved intuitively, yet yield themselves to the development of systematic exploration, argumentation and proof (Maher and Martino, 1996). Third, combinatorics provides a rich source for challenging mathematics. Most combinatorial problems echo the spirit of the NCTM (2000) and qualify as “good problems” (ibid, p. 52), as they have the potential of integrating multiple topics, involving significant mathematics, making connections to the learner’s personal experiences, fostering the use of different solution strategies, linking various representations, and forming different levels of difficulty.

In spite of the above, Combinatorics is considered one of the more difficult mathematical topics to teach and to learn. Most problems do not have readily solution strategies, and create much uncertainty regarding how to approach them and what strategy to employ. Moreover, verifying an answer to a combinatorial problem is a particularly difficult task, because there are no guaranteed ways to ensure the detection of an error. There are numerous examples in which different solutions to the same
problem, resulting in different answers may seem equally convincing. In addition, the
detection of an error does not necessarily yield a correct solution. Several studies
support the assertion that students encounter many difficulties in solving combinatorial
problems and shed light on some factors contributing to these difficulties (Batanero et al,
Although verification plays a critical role in problem solving (Polya, 1957; Schoenfeld,
1984; Silver, 1987), we have not found any studies that have investigated the ways in
which students and teachers cope with the difficulties associated with the verification of
combinatorial problems. Our study is a step towards understanding students’ approaches
to verifying solutions to combinatorial problems.

THE STUDY

Goals: The main goal of the study reported hereof was to identify and characterize the
ways in which students deal with the need to verify their solutions to combinatorial
problems and the verification strategies they employ.

Participants: The participants in the study consisted of 14 undergraduate students all of
which had completed a basic course in combinatorics prior to the study.

Method: In order to be able to follow, describe, and understand the problem solving
processes of the participants a qualitative method was employed. Data collection was
done by audio taped interviews and field noted observations.

Borrowing from Schoenfeld (1985), the participants were encouraged to work in pairs
when engaged in the problem solving tasks. Those who felt comfortable to work with a
peer were grouped in pairs. Thus, there were 3 pairs of students, each of which worked
collaboratively on the combinatorial problems they received. The remaining 8 students
worked individually and were prompted by the researcher to think aloud. Altogether, 11
interviews were conducted with the students. All interviews were transcribed and coded.

Every problem, for each individual or pair, at each stage of the interview, was coded
according to a number of parameters, including its degree of correctness (correct,
partially correct, or incorrect), the number of attempts to verify it, and when applicable,
the verification strategies employed. For most of the analysis we combined the partially
correct and the incorrect solutions in one category named “Incorrect Solutions”.

Research Instruments: The interviews were semi structured and consisted of two parts:
In the first part of the interview participants were asked questions related to their
personal background, as well as their experience with and attitudes towards
combinatorics. The second and main part of the interview focused on problem solving
and verification of solutions to ten combinatorial problems.

The main interview included a set of 10 combinatorial problems specially designed for
the study. The problems varied with respect to their underlying model, according to
Dubois (1984): a selection model, a distribution model, or a partition model. All
problems required only basic combinatorial tools for solution. However, in order to
create some uncertainty that would foster the need to verify the solutions, each problem
required the use of some blend of principles and operations (combinations, arrangements, and permutations) for its solution. In addition, 2 of the 10 problems were very similar problems, and were given to the participants consecutively. This was done in order to see whether the participants, first, identified the connections between the two problems and secondly, built their solution and verification of the second problem on the first one.

For each problem there were 1-2 occasions when the interviewer prompted the student (or pair of students) to verify the solution. Accordingly, for each problem the interview consisted of 2-3 stages: the first stage V₁, in which the student(s) solved the problem with no prompting at all, the second stage V₂, in which they were prompted to verify their solution, independently of its correctness, and the third stage V₃, in which only those that held an incorrect solution were prompted to verify their solution once again, disclosing the fact that their solution was incorrect.

**FINDINGS**

Through the 11 interviews that were conducted with the students (3 with pairs of students and 8 with individual students) we received altogether the total of 108 solutions. The findings include a description of the different types of verification strategies employed by the participants and an analysis of their usefulness.

**The Verification Strategies**

Altogether, 219 attempts were made by students to verify their solutions at Stages V₁, V₂, and/or V₃. All attempts to verify a solution were analyzed and classified into 5 main categories of verification strategies:

1. Verification by *reexamining* the solution;
2. Verification by *adding justifications* to the solution;
3. Verification by *evaluating the reasonability* of the answer;
4. Verification by *modifying some components* of the solution;
5. Verification by *using a different solution method*.

We turn to a description of the verification strategies.

**Strategy 1: Verification by *reexamining* the solution**

The participants who used this strategy reexamined their solution by going over and checking all or parts of it a second time, without adding any substantial justifications to their solution. This kind of checking focused on various aspects of the solution, such as rechecking their calculations or the extent to which their original plan for solution was carried out. In several cases, this strategy served as a springboard for a more profound strategy of verification.

**Strategy 2: Verification by *adding justifications* to the solution**

The participants who used this strategy added justifications to their solution to support it. The justifications referred to either a particular step in the solution or to a more global aspect of the solution. Generally, the justifications were of three mutually related types:
One type was directed to clarify and support some (or all) specific parts of the solution. A second type aimed at justifying in a more global way the model (or formula) used to solve the problem, by showing how the conditions and nature of the problem match the model. A third type of justification was based on an analogy to another, more familiar or previously solved problem, the solution of which was known to the participant. This strategy was particularly helpful for improving partially correct solutions, in which the general solution strategy was appropriate, however, there were some steps in which an error occurred in applying it.

**Strategy 3: Verification by evaluating the reasonability of the answer**

The participants who used this strategy looked at the final result they had obtained and tried to examine its reasonability either by an intuitive estimate, or more commonly, by calculating the size of the outcome-space. In a number of cases, the participant noticed that the result s/he had reached was larger than the outcome-space, which did not make sense. In some cases this strategy led to the identification of wrong answers, however, it was not helpful in locating the specific erroneous considerations and steps in an incorrect solution.

**Strategy 4: Verification by modifying some components of the solution**

The participants who used this strategy made one of the following modifications to their original solution: They either altered the representation they had used in their solution or tried to apply the same solution method by using smaller numbers. Those who used the former approach tried to represent the situation of the problem in a different way, mostly by using some visual symbols (e.g., circles, squares, blocks etc.) to represent the different components of the problem. Unfortunately, this kind of attempt did not prove helpful for them, because they repeated the same considerations and arguments as in their original solution, failing to identify any faulty step. One student used the latter approach, that is, used smaller numbers. This enabled him to detect an error and identify where he went wrong in his solution.

**Strategy 5: Verification by using a different solution method**

The participants who used this strategy employed a completely different solution method for the problem. In these cases, the new solution method led to either the same result that they had reached or to a different one. Table 1 presents the different cases according to the correctness of the first and second solution methods, the difference between the results obtained in each way, and consequently, the decisions the participants made within this strategy of verification.

As seen in Table 1, Strategy 5 was used altogether in 57 cases, of which, 43 cases were with an incorrect solution, and 14 cases with a correct solution. Of the 43 cases with an incorrect solution, in 12 cases this strategy proved helpful in correcting their solutions. In one case a student managed to reach a correct solution in the second time, however, made a wrong choice, thus remained with his first incorrect solution. Interestingly, there were two pairs of students and one individual student who reached the same incorrect
result in two different solution methods, thus their answers remained incorrect leaving them more confident of their solutions.

Table 1: Decisions made by participants employing verification Strategy 5

Of the 14 cases with a correct solution, 12 cases remained correct in both solution methods. However, this strategy led to two unfortunate decisions (in stage V2), where a wrong result was obtained the second time, causing a switch from a correct to an incorrect solution. Luckily, in the following stage (V3) they both corrected their solution.

Some Comparisons between the Verification Strategies

Altogether, there were 219 verification attempts made, in various stages, to incorrect as well as correct solutions. One hundred and sixty six attempts were made by students working individually, and 53 by students working in pairs. Table 2 presents the distribution of the number of verification attempts by the different verification strategies. It should be noted that the distribution of the verification attempts of only the incorrect solutions was similar to the one in Table 2.

It should be noted that there were no conspicuous differences between the students who worked individually and those who worked in pairs, in the distribution of use of the different verification strategies. The most frequently used strategies were Strategy 1 (38%), Strategy 2 (26%), and Strategy 5 (26%).
Types of Verification Strategies | Individual Students (8) | Pairs of Students (3 pairs) | Total
---|---|---|---
1. Reexamining the solution | 66 | 17 | 83
2. Adding justification to the solution | 42 | 15 | 57
3. Evaluating the reasonability of the answer | 10 | 1 | 11
4. Modifying some components of the solution | 6 | 5 | 11
5. Using a different solution method | 42 | 15 | 57
Total | 166 | 53 | 219

Table 2: Distribution of attempts to verify a solution by the type of verification strategy employed, in percents

A further analysis of the use of the different verification strategies focused on the extent to which these strategies were helpful in leading the participants to improving their solutions. In this analysis we considered an improvement as a change from an incorrect solution to a partially or completely correct solution, or from a partially correct to a completely correct solution. Altogether, there were 27 improved solutions as a result of employing a verification strategy (note that some improvements are attributed to more than one verification strategy).

Table 3 presents the distribution of the improved cases by the different verification strategy and by group. As shown in Table 3, the most helpful verification strategies were the 2\textsuperscript{nd} (in 12 cases) and the 5\textsuperscript{th} (in 13 cases). Note, that there were 5 cases in which a combination of verification strategies led to an improved solution. For example, one student used Strategy 3 to detect that an error had been made, then moved to Strategy 4 through which he identified the kind of error that he had made, and finally used Strategy 5 to correct his solution.

Table 3: Distribution of cases in which the use of a verification strategy was helpful in the process of improving a solution, by type of verification strategy and group
A close look at the number of cases, for which the use of a verification strategy was helpful, points to a considerable difference in favor of the individual students compared to the pairs. However, this is due to the fact that the students who worked in pairs were significantly better in reaching correct solutions to begin with.

Another measure of efficiency of the verification of a solution was obtained, for each stage separately, by the percentage of the number of cases in which the use of a verification strategy was helpful out of the total number of incorrect solutions that were verified at the respective stage. Thus, 13% of the incorrect solutions in stage V1 were improved, 12% of the incorrect solutions in stage V2 were improved and 30% of the incorrect solutions in stage V3 were improved. Clearly, there was an increase in the efficiency of the verification attempts in stage V3, when the students became aware that their solution was incorrect.

**DISCUSSION**

Our findings support the merit of encouraging students to verify their solutions to combinatorial problems. Apparently, when pushed to it, students are capable, to a certain extent, of finding efficient ways to verify their solutions. We suggest that through such experiences students are likely to become aware of the potential of verifying their solutions, and hopefully, will be motivated to verify their solutions out of their own initiative. The differences that were found with respect to the efficiency of the various strategies may serve as a springboard for teaching problem solving in combinatorics with a focus on metacognitive processes, in general, and on the use of more efficient verification strategies, in particular.

As shown above, Strategy 1 was the most frequently used, however, it turned out one of the least efficient strategies, in terms of helping students shift towards an improved solution. The low efficiency level of Strategy 1 is in accordance with the view that merely going over a solution of a mathematical problem is insufficient for verifying it (Polya, 1957; Schoenfeld, 1985). For those who applied Strategy 2, which turned out considerably helpful, what proved useful was mainly the need to add justifications to the various steps in a solution. This was helpful particularly in detecting minor errors. Unlike Strategy 2, Strategy 3 was not very frequent. This is mainly because estimating an expected outcome in a combinatorial problem is extremely hard to do. Fischbein and Grossman (1997) found that when asked to estimate such results, students usually gave lower estimates than the actual number. Thus, Strategy 3 was helpful in detecting that an error had occurred only in cases when the answer that was obtained was larger than the size of the outcome-space and when the student(s) applying this strategy compared these two numbers. Strategy 4 was also the least frequent. We speculate that most of the students were not familiar with this strategy and did not know how to apply it. In another part of our study, in which expert mathematicians were interviewed about useful verification strategies to combinatorial problems, they recommended Strategy 4 as one of the most helpful methods, provided the solver does it carefully and is aware of some underlying subtleties of using smaller numbers. Finally, we turn to Strategy 5, that was both frequent and rather helpful, and point to its limitation. There were three cases in
which students reached the same incorrect answer in two different solutions strategies. This raised their degree of confidence in their incorrect solution.

To conclude, we bring a quote from a student, conveying the limitation of Strategy 5: A pair of students who reached stage V3 was told that their solution was incorrect. In response, one of them suggested solving the problem in a different way. Before they started to carry out his plan, he turned to his partner and said: “if we reach the same result in a different way then the answer is right and the question is wrong”.

DEVELOPMENT OF 10-YEAR-OLDS’ MATHEMATICAL MODELLING

Lyn D. English
Queensland University of Technology

This paper addresses the developments of a class of fifth-grade children as they worked modelling problems during the first year of a 3-year longitudinal study. In contrast to usual classroom problems where students find a brief answer to a particular question, modelling activities involve students in authentic case studies that require them to create a system of relationships that is generalisable and re-usable. The present study shows how 10-year-olds, who had not experienced modelling before, used their existing informal mathematical knowledge to generate new ideas and relationships, and how these developments were fuelled by significant social interactions within small group settings.

INTRODUCTION

Our ever-changing global market is making increased demands for workers who possess more flexible, creative, and future-oriented mathematical and technological skills (Clayton, 1999). Of importance here is the ability to make sense of complex systems (or models), examples of which appear regularly in the media (e.g., sophisticated buying, leasing, and loan plans). Being able to interpret and work with such systems involves important mathematical processes that are under-represented in the mathematics curriculum, such as constructing, describing, explaining, predicting, and representing, together with quantifying, coordinating, and organising data. Dealing with systems also requires the ability to work collaboratively on multi-component projects in which planning, monitoring, and communicating results are essential to success (Lesh & Byrne, in press).

Given these societal and workplace requirements, it is imperative that we rethink the nature of the mathematical problem experiences we provide our students— in terms of content covered, approaches to learning, ways of assessing learning, and ways of increasing students’ access to quality learning. This paper reports on one approach to addressing this issue within the primary school curriculum, namely, through mathematical modelling activities. Although these activities provide all students with rich learning opportunities, their use with younger children has received limited attention.

MATHEMATICAL MODELLING FOR CHILDREN

Problem solving over the past couple of decades has typically engaged children in problems where the “givens,” the “goals,” and the “legal” solution steps have been specified clearly; that is, the interpretation processes for the student have been minimalized or eliminated. The difficulty for the solver is simply working out how to get from the given state to the goal state. The solutions to these problems are usually brief answers obtained from applying a previously taught solution strategy, such as
"guess and check," or "draw a diagram." Furthermore, although these problems may refer to real-life situations, the mathematics involved in solving them is often not real world and rarely do the problems provide explicit opportunities for learners to generalize and re-apply their learning (English & Lesh, in press). While not denying the importance of these problem experiences, they do not address adequately the knowledge, processes, and social developments that students require in dealing with the increasingly sophisticated systems of our society. Mathematical modelling activities, in the form of meaningful case studies for children, provide one way in which we can overcome this inadequacy.

As used here, models are systems of elements, operations, relationships, and rules that can be used to describe, explain, or predict the behaviour of some other experienced system (Doerr & English, 2001). The modelling activities of the present study engage small groups of children in challenging but meaningful problem situations that encourage multiple solution approaches and multifaceted products. Key mathematical constructs are embedded within the problem context (which takes the form of a case study) and are elicited by the children as they work the problem. In contrast to typical classroom problems, these case studies require children not only to work out how to reach the goal state but also to interpret the goal and the given information along with permissible solution steps. Each of these components might be incomplete, ambiguous, or undefined; furthermore, there might be too much data, or too little data, and visual representations might be difficult to interpret. When presented with information of this nature, children might make unwarranted assumptions or might impose inappropriate constraints on the products they are to develop. This is where the input from group members plays a powerful role.

Unlike traditional non-routine problems, modelling activities are inherently social experiences (Zawojewski, Lesh, & English, in press). Their design demands the work of small teams of students, who must develop a product that is explicitly sharable. Team efforts are required to generate the multifaceted products that involve descriptions, explanations, justifications, various mathematical representations, and frequently, media presentations. Numerous questions, issues, conflicts, revisions, and resolutions arise as students develop, assess, and prepare to communicate their products. Because the products are to be shared with and used by others, they must hold up under the scrutiny of the team (Zawojewski, Lesh, & English, in press).

**DESCRIPTION OF THE STUDY**

The present study involves a class of 30 ten-year-olds and their teachers, who are participating in a 3-year longitudinal study of children's developments in mathematical modelling. The children are from a co-educational private school that caters for preschool through to Year 12. Drawing upon the multiltiered teaching experiments of Lesh and Kelly (2000), the study has adopted a four-tiered collaborative model that addresses the simultaneous development of researchers, classroom teachers, preservice teachers and classroom students (English, submitted). This paper, however, is confined to the developments of the children.
The data reported here are from the first year of the study (2001) and are drawn from two of the activities the children completed towards the end of the program. The program commenced in June 2001 and continued until November 2001, with a month’s break between September and October. The children had not experienced modelling activities prior to the program. The classroom teacher implemented each of the activities. Preparatory meetings and feedback sessions were conducted with the classroom teacher and with the preservice teachers. The children usually worked the modelling activities twice a week, with each session lasting around 80 minutes.

**Description of the Modelling Activities**

The program commenced with preparatory experiences where the children expressed their feelings about, and their perspectives on, mathematics and mathematical problem solving and posing as they occurred in and out of school. The children also explored a range of non-routine problems, where they analyzed the mathematical structures, identified similar structures, discussed ways they would approach the problems, and shared their solutions. These experiences were followed by introductory modelling activities (from the “Packets Investigators”; ETS, 1997), with more advanced modelling being introduced next, as indicated below.

The activities that elicited the present data are the *Aussie Lawn Mowing Problem* and the *Christmas Holidays Jobs Problem* (adapted from Hjalmarson, 2000, and Lesh & Lehrer, 2000). Both problems involve interpreting and dealing with multiple tables of data, exploring relationships among data, using proportional reasoning and the notion of rate, and representing findings in visual and written forms. The Aussie Lawn Mowing Problem involves three components: (a) a warm-up task comprising a mathematically rich “newspaper article” designed to familiarize the children with the context of the modelling activity, (b) questions to be answered about the article, and (c) the model-eliciting activity. Excerpts from the third component appear as an appendix. The Christmas Holidays Job serves as a model application activity where children apply their learning within a new context (selecting part-time and full-time vendors for an amusement park, based on their performance in the previous Summer). The children spent two sessions in completing each of the problems. After the groups had developed their models, they presented their work to the class for questioning and constructive feedback. Next, a class discussion focused on the key mathematical ideas and relationships that developed.

**Data Sources and Analysis**

The data sources included audio- and video-tapes of the children’s responses to the problem activities, together with their work sheets and final reports detailing their models and how they developed them. Field notes were also taken. The data were analyzed for evidence of children's mathematical and social developments over the course of the activities. In the next section, consideration is given to the progress of groups of children across the two problems. There were six groups of mixed achievement levels. The children's developments are reported in terms of cycles of
increasing sophistication of mathematical thinking, with each cycle representing a shift in thinking (Doerr & English, 2001). The cycles also display significant social interactions that impacted on the children's modelling developments.

RESULTS

Cycle 1: Focusing on Subsets of Information

Each of the groups commenced the Aussie Lawn Mowing Problem by scanning the tables of data to find employees who scored highly in one or more of the categories (i.e., hrs worked, no. of lawns mowed etc.). Limited mathematical thinking was displayed in this unsystematic approach, as evident in Gavin's (Group 1) comments: “Also, I think Jonathon is good because he works top hours and doesn’t drive much. Also mows quite a lot of lawns and makes a bit of money....”

While most groups initially used this approach, Group 4 decided to choose employees “with different specialities” and remained with this decision in developing their model: “We’ll get Travis to work at the shop selling fertilizers and all that—from 8 to 5—that’s about 9 hours. He earns the most money from the info we’ve got, so if we have our best worker at the shop they make the most money.... What’s Matthew’s speciality? He loves big lawns. Matthew could work all the time from 9 to 5 because mowing is a lot...what’s Jonathon like? Jonathon likes small lawns. He could do the small lawns.” Because the Lawn Mowing Problem lacked some information, the groups frequently brought in additional ideas and assumptions based on their real-world knowledge (e.g., hours the garden shop should open; how much customers should be charged; how much the employees should be paid).

With the exception of one group, none of the groups commenced the problem by considering whether some items of information were more important than others or whether some information might be irrelevant. The children did, however, engage in heated debates over how to interpret “kilometres driven” and whether more kilometres driven indicated a more desirable employee. Again, the children used their informal knowledge to make a number of conjectures and justify their claims:

Tim: No, wait a second. We’re looking at how many kilometres you drive in a truck that’s owned by them; that’s bad.

Samantha: No, it's good if you drive a lot because that means that you’re not a slacker, not lazy, and you’re willing to go and drive over to someone’s.

Ben: Isn’t it social, like they’re just going out to buy some beer or something.

Tim: No, Company truck. It costs a lot of money to have company trucks.

Because most of the groups did not use any systematic approach to tackle the problem initially, they frequently argued over which employees should be chosen. This led them to see the need to mathematize, in some way, their employee selection. The groups began to use two main mathematical operations to aggregate the data for each employee, namely, (a) simply totalling the amounts in each category (hrs worked, kilometres driven etc.), and (b) finding the average for each category.
Cycle 2: Using Mathematical Operations

The need to mathematize their procedures was initiated in Group 1 by Joanne, who challenged Gavin over his unsystematic approach: “Gavin, not necessarily he [Jonathon] mows the most lawns..... How about we work out the hours they work. How about we work out their average.” She justified her decision by explaining, “Well, it’s kind of difficult working out how much they worked each month. Sometimes they worked less and sometimes more.” Gavin and Alison remained unconvinced, however, so Joanne, along with Mindy, proceeded to work out the average number of hours worked, lawns mowed (treating, ‘big,’ ‘medium,’ and ‘small’ separately), kilometres driven, and money from products sold for each employee listed in the tables. At the same time, substantial discussion and argumentation took place when the group members tried to convince Alison that she was misinterpreting the table of money from products sold (interpreting it as the amount of money the company paid to the employees.) Despite repeated explanations (e.g., “Average money per week from products sold. They don’t give them this.”), Alison would not accept their arguments. In fact the group became quite bogged down as Gavin and Alison continued to argue over the meaning of the table.

Joanne and Mindy, however, remained very much on task and frequently had to remind Gavin and Alison that they had to apply a systematic method: “You have to work it out properly. Like, you can’t just get someone you like and say, ‘O.K., I like this one’...I don’t think that works. You have to work out like Joanne’s doing—working out the average—and then understanding what they are and everything.”

Because Alison (and at times, Gavin) insisted on using an unsystematic approach, Joanne and Mindy frequently reminded them of the problem goal and clashed over their interpretations of “best people.” For example, when Gavin and Alison were insisting that they include a person “who isn’t that bad,” Joanne and Mindy insisted, “But there are four better people. We need the best people.” Alison retorted, “It [the problem statement] doesn’t say good employees.”

The group continued to be divided over their approaches to solving the problem. While Joanne was working out all the averages, Mindy was repeatedly reminding Alison and Gavin of the need for a method: “Some structurable thing.” Mindy also challenged the selections of Gavin and Alison:

Mindy: Alison, how do you know that? (that Mathew is one of the best)
Gavin: Look at all the stats!
Mindy: So, just on that information, you can’t just say, “O.K., we want him.” This is pulling people out of the hat again.
Alison: We’re not pulling people out of the hat. We’re just compromising.
Mindy: Where’s the structure for that?

Once all the averages had been found, the group did not progress further. They selected those employees who scored high averages across all categories, explaining
in their report: "Well, we worked out the average for average money per week from the products sold and looked for the 4 highest and did the same for the hrs worked."

**Cycle 3: Identifying Trends and Relationships**

Two of the groups progressed to looking for trends and relationships to help them choose the employees for the Lawn Mowing Problem. Group 4, for example, explored trends within categories (e.g., "Kim is always gaining... 200, 250, 256" [in the money category]). This led the group to compare trends across categories: "So Travis should be our first guy. He may have done 5 less hours than Jonathon, but he did more jobs." Group 4 did not progress to the notion of rate, however, in part because they kept conjecturing about why the trends occurred (e.g., "With the lawns mowed, they hand them out maybe, but then if they hand them out, he [Aaron] might not have been able to get them because someone else got them").

On the applied problem (Christmas Holidays Job) all of the groups transferred their learning and frequently referred to what they had done in the previous problem (which they had solved 5 weeks earlier). Furthermore, 4 of the 6 groups extended their understanding by exploring relationships between hours worked (by vendors in a previous Summer) and money collected (for busy, steady, and slow periods). The groups used these relationships as their basis for deciding whom to employ full and part time in the next Summer. In Group 2, for example, Marianne was recapping on what she thought was the group's decision: "I thought the person who works the less or the least but makes the most money we were going to employ because that would work." To counter some disagreement and misunderstanding that followed (e.g., "No, because if they work tons of time they earn tons of money"), Marianne provided a concrete example: "Because, like someone might work for say, 10 days and make $5000, and somebody might work for 5 days and they get $10,000."

Likewise, Group 5 spent considerable time debating the relationship between hours worked and money earned, which led to observations such as, "Chad works 20 hours. Will works 19. Chad earns $1031. Will earns $1034. Will works one hour less, and he makes $3 more." Earlier, Group 5 had been working out averages, but once they had explored these relationships, a couple of the group members noted, "Why did we have to use averages? Why in the world did we use averages? That doesn't make sense!" Using their understanding of kilometres per hour, two of the groups progressed to calculating rates (money per hour) in developing their model.

**CONCLUDING POINTS**

The first year of this study has shown how one class of 10-year-olds was able to work successfully with mathematical modelling problems when presented as meaningful, real-world case studies. On the problems addressed here, the children progressed from focusing on isolated subsets of information to applying mathematical operations that helped them aggregate the given data. Moreover, some children displayed an explicit awareness that they needed to adopt a structured approach to developing their final model. While some groups remained with
averages, other groups moved on to discover relationships and trends in the data, and applied this learning to the second problem. These developments took place in the absence of any formal instruction, and involved the children in describing, constructing, explaining, justifying, checking, and communicating their ideas. Of significance in these developments are the social interactions that took place naturally within the groups. These interactions engaged the children in planning and revising courses of action, challenging one another's assumptions and claims, asking for clarification and justification, monitoring progress, and ensuring the group worked as a team. Few traditional problems generate learning of this nature.

Aussie Lawn Mowing Problem: Green Thumbs Garden to Open Soon

Part (c): The model-eliciting activity

Background Information: At Green Thumb Gardens, James Sullivan will provide lawn-mowing service for his customers. Another local landscaping service has closed, so he has offered to hire 4 of their former employees in addition to taking on some of their former clients. He has received information from the other landscaping business about the employee schedules during December, January, and February of last year. The employees were responsible for mowing lawns and selling other yard products like fertilizer, weed killer, and bug spray. The other business recorded how many hours each employee worked each month, the number of lawns each employee mowed, and how much money they made selling other products. The lawns mowed are divided into big, medium, and small jobs. Big jobs may have larger lawns or additional work than medium or small jobs. Some lawns may be small, but may have many obstacles for the mower to get around or there may be different kinds of edging or trimming to be done which determine the size of the job. They also recorded the kilometres driven to clients in one of the green company trucks during each month.

Problem: James needs to decide which four employees he wants to hire from the old business for this summer. Using the information provided, help him decide which four people he should hire. Write him a letter explaining the method you used to make your decision so that he can use your method for hiring new employees each summer. (The following tables were supplied [data for 5 of the children have been omitted here].

IMPLICATIONS OF COMPETING INTERPRETATIONS OF PRACTICE TO RESEARCH AND THEORY IN MATHEMATICS EDUCATION

Ruhama Even
Weizmann Institute of Science

Baruch B. Schwarz
The Hebrew University

In this article we explore the issue of interdependency of theory and research findings in the context of research on the practice of mathematics teaching and learning at school. We exemplify how analyses of a lesson by using two different theoretical perspectives lead to different interpretations and understandings of the same lesson, and discuss the implications of competing interpretations of practice to research and theory in mathematics education.

INTRODUCTION

In their chapter on ‘Competing paradigms in qualitative research’, Guba and Lincoln (1994) point to an interesting, sometimes unforeseen, connection between the theoretical framework used by the researcher and the findings of the research. They claim that “theories and facts are quite interdependent – that is, that facts are facts only within some theoretical framework” (p. 107). Moreover, they assert, “Not only are facts determined by the theory window through which one looks for them, but different theory windows might be equally well supported by the same set of ‘facts’.” (p. 107). In this article, we explore this issue of interdependency of theory and research findings in the context of research on the practice of mathematics teaching and learning at school. We exemplify how analyses of a piece of practice – a lesson – by using two different theoretical perspectives lead to different interpretations and understandings of the same lesson, and we discuss the implications of competing interpretations of practice to research and theory in mathematics education.

BACKGROUND

The lesson to be analyzed was part of an innovative yearlong introductory course on functions for ninth-grade. The curriculum developers aimed for the students to investigate problem situations with computerized tools, raise hypotheses, collaborate on problem solving, explain and discuss their solutions, and reflect on their learning in individual or collective written reports. After a successful implementation of the course in high-achieving classes (A-level), the function course is tried in lower-achieving classes (B-level).

The teacher of this trial has been a central member of the curriculum development team. She has decades of experience in the dual role of high-school mathematics teacher and curriculum designer. In both roles she regularly sought for innovations in content and ways of teaching, and systematically reflected on her own teaching and the learning processes of her students. The year preceding the present experiment, she successfully taught the function course to an A-level class in the high school where she
regularly teaches mathematics – a religious all-girl academic oriented school. The experimental B-level class belonged to the same school.

The lesson we analyse in this article took place rather early in the school year. It centred on the “Fence Problem”, displayed in Figure 1.

--------------------------------------------------------------------------------------------------------------------------

The Fence Problem

Oranim school received a 30m long wire to fence a rectangular vegetable garden lot. The lot is adjacent to the school wall, so that the fence has three sides only.

![Figure 1. The Fence Problem](image-url)

a. Find four possible dimensions for the lot and their corresponding areas.
b. For which dimensions does the lot have the largest area?
c. If one of the dimensions is 11m, what is the area of the lot? Can you find another lot with the same area? If you can, find its dimensions; if not, explain.
d. How many lots with the following areas are there: 80m²? 150m²?

--------------------------------------------------------------------------------------------------------------------------

VERBAL ANALYSIS: A CLASSIC COGNITIVE APPROACH

Cognitive Science focuses on processes and representations. The research question of the cognitive component of the study concerns with the extent to which students, during the Windows lesson, conceive the passage to a new (especially graphical) representation of a function as a problem solving method. We use verbal analysis (Chi,
1997) as a representative of Cognitive Science approach. The data for the verbal analysis is the protocol derived from the video recording of the three whole-group discussions that comprised about one-half of the class time (the rest of the lesson comprised of small-group student work). The whole-group discussions provided rich and coherent verbal data, enabling us to consider the whole group of students as an entity interacting with the teacher.

Segmenting the protocol

In line with the research question focus, we chose the passage from one representation to another, as well as the passage within the same representation — between referring to it as a display or an action representation (Kaput, 1992) — as a natural boundary for segments. The different representations of function in the Windows lesson were algebraic, tabular, graphic, and verbal. We identified 19 segments in the reduced protocol.

Coding

For each segment we identify who initiated the passage to a new representation (the teacher or the students), who was the trigger for this passage, and what was the nature of the interlocutor's response (if any). We define five kinds of responsiveness. Accompanying talk refers to talk in which the interlocutor attends to the other’s talk without elaboration, typically acknowledging that the interlocutor follows the other’s talk. Elaborating talk refers to talk in which the interlocutor elaborates utterances and expresses deeper cognitive involvement. Opposition refers to talk in which the interlocutor explicitly expresses disagreement and objection. Puzzlement points to talk expressing confusion, perplexity or bewildering. Finally, non-responsiveness refers to the absence of talk subsequent to the initiator’s talk. We also distinguish between a passage to a different representation that is embedded in the context of the Fence problem situation and a passage to a different representation that is disconnected from a situational context. Moreover, as we assume that the nature of the class discourse is related to student understanding, we characterise the types of utterances at each segment according to the following categories: Presentation (Pr), Short Questions (SQ), Extended Questions (EQ), Short Answers (SA), Extended Answers (EA), Rephrasing/re-voicing (R), Objection (Ob).

Depicting the coded data

Depicting the coded data is conducted in two ways. One way is displayed in Figure 2. The segments of the lesson are marked in the first row (segments I, S and V indicate the small-group work parts of the lesson which are not part of the analysis). Each of the following four rows designate one of the four representations to which the class talk refers when the context concerns the Fence situation. Sit designates segments in which participants focus specifically on objects and events of the Fence task; Gr, Tab, and Al designate segments in which the talk refers to graph, table and algebra/formula (respectively). The last three rows similarly designate the representational systems to
which the talk refers, but here, with no connection to the Fence situational context but rather related to a formal task.

Figure 2. Schematic description of the Windows lesson

Circles represent the teacher and squares, the students. For each segment we mark who initiates the passage to a new representation or the change in the way the representation is used (display or action) by an arrow targeted to the initiator. The trigger for the passage to a different representation is marked at the beginning of the arrow. The nature of responsiveness is marked as following: gray represents accompanying talk, black – elaborating talk, inscribed question mark – puzzlement, crossed – opposition, and white – non-responsiveness.

Figure 2 displays a comprehensive picture about initiatives and the nature of responsiveness regarding the passing from one representation to another. But it does not show information on the nature of the utterances that comprised the talk. Another method we use to depict the coded data focuses on the categories of utterances. Table 1 presents the percentages of the following kinds of utterance: Presentation (Pr), Short questions (SQ), extended questions (EQ), short answers (SA), extended answers (EA), rephrasing or re-voicing (R), and Objection (Ob).

Seeking patterns and coherence in the depicted data

Figure 2 shows that the teacher has a major role in initiating the passage to a new representation throughout the lesson while the students generally only respond to the teacher’s initiative. An examination of the protocol indicates that even when students react to the teacher’s initiatives with elaborating utterances it is often only few specific students who do it.

Table 1 that shows the nature of all the utterances during class talk (and not only those related to the passage between representations) confirms the central role played by the teacher. About two-thirds of the utterances are the teacher’s and she is the only one to make Presentations. When students do participate in the class talk, they typically respond with Short Answers to teacher’s Short Questions. Students almost never ask questions. Throughout the lesson both students’ and teacher’s extended Questions as well as Extended Answers are rare.

Interpreting the data

A reasonable interpretation of the findings is that for the students to use multiple representations to solve problems is a cognitive obstacle. Detailed analysis of different parts of the Windows lesson supports and verifies this interpretation. This conclusion fits with findings of other cognitive studies where it was found that interpreting information from one representation to another is cognitively difficult (e.g., Even, 1998; Schwarz & Dreyfus, 1995). While it is frequently argued that the multiplicity of representations facilitates the learning of concepts as it helps in the integration of perspectives, the multiplicity of representations could also be a cognitive load that hinder learning processes.

ACTIVITY THEORY APPROACH

Activity theory (Leont’ev, 1981) takes into account social origins of cognitive processes. The unit of analysis is the human activity. Need is always an essential part of an activity. Activities are chains of actions related by the same object and motive. Actions are the basic “components” of human activities that translate them into reality and can be understood only within the activity in which they are embedded. The actions that constitute an activity are energized by its motive, and are directed toward
conscious goals. *Operations* are the means by which an action is carried out. They depend directly on the conditions under which a concrete goal is attained.

The research question guiding the analysis from an activity theory perspective is: What is the nature of the activity in which the teacher and the students participate during the Windows lesson? Data sources for the analysis include the video recording of the lesson, classroom observation, the protocol used for the cognitive analysis, the two ways of depicting the coded data (Figure 2 and Table 1), and numerous formal and informal discussions with the teacher and the curriculum development team.

**The Teacher**

Examination of the data for identification of the teacher’s motive, actions, goals, and operations indicates that the teacher’s overall motive when teaching mathematics is that her students understand and learn mathematics in meaningful ways. More specifically in the Windows lesson her motive is that her students learn about different representations of functions and understand how to use the graphic calculator to solve problems that require the passage from one representation to another. The teacher’s actions during the lesson aim at helping the students learn and understand the above and at creating a need to use the graphic calculator as a problem solving tool and to choose cleverly a Range that would enable them to see the relevant part (window) of the graph. Throughout the lesson, the teacher’s operations reflect her desire to engage her students in the activity while being attentive to their understandings. The operations are aimed to help the students become involved, understand, and develop a sense of shared ownership of the activity’s motive as well as the actions’ goals. The teacher’s actions and operations suit the teacher’s general approach to learning and her belief that students learn by constructing their knowledge through active participation in mathematical investigations.

**The Students**

Analysis of the lesson observations and of the video recording indicates that many students in the class appear uninvolved and uninterested in the intellectual challenges presented by the teacher to the whole class. Only a small number of students participate in the whole class discussions that the teacher strives to conduct. Even then, as Table 1 and Figure 2 also show, their participation is rather shallow and of low-level, characterized by short answers to teacher’s short questions. The majority of the students become involved in the mathematics tasks only during the small group work parts. But also then, most of the students are not involved in exploration, problem solving, debates among themselves, and the like, as was common to the A-level students the teacher has taught in a previous year. Rather, many of the current students tend to yell for teacher help after minimal attempts to solve the tasks, asking her to tell them what the correct answers are. In general, students seem satisfied when they quickly reach the correct final answers and frustrated when they do not. These students, who have a history of learning difficulties and low achievement in years of traditional mathematics teaching, behave according to common beliefs about school
mathematics, adapting social and socio-mathematical norms prevalent in traditional mathematics classes. Thus we may conclude that the motive of many students is *surviving* the lesson.

**Same Lesson But Different Activities**

The analysis of the lesson from an activity theory perspective suggests that the teacher and the students in the Windows lesson participate indeed in the same lesson but in different activities. Their motives are different and consequently the different actions that constitute the activity and are energized by its motive are different. The teacher’s actions during the lesson are derived from her overall and specific motives. Her actions are well connected, one leading to another, creating a complete whole. However, beauty is in the eye of the beholder – what the teacher sees is not necessarily seen by the other lesson participants – the students. Many students do not make connections between the different parts of the lesson. Students’ goals are different from those of the teacher’s – theirs usually centre on obtaining correct final answers to the problems assigned by the teacher, not on making sense of the mathematical situation nor on using connections between different representations of functions as a tool to solve problems. As such, the nature of the students’ participation in the activity is very different from what the teacher had wished for and does not contribute to the development of the activity as designed by the teacher. While this may seem odd when the teacher’s design of the activity is considered, it makes perfectly sense when *surviving* is taken as the student’s motive.

**CONCLUSION**

Both the cognitive verbal analysis and the activity theory based analysis of the Windows lesson indicate that things are not going smoothly in this lesson. Both analyses show that students do not behave mathematically as desired by the teacher. However, the two approaches suggest different interpretations of the situation and of the sources of the problems observed. The verbal analysis points to students’ cognitive difficulties taken as independent of context. The activity theory based analysis suggests that the teacher and the students participate in the same lesson but in different activities, where different motives, goals, beliefs and norms regarding school mathematics drive and guide them. As a result, students’ ways of participation in the lesson are different from what the teacher had wished for.

The discrepancy between the two interpretations is disturbing, as it seems to suggest that different methodologies yield different explanations of the same phenomenon. An immediate response is that the two analyses are guided by two different research questions. Naturally, answers to different questions may not coincide. Still, another question emerges: Are the two answers provided by the two perspectives compatible?

For several decades mathematics education research used to focus on cognitive development of mathematical concepts. Recently, the focus of research in mathematics education has extended from the individual student’s cognition and knowledge to contextual, socio-cultural and situated aspects of mathematics learning and knowing.
The practices and culture of the classroom community (e.g., the nature of social engagements and norms) have become an important factor in studying learning processes, and mathematics education researchers started to incorporate the two perspectives — cognitive and socio-cultural — into a complex view of mathematics learning. This new focus signals a shift from examining human mental functioning in isolation to considering cultural, social, institutional and historical factors. The mathematics education community increasingly embraces the view that cultural and social processes are integral components of mathematics learning and knowing. In line with the current trend in the field of research in mathematics education we respond by proposing that a lesson, which is part of the practice of teaching and learning mathematics, is too complex to be understood by only one perspective. Consequently, a more complete understanding of the complicated practice of teaching and learning mathematics requires the use of both cognitive and socio-cultural perspectives.

This suggestion settles what at first seemed to be two conflicting interpretations of the same phenomenon. However, such resolution raises an epistemological issue that is crucial to the advancement of research in general and to our domain of mathematics education. The two interpretations of the Windows lesson and their harmonisation fit well with Guba and Lincoln's (1994) reflections on the relations between theory and research findings mentioned at the beginning. To a large extent, research findings could be explained by the theories they rely on, and confirm what the theories already could have predicted. Theory and research are then trapped in a vicious circle, which might not be productive. The effort to harmonise the two interpretations is in itself laudable, but is it legitimate?

MATHEMATICAL SYMBOLISM: A FEATURE RESPONSIBLE FOR SUPERFICIAL APPROACHES?

Annick Fagnant
University of Liège, Belgium

Abstract

In arithmetical problem solving process, young pupils' competencies were stressed on through analyses of their informal solving strategies. Other research works have shown pupils have significant difficulties to use the mathematical symbolism. Symbols seem to be meaningless for some of them and that feature could be responsible for the starting of some superficial approaches. Through individual interviews, we analysed the approaches developed by first graders who were not able to solve some problems. These solving errors are mainly due to conceptual difficulties, whereas the number sentences-writing task seems to develop superficial approaches.

BACKGROUND

Today's research concerns mainly focus on studies about the links between mathematics and everyday life situations. Those links can be considered according to a double research aspect, depending on whether we are interested in the use of school knowledge in situations outside of the school, or whether the issue is considered as the integration of real life knowledge into the school (Verschaffel et al., 2000). Research pointed out a gap between both types of knowledge. One of the reasons of that gap could be found within mathematics themselves: at school, children learn rules and symbols but tend to lose the relationship to what these symbols represent (Asman and Markovits, 2001, p. 66).

In early school years, the link between mathematics and real life situations should appear through arithmetical problem solving. More specifically, the word problems should help to establish some relationship between, on the one hand, the mathematical symbolism used to represent additions and subtractions, and on the other hand, the actions on the objects or the relationships mentioned through described situations.

Some reflections about the first mathematical learnings could bring some light on the general issue mentioned here above. Several studies (see Fuson, 1992, for a review of the literature) focused on the analysis of informal solving strategies developed by young pupils. The categories elaborated by the authors helped to enlighten a large variety of the strategies aiming at modelling the actions or the relationships described in the problem. Hiebert and Lefevre (1986) think that at that
level, pupils generally do not develop any superficial strategies and that only the problems that are understood can be solved.

Other researches (Carey, 1991; Carpenter et al., 1983, 1988; De Corte and Verschaffel, 1985; Fagnant, 2002) focused on the analysis of the mathematical symbolisation abilities shown by young pupils. Most of these studies are based on individual interviews and help to analyse the relationships between the informal solving strategies and the number sentences writing task. These studies pointed out specific difficulties at the stage of symbolisation: pupils are not always able to produce a correct number sentence when they are confronted with a situation, even if they solved it correctly.

Furthermore, various studies have shown that young pupils' informal strategies, based on the word problem analysis as well as on a modelling of the involved actions or relationships, are often replaced by superficial strategies in which the pupils only wonder which operation they are going to perform (Carpenter et al., 1983; Verschaffel and De Corte, 1997).

Why do pupils develop superficial strategies in which mathematics consist in applying operations without trying to build some sense related to the suggested situations? Given the difficulties enlightened by the studies focused on mathematical symbolisation, it is possible that part of the answer may lie in the transition from informal knowledge of addition and subtraction to the formal symbolic system of arithmetic (Carpenter et al., 1983, p. 55). Generally, nothing is done to connect number sentences to the informal strategies of young pupils, they are not linked to concrete referents and we can therefore wonder which meaning they acquire. Many students seem to learn symbols as meaningless marks on paper... After instruction on writing number sentences (equations) many first graders still not see the connection between the story problems and the number sentences that represent them (Hiebert and Lefevre, 1986, pp. 21-22). That lack of meaning attributed to symbolism at its very introduction could be a feature responsible for superficial strategies.

This study aims at clarifying this issue through a quite particular perspective. Through the data collected during the individual interviews, we will focus particularly on the results of pupils who were unable to solve and to symbolise some problem situations. Most current errors made by young pupils consist in answering with one of the given numbers. On the contrary, wrong-operation errors are the most current among pupils with several months of experience in formal arithmetic in general and in problem solving in particular (Carpenter et al., 1983). The first types of error are generally due to conceptual difficulties (misunderstanding of some terms, lack at the semantic schemata,... - Lewis and Mayer, 1987; Stern, 1993; Riley et al., 1983). Wrong-operation errors can be explained in various manners; they can notably result from superficial strategies. It is generally considered (Verschaffel and De Corte, 1997) that the reason of these approaches lie in the stereotyped nature of
the problems and in some focalisation of teaching on the final product, to the
detriment of the process (not enough attention is paid to the building of the
representation). The introduction of the mathematical symbolism could also be an
explaining feature; that’s what we are going to investigate now.

**METHODOLOGY**

This study focuses on 25 first graders who were selected randomly from 6 distinct
classes of 4 different schools. They did not receive any teaching related to problem
solving. Mathematical symbolism was introduced very early in the year but the word
problems are only used in grade 2, in order to illustrate the applicability of formal
operations. They are not used in grade 1 to promote a thorough understanding of the
basic arithmetic operations (Verschaffel and De Corte, 1997, p. 69). The
methodology consisted in individual interviews about the 14 problems of the Riley et
al.’s classification (1983). These interviews were performed in the middle and at the
end of grade 1. It was an approach almost similar to that used by De Corte and
Verschaffel (1985) : the interviewer reads loudly the problem, the child retell it and
tries to solve it with the help of physical objects, he is invited to write down a
number sentence which corresponds to the story and/or to his solving strategy, the
interviewer repeats the question to the child and asks him to tick the answer within
his number sentence, the interviewer finally asks the child whether he could propose
another number sentence (flexibility – Carey, 1991). The task requiring to tick the
answer within the number sentence is essential for the future analysis. One of the
advantages of the interview technique is that it helps to check whether the child tick
really the number he identifies as the solution to the problem (the answer to the
asked question). When this requirement is just proposed as a paper/pencil test,
children tend to tick rather systematically the number located just after the equal sign
(Fagnant, 2002), because they consider it as signifying “becomes” or “results in”
(Fuson, 1992). Another advantage of that procedure is that it helps to analyse the
solving strategy developed by the child before he produces his number sentences
and, therefore, the link (or the absence of link) between informal and formal solving
strategy.

We considered that the problem solving process was correct when it helped to end
up in the expected answer. For number sentences, several criteria were taken into
account: the number sentences must present a correct structure and be built from the
expected number triple. Moreover, the answer must be correctly identified in the
number sentence. For the present analysis, we chose to focus on the pupils who were
neither able to solve nor to symbolise the analysed problem(s). We thus try to
analyse the solving errors themselves and those in the number sentences. That could
help us to perceive how the first ones can be explained by conceptual difficulties,
whereas the second ones would rather be due to superficial approaches. And that is
how we will try to support the hypothesis according which the introduction of
mathematical symbolism could be a feature responsible for superficial approaches.
RESULTS

The analyses are mainly focused on 3 problems of the classification of Riley et al. (1983): compare 1 (Peter has 5 candies. Ann has 11 candies. How many more candies does Peter than Ann have?), compare 3 (Peter has 3 apples. Ann has 9 more apples than Peter. How many apples does Ann have?) and compare 5 (Ann has 11 books. Ann has 6 more books than Peter. How many books does Peter have?).

The errors at the level of the informal solving strategies

For the three problems, we can notice that most errors at the solving level are given-number errors (the number to which it is referred in the relational sentence: respectively 11, 9 and 6 for the three problems). To explain the error committed in solving compare 3 problem, we can consider that the child interprets the relational sentence (Ann has 9 more apples than Peter) as a belonging sentence (Ann has 9 apples) or as two distinct sentences (Ann has 9 apples. She has more apples than Peter – Riley et al., 1983). We list 27 errors of that type (19 in January and 8 at the end of the school year). According to the Consistency hypothesis (Lewis and Mayer – 1987), compare 5 problem would be presented in a structure that does not correspond to the child’s “preferences”. It is the reason why the child would try to modify the relational sentence: “Ann has 6 more books than Peter” would become “Peter has 6 less books than Ann”. An incomplete modification would then make him think that “Peter has 6 more books than Ann” and would lead him to propose “17” as the solution (6 more than 11). We only list 2 cases of this type at the end of the school year. Furthermore, considering the relative sentence as a belonging sentence could lead the child to answer “6” (Peter has 6 books), whether he made the complete modification (Peter has 6 less books than Ann) or not (Peter has 6 more books than Ann). We list 11 errors of this type (6 in January and 5 at the end of the school year).

It is also interesting to observe that a superficial key-word strategy (based on “more than”) would bring to produce the answer inverse to the expected solution for compare 1 and 5 (for compare 3, that brings to the expected solution). No case of this type has appeared for compare 1 (no pupil answered 16) and only two cases of this type emerged for compare 5 (they can also be explained thanks to the Consistency Hypothesis). The remaining errors are either omissions, or errors difficult to explain but which are not an indicator of superficial approaches.

In relation to our hypothesis, errors at the solving level could be explained by conceptual difficulties rather than by superficial strategies. Stern (1993) had end up to similar conclusions through several studies aimed at compare problems.
Errors at the level of number sentences production

Now, what does happen when pupils are requested to produce a number sentence whereas they solved the problem by proposing a data from the problem text (given-number errors)?

About half of them do not propose any number sentence, which is quite a “logical” behaviour in relation to their wrong solving process. Some pupils propose a wrong operation, quite difficult to interpret. These number sentences are detached from the informal solving and indicate some type of gap between both tasks. Finally, the remaining pupils propose number sentences corresponding to the sum of the data from the text (the brackets indicate the number identified by the child as the solution of the problem) : $4+(9)=13$ for compare 3 (11 number sentences); $5+(11)=16$ for compare 1 (3 number sentences) and $11+(6)=17$ for compare 5 (3 number sentences).

About compare 3, the number sentences could had been considered as correct if the solution identification would not have been taken into account. For compare 1 and 5, number sentences lead to produce the operation inverse to the expected solution, but the answer identified by the child is a data from the problem text. For the three problems, it can be supposed that the number sentence is the result of a superficial strategy based on the key words (more) (or an « extract-and-add » strategy – Bebout, 1990). These number sentences are detached from the pupil’s problem solving approach and the final answer is not considered as the problem solution. Some pupils interpret the number corresponding to the data sum as being what the children (of the problems) have together. Other pupils are not able to give a concrete meaning to that number. In any case, the children are able to explain their number sentence in relation to their understanding of the situation.

If we had tried to interpret the number sentences only, we would have been led to consider that the number sentence « 4+9=13 » was correct in relation to compare 3 problem and that the number sentences « 5+11=16 » and « 11+6=17 » resulted from superficial strategies in relation to compare 1 and 5 problems. The implementation of the interview procedure (solving before writing the number sentence and task requiring to tick the answer) helped us to observe the gap between the solving process and the number sentence. It is thus really the symbolisation task (and not the solving process) that seems to be responsible for the superficial strategies of some children.

Though that type of error does not occur very often, we have to admit that it appears systematically for most problems of the Riley et al.’s classification (1983). For instance, for combine 2 problem (Peter has 5 candies. Ann has also some candies. Together Peter and Ann have 11 candies. How many candies does Ann have?), a current error at the solving level is to answer by proposing the great number (the whole). This error can be interpreted as a conceptual one (Riley et al., 1983). We do not list any answer resulting from an inverse operation (which could
be the mark of a superficial approach) but the number sentence production task leads some pupils to propose number sentences of that type \((5+11=16)\). For combine 1 problem \((\text{Peter has 4 apples. Ann has 9 apples. How many apples do Peter and Ann have together?})\), some pupils answer proposing both numbers of the terms \((4 \text{ and } 9 \text{ -- confusion in words } \text{"together" } = \text{"each one"})\). The number sentence production task leads them to propose the number sentence \((4)+(9)=13\); considered as incorrect, since \("13\" is not identified as the solution (pupils do generally not give it any concrete meaning).

CONCLUSIONS AND DISCUSSIONS

The results presented here above focus on a few cases only. However, it is important to note that this type of analysis turns out to be relevant for most proposed problems: if pupils do not seem to develop superficial approaches at the level of the problem solving process, the task requiring to produce a number sentence seems, on the contrary, to generate the development of superficial strategies, of the \("\text{extract-and-add}\"\) type (Bebout, 1990). Faced with addition problems, that strategy leads to produce a number sentence which would had been considered as correct if the solving identification criteria had not been taken into account. Faced with subtraction problems, that leads to produce the number sentence inverse to the expected one. The gap between the solution and the number sentence is important: the child generally does not consider the number resulting from the number sentence as the problem solution.

To strengthen those observations bringing out a tendency to develop a superficial approach at the very moment of the number sentence production, we can briefly evoke the results concerning children who have been enable to symbolise the problems they had yet correctly solved. The wrong number sentence analysis (that we have no opportunity to detail here) shows also a strong tendency to develop superficial approaches of the \("\text{extract-and-add}\"\) type. Furthermore, even the results of the pupils who had correctly solved and symbolised the problems reflect that tendency to detach completely the symbolisation stage from the solving one. The change 2 problem \((\text{Peter had 12 cherries. Peter gave 7 cherries to Ann. How many cherries does he get now?})\) helps us to illustrate both cases. The child correctly solves the problem by taking 12 blocks, by removing 7 blocks, then by counting it remains 5 blocks \((5\text{ is thus proposed as the solution of the problem}).\) He may then produce either the incorrect number sentence \("12+7=19\"\) or the correct one \("7+(5)=12\"\) (this type of number sentence is produced by about half of the pupils who propose a correct number sentence faced to that problem).

The various results presented here show the detachment between the solution process and the number sentence. Those difficulties can partly be explained by the way the symbolism is introduced: Because the operations are initially learned outside the context of verbal problems and children are simply told that addition and
subtraction can be used to solve these problems, they have no basis for using their natural intuition to relate the problem structure to the operations they have learned (Carpenter et al., 1981). That way to proceed places the pupils in a difficult position: not only they do not attribute easily any concrete meaning to the mathematical symbolism, but they are too “constrained” to develop superficial approaches in order to perform tasks which are not much connected to their intuitive understanding of the situations.

Faced with those observations, we are induced to think that the first mathematical learnings are already partly responsible for the behaviour of « suspension of sense making » (Verschaffel et al., 2000), noticed among older children. There is indeed a risk that the pupils consider mathematics as meaningless and consisting in applying the rules taught by the teacher and that they do finally not understand a lot (Schoenfeld, 1992). In other words, it can be said that at the early school years, children have some opportunities to make them think that mathematics are quite distinct from real life.

In the classrooms we worked in, the problem solving teaching is coming later on, in grade 2, with the objective of showing the applicability of mathematics in everyday life situations. The results we got make us think it would be very more productive to build learning of problem solving on basis of pupils’ informal solving strategies, rather than to choose to be supported by a basic expertise of operation techniques (wrongly considered as a pre-requisite). If problem solving teaching could begin earlier, we would get more chances to be able to build on the pupils’ experience (i.e., on their informal approaches), to give more meaning to the mathematical symbolism, to “avoid” the development of superficial approaches and then, perhaps, to create from the very beginning a less important gap between the mathematics and the real world...

DEVELOPING LANGUAGE THROUGH COMMUNICATION AND CONVERSION OF SEMIOTIC SYSTEMS

Pier Luigi Ferrari

Università del Piemonte Orientale 'Amedeo Avogadro'

This paper investigates the use of language by 2 classes of 7th graders in a context involving linguistic exchanges and conversions between representation systems in mathematical setting. The pupils were given tasks requiring the verbal description of a figure by means of a written text with no drawings for one class, and the interpretation of the text for the other. Both the tasks have been dealt with through discussion. The constraints involved in the experiment (communication with people not sharing the same context of situation; conversion between figures, written and spoken texts) have been designed in order to promote the acquisition of linguistic skills suitable for the learning of mathematics.

INTRODUCTION

This study is concerned with the role of language in mathematics learning. Recently various frameworks have been proposed that underline the role of languages in the learning of mathematics. For example, Sfard (2000) interprets thinking as communication and regards languages not just as carriers of pre-existing meanings, but as builders of the meanings themselves. So, under this perspective, language heavily influences thinking. On the other hand, there is evidence that a good share of students' troubles in mathematics, at any school level, including undergraduates, can be ascribed to the improper use of verbal language. More precisely, students often produce or interpret mathematical texts¹ according to linguistic patterns appropriate to everyday-life contexts rather than to mathematical ones (for examples see Ferrari, 1999). The difference is not just a matter of vocabulary, grammar or symbols, but heavy involves the organization of verbal texts, their functions and relationships with the context they are produced within. In other words, as appropriately claimed by Morgan (1998), the distinctive features of mathematical language are not confined to the symbolic component but involve the verbal one as well.

Through the paper I am interpreting mathematical language from the functional linguistic perspective. This means that I am focusing on the functions that language plays in the various contexts. I will use the idea of register (defined as a linguistic variety based on use, i.e. the linguistic means developed to express meanings related to some context and goals) to link contexts, texts and the functions that the latter are expected to play. For examples see Morgan (1998), and Ferrari et al. (2001). Even if, as suggested by Morgan (1998, p.3) the "unity across mathematical texts that makes

¹ Through the paper by 'text' I mean any written or spoken instantiation of language, possibly longer than a sentence, not necessarily a textbook.
it possible to talk of 'the language of mathematics' ... is an illusion", there are nevertheless some features of 'institutional' mathematics registers (e.g., those adopted in research, academic communication or mathematics textbooks, at almost any school level) that are common to a wide range of literate registers. Most of these features, at least in principle, are functionally appropriate for the needs of mathematical practice (but not necessarily for those of learning). Among them, in this paper I will focus on the relationships between a text and the context of situation\textsuperscript{2} it is produced within; in most written mathematical registers, texts do not depend upon the context of situation, whereas in everyday-life ones they heavily do. The dependence of a written text on the context of situation may lie, for example, in the reference to space and time (use of expressions like 'this', 'here', 'now', ...) or to participants ('you', 'she', ...) also as physical subjects. The progressive construction of the ability to write and interpret texts not depending on the context of situation is a necessary step for both linguistic and mathematics education. Unfortunately, in mathematical practice and teaching, mathematical registers are often used or taught with little reference to their functions. Students at any level and often teachers are hardly aware of the reasons why certain constructions and styles are adopted and are induced to use them as formal\textsuperscript{3} patterns detached from their functions. This is one of the factors that may induce students to deal with language in mathematics without taking care of meanings. It is worth mentioning that in mathematics education students (and teachers) are exposed to continual shift of registers, as it is necessary to adopt both conversational forms to effectively communicate and other forms taken from mathematical registers to express mathematical relationships. Thus a goal of mathematics education as concerns language is promoting flexibility in the use of registers and awareness of the relationships between linguistic forms and contexts and purposes. This is by no means spontaneous but must be carefully promoted\textsuperscript{4}. This suggests to work within contexts that underline the functions and the meanings of texts rather than just their linguistic form. This means to design learning situations that force a more and more refined use of language as an answer to specific requirements and constraints explicitly posed by the context. The relative autonomy of the texts from the context of situation, for example, is to be regarded as an answer to explicit (and recognizable) communicative needs (such as communicating with people not sharing the same context of situation) rather than as conformity to some

\textsuperscript{2} The context of situation refers to specific aspects of the situation including also those related to the physical environment such as space, time, participants as physical subjects, and so on. Independence from the context of situation does not imply independence from any level of context.

\textsuperscript{3} I am aware that 'formal' is used in literature on mathematics education with a variety of meanings often incompatible each other, such as: formal as 'symbolic'; as 'devoided of content'; as 'institutional'. According to the use prevalent in linguistics, here I mean 'related to linguistic form', in opposition to 'functional'.

\textsuperscript{4} This is one of the reasons why I am not using the expression 'natural language' to denote any variety of verbal language in opposition to symbolic one.
linguistic pattern. Methods based on the teaching of grammar and lexicon detached from use can hardly achieve the goal proposed. Most often students exposed to these methods achieve some knowledge of linguistic structures, but can hardly apply this knowledge to scientific contexts.

THE EXPERIMENT

The experiment involved 2 middle-school classes (namely, A and B) located in different places (both in rural areas in North-Western Italy). Class A had to solve a measurement problem involving the ground floor of their school and to propose the same problem to the other class, communicating the data in verbal written form with the help of no drawings. The task of class B was to reconstruct a drawing, based on the verbal description only and with no knowledge of the building, to solve the problem and to submit their answers. Class A was then requested to evaluate the other pupils' solution and point out both ambiguities in their own verbal text and improperties in the drawing or in the solution, if any. All the tasks were dealt with by the whole classes and the answers were adopted through discussions which were guided by a teacher and a graduate prospective teacher, leaving the pupils completely free to decide the formulation of the problem or its interpretation.

A priori analysis

The situation involves 2 kinds of constraints both relevant from the semiotic perspective. First, the requirement of communicating (in written form) with unknown pupils (even if of the same age and from a similar socio-cultural environment) asks for an effort (mostly by class A) to make explicit a portion of the knowledge that usually is left implicit in spoken conversations, as writers and addressees did not share the same context of situation. Second, the requirements of converting a geometrical figure into a text or a text into a figure asks for some explicitation and selection of the relationships embodied in both the representations. Both the requirements should prevent pupils from exploiting the context of situation and force them to convey all the information in explicit form and to reflect on the pieces of knowledge they could assume as shared by the other pupils. The situation essentially involves figural, verbal spoken and verbal written expressions. Written and spoken productions may play different cognitive functions (see Duval, 2000, for a convincing account); it may be expected that written texts and drawings should be used as relatively stable products to reflect upon, whereas spoken language could be used to explore provisional, unsettled ideas, to compare different opinions (exploiting interpersonal relationships and processes) and to focus on the aspects regarded important, temporarily neglecting the others.

All the sessions have been audio-recorded. To illustrate the arguments adopted by pupils I include some transcripts and try to analyse them. A deeper linguistic analysis

5 The cognitive role of conversion of semiotic systems has been widely discussed by Duval (1995).
of the transcripts requires to deal with the original texts, as the English translation, although it may properly convey basic aspects of the text, may fail in preserving some features such as register and focus.

**OUTCOMES**

**Constructing a text**

Pupils of class A chose to base their text on the drawing in Fig. 1. They agreed to describe the problem situation by means of the text reported below.

Notice that they chose to give measures referred to the drawing, rather than to the real building. I have tried to translate the text as literally as possible. To make reference easier, the sentences are numbered.

1. Our school is much alike a cradle seen in profile.
2. Our building consists of 3 rectangles, 2 of which are placed vertically and one horizontally, which joins them in the upper part.
3. Let us name the 2 vertical rectangles A and B and the horizontal one C.
4. Trapezium D (which is our gymnasium) is right-angled and is placed on rectangle A and part of rectangle C, with its oblique side adjacent to the altitude of rectangle A.
5. The two rect. A and B are equal.
6. Now we give you measures: the base of rect. A (thus of B too) is 11 cm long, and the altitude 21 cm.
7. The base of rect. C is 22 cm long and its altitude is equal to the altitude of rectangle A minus a 10 cm recess.
8. In trapezium D the greater base laid on the 2 rect. A and C is 18 cm long and the smaller one 16 cm, altitude is 19 cm long.

**Interpreting the text**

All the pupils of class B have been given a printed copy of the text which has been also read aloud by the teacher. Pupils immediately produced a number of drawings based on the first two sentences only. They are reproduced in figures 2.A-F, with on the right some of the arguments produced to discard some of them.

**Fig. 2**

<table>

<tbody>
<tr>
<td><img src="image1.png" alt="A" /></td>
<td><img src="image2.png" alt="B" /></td>
</tr>
</tbody>
</table>

A: "The horizontal rectangle doesn't join both in the upper part, but one in the upper and one in the lower."

B: "There are two horizontal rectangles, the text speaks of just one."
After some discussions, all pupils agreed to discard drawings A, B, C, E. The choice between D and F elicited further discussions, focused on the interpretation of "... which joins them in the upper part". Here is an excerpt from an exchange between Alessandro, a boy supporting drawing F and Barbara, a girl supporting drawing D.

Barbara: "The first drawing doesn't work because it doesn't join them in the upper part, it joins them sideways"

Alessandro: "The triangle below...

Barbara: "It's a rectangle!"

Alessandro: "Ok, the rectangle, it's the same, is joined in the upper part, but the triangle, joins them in the lower part."

Barbara: "There is no measure that tells us which is the upper part."

Through the whole discussion Alessandro often used 'triangle' in place of 'rectangle'.

When the teacher asked him "Where is your triangle?" Barbara replied for him: "Oh, he means 'rectangle', you know"

After reading the text up to sentence (4), all pupils agreed in choosing the drawing in fig.3. Immediately after 2 questions arose: the interpretation of 'on' ("...placed on rectangle A ...") and of 'adjacent'.

As regards the first, some pupils proposed drawings like that in fig.4, which were discarded at once by arguments like "It isn't like a cradle anymore" or "Where you put your trapezium there are the classrooms"

As regards the second question, pupils were puzzled by 'adjacent'. Barbara actually searched a textbook and found out that 'adjacent segments' are collinear ones. After some discussion, the contradiction between the definition of 'adjacent' and the other information was disregarded and pupils decided to adopt the drawing in fig.3 and to solve the problem accordingly.
Rearranging the text

Pupils of class A were keenly interested by the report of the interpretation of their text by class B. The discussion focused on the fact that the drawing produced by class B was not congruent to their own, even if the values of area found by both classes was the same and on the interpretation of 'adjacent'. In both cases they conceded that the interpretations produced by class B were legitimate. The text was revised by modifying sentences (3) and (4) as follows:

(3) "Let us name A the vertical rectangle on the right, B the one on the left and C the horizontal one."

(4) Trapezium D (which is our gymnasium) is right-angled and laid\(^6\) on rectangle A and part of rectangle C, with its oblique side consecutive to the altitude of rectangle A."

Some doubts have been raised about the correctness of referring to 'left' and 'right' ("They aren't mathematical words")\(^7\). The whole class approved the following final remark by Barbara: "Next time we should throw four or five of us out of the classroom, then write down the text, let them in and see if they can draw the figure."

DISCUSSION

The experiment has provided a wide range of suggestions and ideas worth to be developed. Here I am focusing on some of them only.

Pupils of class A adopted various means to describe the figure, from the metaphoric reference to a cradle to the introduction of letters to name the basic figures involved. The need for communicating (along with the feedback received) forced pupils to reflect on the meaning of some of the expressions they were using (e.g.: 'upper part', 'adjacent', 'placed/laid'). The outcome has not been the adoption of a register nearer to those adopted by textbooks, but rather the exploitation of all the linguistic and cultural resources available in the context they were acting within. The use of letters to name figures, for example, is different from standard school notation, according to which capitals would represent points; the same holds for their use of 'adjacent' or the replacement of 'placed' by 'laid'.

As regards class B, at least two points of the interpretation process are worth mentioning: the interplay between the text and the drawings produced, and the spoken register adopted. When interpreting the text, pupils proposed a number of drawings immediately after reading sentences (1) and (2), and ruled most of them out after discussion or after reading sentences (3) and (4). Some of these drawings were clearly inconsistent with the first two sentences. Pupils may have paid more attention

\(^6\) The original italian words were 'posto' (placed) in the first version, 'appoggiato' (laid) in the revised one. 'appoggiato' suggests the idea of physical contact (including weight) much more than 'posto' (which is a more formal word common in standard geometry vocabulary).

\(^7\) In the same context, 'top' and 'down' did not raise any doubts.
to the reading aloud of the text, rather than to their printed copies, and to some isolated words (not necessarily the same for all) rather than to the text as a whole. Anyway, this behavior may be explained by the need for an explicit representation as a common ground for reflections and discussions that may help in taking into account the meanings of the text neglected at first. Generally expert people neglect at once clearly inconsistent interpretations and rule them out through inference (or other methods) with no need for explicitly representing them. Most likely, they can deal with a text as a whole and can select the features that are relevant directly from the text; these behaviors are all typically associated to the use of literate registers. For pupils, on the contrary, reflection on explicit models and discussion and comparison of different opinions (with the activation of interpersonal processes based on their mutual relationships) seem to play a relevant function in the interpretation process. Also the final choice of drawings sometimes has proved inconsistent with the interpretation of some parts of the text. When interpreting sentence (4), no pupil objected against Barbara's interpretation of 'adjacent', which was inconsistent with the drawing adopted; nonetheless this was not rejected, maybe because the reference to a cradle or their knowledge of what schools are like were regarded (more or less consciously) as more reliable than the interpretation of a single word, taken from a textbook. Processes like those described here are quite common in everyday-life interpretation processes, whereas in mathematical registers consistency and the meaning of each word are more important.

As regards the spoken register adopted, it may appear that in some exchanges pupils have been quite inaccurate; Alessandro, for example, employs the word 'triangle' in place of 'rectangle' but the others nonetheless do understand what he is saying. Some other pupils discussing fig.2B speaks of 'two horizontal rectangles', referring to a drawing where all the rectangles have altitudes longer than their bases. These behaviors are not uncommon in spoken interactions; they might even be regarded as good features of everyday-life registers, as they allow to build sentences focusing on some aspects only (for Alessandro, the mutual positions of the figures rather than their classification) without paying too much attention to the others. So Alessandro's 'triangle' is not meant to express the whole of the meanings usually attached to it in mathematical registers but rather works as an indexical (such as 'this one' etc.), maybe associated with some gesture of hands, and is strictly related to the context of situation: his classmates understand him quite well whereas pupils of class A most likely would not understand a written transcription of his argument. Mathematically speaking, these behaviors are errors, but it is not deniable that in everyday-life registers they are standard ways of constructing and interpreting texts.

Teaching implications

The results of the study point out that 7th graders may successfully use verbal language to represent mathematical ideas and communicate them to peers not sharing the same context of situation. It seems that the methods they use are quite different from those adopted in institutional mathematical registers (in particular, textbooks).
This paper has presented examples of linguistic behaviors that are inconsistent with the organization of standard mathematical registers (e.g. 'inaccurate' use of some words; lack of consideration for inconsistency) but may be regarded as effective for the purposes of communication and thinking. It seems that pupils attempt to use all the resources available at the level of context they recognize as suitable to carry out communication successfully. For example, pupils of class A when writing the text do not rely on the physical environment of their school, but do use other pieces of knowledge they expect to be shared with the other pupils (reference to a cradle, to geometry vocabulary and so on). All this means that one cannot expect that pupils (and even students at almost any level) can recognize standard mathematical registers as the answer to actual representation and communication needs, as the methods they would adopt to deal with the same needs are quite different. It is necessary from the one hand to avoid any use of mathematical language (not just lexicon but also construction and interpretation processes) that does not correspond to recognizable representative and communicative needs, from the other hand to design activities (like the one I have described) that force pupils to produce and interpret texts accurately without asking them to conform to the patterns proposed by institutional mathematical registers.

In my opinion, further research should focus on the long-term outcomes of activities like those I have described in the paper.

ROBOTICS ACTIVITIES AND CONSTRUCTED PROBLEM SOLVING: CREATING SPACES FOR LEARNING/DOING

M. Jayne Fleener  Keith Adolphson  Stacy Reeder
University of Oklahoma

The case of students solving complex tasks for autonomous robots is explored as an example of the dynamic of learning/doing. Related to the interdependence, emergence and form of classroom dynamics, as discussed by Davis et al. (2000), and to the complexity of relationship, systems and meaning dynamics as described in Fleener (2002), learning/doing extends traditional notions of constructivist learning by considering the social and cognitive spaces of learning and doing as a complex system of relationship, meaning, and activity.

FOCUS OF THE PAPER

In Engaging Minds, Davis et al. (2000) discuss the complexity of the interdependence, emergence, and form of classroom dynamics, including the web of relationships among teaching, learning, and curriculum. We will offer a glimpse of their vision of a dynamic learning environment by describing how students, engaged in robotics activities, create spaces of meaning for mathematics learning and discourse. Focusing on learning rather than teaching, as do Davis et al. (2000), while emphasizing meaning-making as a hermeneutical and social process of relationship, meaning and system, we will consider how rich activities may provide opportunities for “recreating heart” – reviving schools as places of learning/doing.

THEORETICAL FRAMEWORK: LEARNING/DOING DYNAMIC

Foucault (1986) developed the notion of knowledge/power as the inextricable relationship between knowledge and power. According to Foucault, “power can never be the property of an individual” (Appelbaum, 1995, p. 39), and knowledge, as well as power, are aspects of the social dimension. Knowledge/power, then, is something separate from either individually and is the dynamic between the two. Similarly, neither learning nor doing can be separated from the social dimension or from one another. Learning/doing, like Foucault’s knowledge/power relationship, is a structural dimension of the social context. This relationship extends the constructivist notions of learning beyond the cognitive realm to include the active embodiment of knowledge as a complex of relationships.

The logic of relationship can be found in Dewey’s logic as inquiry (Dewey, 1938), and Whitehead’s process philosophy (Whitehead, 1929). A logic of relationship understands that all that is and that we know is in interdependent, dynamic relationship. Nothing exists, posits Whitehead, that is not in relationship. The logic of systems challenges fragmented, piecemeal approaches to meaning and purpose,
considering the form of systems per se. Inextricable relationships within systems cannot be studied apart from the complex web of relationships that give the system its identity and purpose. Chaos, complexity, and complex adaptive systems approaches explore system dynamics from this perspective of interdependence and connectivity. Finally, a logic of meaning, as first explored by Wittgenstein (1953), suggests that meaning structures themselves do not exist and cannot change until we change the language we use to describe our world.

We cannot re-vision schooling while maintaining our traditional ideas about teaching, learning, and knowing. Until we change the ways we talk about what it means to know mathematics, we cannot hope to recreate classrooms where the very soul of mathematical inquiry, as a process of discovery and invention rather than consumption or transmission of inert facts, is possible. The learning/doing dynamic captures the complexity of learning as active, social, and contextual processes.

This paper presents a description of a team of students engaged in creating an autonomous robot. The nature of their problem solving efforts, both in programming their robot to solve particular tasks and in their creation of tasks for their robot to solve, will be explored using case study methodology. From the perspectives of meaning, relationship and systems, the students’ construction of an autonomous robot will exhibit the interdependence, emergence, and form of a learning environment that engages the minds (Davis et al., 2000) and souls (Fleener, 2002) of these students as dimensions of learning/doing.

RELATED LITERATURE: OPPORTUNITIES FOR LEARNING/DOING

Seymour Papert (1980) was among the first to envision the potential of students’ programming robots to transform schools. His Logo environment, he argued, supported Piaget’s notions of students’ needs to actively construct mental structures through experimentation, experience, and activity. He hoped that by programming turtles in his virtual Logo environment, students would themselves become mathematically empowered by gaining confidence in their abilities to do mathematics, deriving new understandings of and appreciations for mathematical relationships, and engaging in problem solving and reasoning activities to achieve complex tasks.

The early Logo virtual environment was extended with the invention of the floor “Turtle” in the 1980’s. Mirroring the moves of the Logo turtle on the screen, the floor turtle was linked to the computer so students could solve problems in three-dimensional space. While the move from two-dimensional virtual space to three-dimensional “meso” space (Berthelot & Salin, 1994) greatly enhanced the opportunity for students to experience the movement of the turtle as an “object to think with” (Papert. 1980, p.11), the tasks to be solved and the inability to instill in the Turtle its own abilities to “think,” limited the impact of Logo in either its virtual or three-dimensional applications.
In the last decade, Papert's vision has been revisited as computers have become more powerful and accessible. While research on the impact of students' programming, per se, has not been definitive, current research (see, e.g. Kaput, 1992) re-examines how general-purpose programming may be valuable as tools for problem solving. Yelland (1995), for example, suggests solving problems through programming may promote higher order thinking skills, develop flexible and creative thinkers, and strengthen problem-solving abilities.

Current research on brain dynamics supports approaches to learning that include rich contextual problems allowing for multiple levels of and approaches to understanding. Richardson's book (2000) *The Making of Intelligence* suggests traditional constructs of intelligence that reduce it to either genetic endowment or environmental factors fail to capture the complexity of the dynamics of active engagement and multiple levels of representations that occur as we interact in rich environments.

Still unexamined, however, is how students' efforts to program autonomous robots capable of interacting with their environments, may challenge traditional notions of problem solving and extend ideas about learning. No longer programming the turtle to solve a particular task, students must explore how to make their robots "think" – how to program a robot to interact with its world in order to solve tasks. More authentic, the challenge becomes not how to set the robot in motion but, rather, how to instil in the robot the ability to take in sensory data as information about its environment and react and respond in ways that still allow the robot to accomplish a particular task. It may be that by moving between spaces of self and robot, thinking and doing, students are afforded opportunities for engaging in what Foucault describes as technologies of the self: "models proposed for setting up and developing relationships with the self, for self-reflection, self-knowledge, self-examination, for deciphering the self by oneself, for the transformation one seeks to accomplish with oneself as object" (Peters, 1999, p. 12). Beyond the cognitive dimension alone, working with robots that are capable of sensing light, touch, and other environmental dynamics, students are afforded opportunities to engage in learning/doing.

**METHODOLOGY**

The students described in this paper participated in an after-school robotics club, and were members of a middle school team that competed in the Spring 2001 Botball competition. Botball is a six-week K-12, national robotics competition sponsored by the KISS Institute of Practical Robotics (www.kipr.org). Teams that enter receive two small processors (a Handyboard and a Lego Mindstorms RCX processor), software (Not Quite C for the RCX and Interactive C for the Handyboard), various sensors for both processors, and Lego parts for constructing their robots. The teams must design, build and program robots using the C computer language to compete against other teams' robots in a competition arena.
Our case study explored how these students came together and approached creating and solving problems for their robots as they learned about robot construction and programming. We used categories described by Davis et al. (2000) as our interpretive framework for exploring the complexity of learning/doing afforded by the robotics activities of this group. Thus, interdependence, emergence, and form (see Davis et al., 2000) were the multiple lenses through which we examine the problem solving activities of this group of students.

RESULTS: TEACHING ROBOTS TO THINK

Our Botball team organized into three groups: one robot team for each of the two processors and a web design team. Each group further divided into teams of builders and programmers. The builders constructed the mechanical structure of the robot. They had to figure out how to integrate the processor, motors and sensors into their designs while working with the programmers to determine design features that were necessary to interface with program objectives. The programmers wrote the computer code to coordinate the robot’s actions. Recognizing and anticipating environmental characteristics were aspects of the problem solving space that required discussion among both builders and programming groups. After the Botball competition, the BOTS club continued to meet, creating and solving their own robotics problems.

The robotics club met every week after school for the remainder of the semester. All but one student remained active after the competition while several new students joined the club. The students determined procedures for deciding what tasks they wanted their robots to accomplish. Club sponsors, including two of the co-authors of this paper, facilitated club activities. Student sense-making activities included problem posing, anticipation of environmental and design features, and explaining, listening, justifying, facilitating and probing each other’s ideas. The adult facilitators enabled sense-making activities rather than providing solution strategies or setting parameters for problem posing and/or solutions (Wood, 1999). This approach is consistent with Cobb and Steffe’s (1983) teaching experiment where the teachers assume the role of participant observers, engaged in student activities through their own listening, querying, and interactions as students work toward problem definitions and solutions. This research approach is particularly relevant in robotics activities as a case where the teachers seldom have a single “best” approach in mind. Creativity as an aspect of solution strategy is supported by the richness of the potential of robotics activities.

As the students in the robotic club learned to work with their robots and use them to accomplish particular tasks, it became clear that there were multiple dimensions to their problem solving. The complexity of the activities in which they engaged can be captured by examining their efforts from the perspectives of the structure of problem solving efforts, interdependence of activities, and emergence of meaning as aspects of learning/doing.
Structure of Problem Solving Approaches. Initially, determining the task for the robots to accomplish was the responsibility of the organizers of the competition and the facilitators of the club, especially during team competition. As students became more adept at working with the robotics components, they began to take responsibility for defining their own tasks. Whether the tasks were defined by the facilitators or by the students, however, there were specific components of the problem solving process that were identifiable.

For example, whether the task was simply to get the robot to move forward and knock down an object, follow a straight line using sensors, or negotiate a maze, students had to design their robot for movement and appropriate sensory inputs, program the computer to use the sensory data the robot received through the various sensory input devices, and write a program that allowed the computer to use this data and take the appropriate actions. Decomposing the problem into these structural characteristics was just one aspect of successfully programming their robot to complete its tasks, however. Anticipating environmental complexity was a problem solving feature beyond the structural dimension of task completion.

Interdependence of Activities. The mechanical or structural features of programming their robots to accomplish tasks were not separate from learning to respond to and anticipate aspects of the environment in which the robot acted. The interdependence of learning to interface with and respond to the complexity of the learning environment, including learning to respond to and anticipate obstacles to task completion, were seamless with learning the mechanics of programming, robot design, or sensory interfacing. Thus, an important feature of the richness of the robotics learning environment seemed to be the complexity of tasks necessary for problem solutions. The students couldn’t first concentrate on the mechanics, then focus on the problem for the robot to solve. Linear problem solving approaches (Polya’s approach, for example) were not viable for solving the tasks these students were tackling. Neither “top-down” nor “bottom-up” strategies seemed to work as students’ problem solving efforts fluidly oscillated between the mechanics of problem solving and the strategies of problem solving.

Learning to navigate was a complex activity that exemplifies this dance between mechanics and inspiration, knowledge and creativity. Students initially approached the problem of robotic navigation by programming the drive motors to propel the robot for a specified time. Backward or turning motions were conceived as reversing or differentially turning motors at each wheel. The students typically started with dead reckoning to determine the length of time necessary for motors to run. Gear slippage and loss of power in the batteries, however, created drift and affected the distance and direction travelled, resulting in missed targets and errant robot motion. Students learned to anticipate these problems and developed strategies that reflected an understanding of motion as an interaction with the environment and not simply movement through space and time. Thus, for example, students typically solved this
problem by using the encoder sensor to determine wheel revolutions allowing for more precise determination of movement distances. Later approaches incorporated the range sensor allowing the robot to determine relatively precise distances from objects. This later approach extends robot motion from a calculation of distance to an intelligent response to its environment.

Emergence. While attending to the larger problem solving task, students learned to communicate with one another as well as with the robot. The interdependence of mechanical and inspirational aspects of problem solving is extended as new meanings and skills are gained. As problems with solution strategies became apparent, opportunities for accommodating these difficulties qualitatively extended the learning opportunity. These emergent understandings were facilitated by the learning/doing interface.

Learning/doing became apparent to us as students alternated among skill development, creative problem solution, brainstorming, mechanical engineering, and programming. Within each problem context, there were multiple events of emergence accompanied by routine activity. Without emergence, however, problem solving efforts were stymied or reached a plateau.

IMPLICATIONS: THE SOUL OF LEARNING

Davis et al. (2000) suggest “teaching is about affecting perception” rather than “helping students to know what they don’t know” (p. 26). The importance of the robotics activities was not in solving particular tasks, or even in the process of solving the tasks. Instead it was in changing how the students looked at their world, problems, and communication. By trying to anticipate how the robot would experience its world and creating a program that would allow the robot to respond appropriately, there were multiple opportunities for the learning/doing complex to unfold.

Just as Whitehead (1929) rejected Newton’s idea that the most basic, fundamental reality is entities in space and time, elevating relationship as the essence of all being, so this robotics case illustrates that learning is not about “knowing,” “thinking,” or “communicating” but is about knowing-relationships, thinking-relationships, and communication-relationships. Learning/doing captures the dynamic of these multiple relationships as our students’ problem solving efforts changed when they stopped looking for solution (things) but instead started seeing problems as rich environment-interpretation interactions.

REFERENCES

The fields of mathematics and computing have been stereotyped as 'male domains'. Efforts to challenge the stereotype within mathematics appear to have had some measure of success. Computers are now common in schools and it is widely believed that using them for mathematics will enhance student learning. However, not much is known about students' beliefs about using computers for the learning of mathematics. In this paper, findings from a large scale survey that included questions tapping attitudes towards mathematics, computers, and computers for mathematics learning are presented. The results appear to confirm recently reported changes in beliefs about the gender stereotyping of mathematics, but lend some support to the view that computers for the learning of mathematics may be more suited to boys.

INTRODUCTION

Historically mathematics was viewed as a male domain, that is it was considered a discipline more suited to males than to females. Research on affective dimensions and gender issues in mathematics education is extensive (see Leder, 1992). A range of affective variables was included in models explaining gender differences found to favour males in mathematics learning outcomes – achievement and participation rates (Leder, 1992). In general, males have been found to have more functional (likely to lead to future success) patterns of beliefs and attitudes associated with these affective dimensions. More recently, it has been reported that students' gendered patterns of beliefs associated with the stereotyping of mathematics as a male domain appear to be changing, at least in some countries (see, for example, Forgasz, 2001a, 2001b).

The same male stereotype has been attached to the field of computing. The variables examined and the research findings on secondary school students' attitudes towards computers are similar to those in the mathematics education literature. Compared to males, females are generally reported to be less positive about computers, like them less, perceive them as less useful, fear them more, feel more helpless around them, view themselves as having less aptitude with them, and show less interest in learning about and using computers; females are also less likely than males to stereotype computing as a male domain, to have received parental encouragement, to use computers out of school or to own one (e.g., Busch, 1995; Colley, Gale, & Harris, 1994; Durndell, Glossov & Siann, 1995; Levin & Gordon, 1989; Makrakis & Sawada, 1996). Shashaani (1993) concluded that gender differences were influenced by socialisation and, as a result, females "have low expectations for success in computing" (p.179). Loyd, Loyd and Gressard's (1987) findings were at variance with those reported by others. They found that grade 7 and 8 female students' computer anxiety levels were lower and their liking of computers was higher than males' and suggested that it may be possible to compensate for females' less positive
Galbraith, Haines and Pemberton (1999) developed a computer attitudes instrument and found that their computer-mathematics subscale correlated more strongly with computer confidence and computer motivation than with the equivalent mathematical scales. They claimed that the consistent and strong relationship often reported between mathematics confidence and performance meant "that the implications of a nexus between technology and mathematics needs specific research attention" (p.216). Gender should also be included as a variable in such research. Hoyles (1998) claimed that introducing computers into mathematics classrooms might widen the gap between males and females, typically those with less confidence or prior experience with technology.

Computers are now commonly found in mathematics classrooms and there is much pressure to use them. It is crucial to know whether using computers for mathematics learning exacerbates or challenges previously identified gender differences in mathematics education. Of interest in this study were students’ gendered perceptions of mathematics, of computers, and of computers for the learning of mathematics.

**THE STUDY**

**Aims**

The findings reported in this paper are based on data gathered in the first year of a three year study [1]. The main aims of the entire study are: (i) to determine the effects on students’ affective and cognitive learning outcomes of using computers for mathematics learning, (ii) to identify factors which may contribute to inequities in these learning outcomes, and (iii) to monitor how computers are being used for the learning of mathematics in grades 7-10. Students’ attitudes and beliefs about using computers for the learning of mathematics were gathered in the first year of the study.

**Sample, instrument and methods**

Students in grades 7-10 from 28 co-educational schools in Victoria (Australia) participated in the study. There were 15 metropolitan and 13 rural schools from across the three educational sectors — government (17), Catholic (4), and Independent (7). The total sample size was 2140 (F=1015, M=1111, ?=14).

A survey questionnaire was administered to the students in semester two of the 2001 academic year. Included in the survey were three sets of ten items tapping students’ perceptions of the gender stereotyping of mathematics (Who & mathematics), of computers (Who & computers), and of computers for learning mathematics (Who & computers for mathematics) — see Table 1 for the three sets of ten items.

Nine of the ten Who & mathematics items were drawn from the 30 item instrument described in more detail elsewhere by Forgasz (2001a, 2001b) and Leder (2001). The tenth item — Tease kids who are good at mathematics — was a combination of two of the 30 items — Tease girls who are good at mathematics and Tease boys who are
good at mathematics. The ten items reflected several dimensions previously identified as associated with the gender stereotyping of mathematics: ability, general attitude, future careers, parents, teachers, and classroom factors (see Leder, 2001). The ten Who & computers and the ten Who & computers for mathematics items were developed to replicate the same dimensions of gender stereotyping — see Table 1.

For each item in each of the three sets of ten items, students were required to consider the wording of the item and then to select one of the following responses with respect to the behaviour or belief represented by the item:

- **BD** boys definitely more likely than girls
- **BP** boys probably more likely than girls
- **ND** no difference between boys and girls
- **GP** girls probably more likely than boys
- **GD** girls definitely more likely than boys

**Analyses, results and discussion**

In order to determine an average directional response to each item, mean scores were calculated based on assigning scores to each response as follows:

- **BD** = 1
- **BP** = 2
- **ND** = 3
- **GP** = 4
- **GD** = 5

Mean scores less than 3 thus indicate that, on average, respondents believe that “boys are more likely than girls” to reflect the behaviour or belief encompassed by the item; means greater than 3 that they believe that “girls are more likely than boys” to do so. For mean scores close to 3 (no difference between boys and girls), one-sample t-tests were used to determine if the mean score obtained was significantly different from 3. Response directions for each item are shown in Table 1:

- **F** = “girls are more likely than boys to...”
- **M** = “boys are more likely than girls to...”
- **nd** = mean not different from 3 ie. “no difference between girls and boys”.

The mean scores are shown graphically in Figure 1. It should be noted that the vertical axis passes through 3, the score indicating a belief that there is “no difference between girls and boys”. Bars to the right of the axis therefore reflect means > 3; those to the left, means < 3. The length of the bars shows the extent of deviation from 3, thus revealing the relative strength of students’ beliefs with respect to each item.

Interesting patterns emerged when responses to the three sets of items were examined individually and then compared. The data were also analysed by gender to explore for differences in the response patterns of male and female students.

**Who and mathematics**

The directional responses to the ten items replicated those reported by Forgasz (2001a, 2001b) for a different sample of grade 7-10 Australian students. The findings appear to challenge the stereotype of mathematics as a *male domain*. The results indicate, for example, that students believe that girls are more likely than boys to say
that mathematics is their favourite (item 2), to find mathematics interesting (7) and easy (1), and to get on with their work in class (10). Boys are believed to be more likely than girls to give up when a problem is too difficult (item 6), to need more help with mathematics (4) and to tease students who are good at mathematics (3).

Means < 3: "Boys more likely than girls..."; Means > 3: "Girls more likely than boys..."

Figure 1. The three sets of “Who & ...” items: Mean scores (Australian grade 7-10 students)
**Who and computers**

For these ten items, students’ beliefs appear to reflect the stereotyping of the field of computing as a *male domain*. The results indicate that students believe boys like using computers (item 11), are good at fixing software problems (12), are encouraged by parents (18), and that teachers expect them to be able to use computers (15). Boys are considered more likely than girls to take control of computers in the classroom (19), tease students who are good with computers (15), be easily distracted when using computers (20), and be able to use computers for future jobs (17). Girls, on the other hand, are believed to need more help with computer activities (item 13) and to give up when something goes wrong with the computer (16).

**Who and computers for mathematics**

The extent of stereotyping seems less marked on these ten items than for the *Who and computers* items and more consistent with the *Who and mathematics* items. Students believed, for example, that there was no difference between girls and boys in not enjoying using computers for mathematics (item 25), giving up when using computers for a mathematics problem is difficult (27), and regarding who parents think it is important use computers for mathematics (30). Students considered that boys were more likely than girls to be good at using computers for mathematics (item 21). Although it was boys who were also believed to think that using computers for mathematics was boring (item 24) but important for their future job prospects (23), these beliefs were not strongly held (mean scores just less than 3). Boys were strongly considered to be the teasers of students who were good at using computers for mathematics (26), as well as the ones to distract others (29), and to take control of the computer when working with others (28). Students believed girls received more help from the teacher (item 22).

**Gender differences**

For each item, independent samples t-tests were conducted to determine if there were statistically significant differences by gender. The results of the t-tests including mean scores by gender and significance levels for the 30 items are shown in Table 2 [See Table 1 for wording of items].

A close inspection of the means in Table 2 reveals that for the vast majority of items males and females responded in the same direction, that is both means were either >3 or both were <3. [Some means were not significantly different from 3 indicating a belief that there was “no difference between girls and boys” and are shown in *italics*.]

As can be seen in Table 2 there were many items with statistically significantly different means by gender. Among those for which males and females responded in the same direction, there is no consistent pattern of either males or females holding the stronger view. Interestingly, there were only four items with significantly different means for which males and females held beliefs that were in opposite directions: items 8, 9, 24 and 25. For item 25, for example, females believed it was girls who were more likely than boys “not to like using computers for doing
mathematics”; males believed that boys were more likely to do so.

CONCLUDING COMMENTS

It would appear that Australian grade 7-10 students no longer stereotype mathematics as a male domain, at least along the affective dimensions previously reported in the mathematics education research literature and tapped in this study. The same cannot be said about the discipline of computing. The students’ beliefs seem consistent with the traditional gendered perception of male competence and female incompetence with the technology. Interestingly, however, when computers are associated with the learning of mathematics the students appear a little more ambivalent. Their views appear to sit somewhere between their beliefs about the stereotyping of mathematics and of computing. Within the constraints of the affective dimensions included in the three sets of items examined here, the data revealed that the views of male and female students were remarkably similar, at least with respect to the gendered directions of their responses to individual items. Although numerous statistically significant differences in mean scores were noted, there was also no clearly apparent pattern that one group held consistently stronger views than the other.

Further work is needed. The study needs to be replicated in different contexts. When other variables such as school type, socio-economic status, and ethnicity are considered, more clearly discernible patterns of differing stereotyped perceptions may emerge.

Students' notebooks are frequently the source of data concerning students' mathematical thinking and practice. But the part the notebook itself plays in the mathematics classroom and the students' mathematical life has rarely been the subject of research in mathematics education. This paper presents some observations showing how notebooks tend to be of an exclusively public nature, and it explores theoretical implications of this tendency. A brief description is also given of the Learners Perspective Study in which these observations were made. That study is an ongoing international project concerned with understanding school mathematics practice from the students' point of view.

INTRODUCTION

Among the accoutrements of mathematics learners, hardly any could be more universal than notebooks. Yet, while student notebooks are a never neglected source of data about students' mathematical work and thinking, the place of the notebook itself in students' school mathematical life seems to have been little studied. In considering the notebook and its significance for the student, one question that arises is to what extent the notebook is a private or public object. In this paper, we shall explore this question and present some observations made in an eighth grade algebra class. These observations indicate that, in the classroom, the mathematics notebook takes on an utterly public character, a character unchallenged by the student and unwittingly encouraged by the teacher. We believe that this has practical and theoretical implications which touch on such issues as the importance of communication in the mathematics classroom (as emphasized in NCTM, 2000), of reflection, and of writing in the development of mathematical thinking.

We shall proceed in a somewhat unorthodox fashion, beginning with the research setting in which we made our observations about notebooks, namely, the Learners' Perspective Study, going on from there to the observations themselves, and only ending with the theoretical background and implications. In this way, we believe, the paper will better reflect the process by which we came to ask our questions, make our observations, and draw our conclusions concerning student notebooks.

THE SETTING: THE LEARNERS' PERSPECTIVE PROJECT

Our observations concerning students' notebooks in the mathematics classroom were made in the course of a more extensive, and still ongoing, study of the students' point of view, called the Learners' Perspective Study (Clarke, 1998, 2000). This project, which involves eight countries including Australia, Germany, U.S.A, Hong Kong,
Japan, Israel, Sweden, and South Africa, seeks to explore a number of questions concerning the way students conceive mathematics classroom practice and mathematics learning. The project arose out of the Third International Mathematics and Science Study (TIMSS). As is well known, the TIMSS study not only established national profiles of student achievement, but also sought to identify national norms for teaching practice that might account for “poor” or “high” achievement scores by videotaping and analyzing a statistically representative sample of eighth-grade mathematics classes in Japan, Germany and the USA (Fernandez, C. et al., 1997). Although this component of the TIMSS study was impressive and unprecedented in international comparative studies, the validity of the “effective scripts” discerned in the TIMSS videos was widely debated and not universally accepted (e.g. Keitel & Kilpatrick, 1999; Stigler & Hiebert, 1997, 1998, 1999). Among the major objections was that the TIMSS Video Study focused exclusively on the teacher and ignored the important role students have in the learning process. The present project, accordingly, expands on the work done in the TIMSS study by focusing on student actions within the context of whole-class mathematics practice and by adopting a methodology whereby student reconstructions and reflections are considered in a substantial number of videotaped mathematics lessons.

The particular case on which we focus in this paper was a sequence of 15 lessons on systems of linear equations taught by a dedicated and experienced teacher, whom we shall call Danit. Danit’s 8th grade class is heterogeneous regarding level; it consists of 38 students, mostly native born Israelis, but also new immigrants from the former Soviet Union and one new immigrant from Ethiopia. As specified in Clark (2000), classroom sessions were videotaped using an integrated system of three video cameras, one viewing the class as a whole, one on the teacher, and one on a “focus group” of two or three students. Following each lesson, the students in the focus group were interviewed, and their notebooks, containing the notes for that particular lesson, were photocopied. Moreover, once a week Danit herself was interviewed. Although we had a basic set of questions for both the student interviews and the teacher interview, we allowed the interview protocol to remain flexible so that we could freely pursue particular classroom events; in this respect, our interview methodology was along the lines of Ginsburg (1997). An important aspect of the interviews was that in the course of them the students could view and react to the videotape of the lesson for which they were the focus group. Needless to say, the interviews themselves were also videotaped.

DANIT’S LESSONS AND NOTEBOOKS IN DANIT’S CLASSROOM

The sequence of lessons viewed in Danit’s classroom began with the idea of an equation in two variables, went on to the graphical representation of linear equations, to the graphical solution of a system of two linear equations, and, finally, to the algebraic solution of such systems. The lessons followed a fairly consistent pattern: a frontal lesson for roughly 10 minutes, then independent work on exercises by the students, followed by a discussion led by the teacher.
students for the remaining 35 minutes of the class period. On days when there were two consecutive lessons, the work period was often extended through the second class period. The students worked in groups of two or three while Danit went from group to group, checking the students' work, asking questions, and helping with difficulties.

In each meeting, we noted that all of the students opened their notebooks only after Danit finished the frontal lesson; at the beginning of the class period, when she presented new material, gave examples, went over exercises from the previous lesson, the students' notebooks lay closed on their desks (there was one meeting that deviated from this pattern; it is the first incident recounted below). We found this curious: did the students not find Danit's examples and lessons worth recording? Did Danit not think that the students ought to write down her remarks and examples so that they would have them to think about and to refer to later? In several of the interviews, we asked the students about this. They replied that Danit allows them to choose whether they use their notebooks or not. In fact, however, the use of notebooks among the students bore no individual stamp; it was determined by Danit, as the two following incidents show. The first incident occurred when Danit began her lessons on the graphical representation of equations. In that lesson, she not only told the students to take out their notebooks and copy the coordinate system, but she also told them what heading to write, and she also told them to use a ruler in setting out the axes of the coordinate system. Afterwards, in the lessons involving graphs, the students produced coordinate systems just as they had done in this particular lesson. The second incident occurred in the meeting following the one above. In that meeting, Danit began immediately with exercises and opened the lesson by saying "Take out your notebooks—I want to see that you're doing the work correctly." The students showed no expression of surprise; this was not an odd request.

Both these incidents, which, we remark, are not at all unusual in Israeli schools, show Danit's control over what the students write in their notebooks and when. The second, however, was striking because it was in such blatant contradiction with the students' claim that Danit lets them choose whether or not they write in their notebooks. Indeed, if they know that Danit will eventually inspect their work, surely they must weigh how Danit might react if nothing were written, or if what was written was written badly, or wrongly. Far from being a matter of choice, then, three basic rules of notebook use seem to be followed in Danit's class:

1) During frontal lessons, students only listen; their notebooks are closed.

2) When given exercises, notebooks are to be opened immediately, and all the exercises are to be recorded neatly (the students should use rulers, for example) in them.

3) The teacher will occasionally look at the notebooks, so these rules must be followed.
The knowledge that the students' notebooks are to be open for inspection, in particular, means that they are a public matter—they are not to be a record of the students' private thoughts about what they are learning: desultory reflections; false starts; mistaken conclusions and their, perhaps embarrassing, corrections. In fact, to their chagrin, Israeli teachers commonly find their students carrying out preliminary work for exercises, calculations for example, not in their notebooks, but on their desks! What students seem to learn is that the notebook must contain finished work that can be confidently held open to view (see the example reproduced in the appendix). The notebook is, in this respect, a sort of rehearsal for that part of school life in which the students' work is inspected most closely, the examination. Thus, students emphasize the use of notebooks to record the sort of exercises that will appear on examinations rather than the explanations behind them:

Interviewer [referring to examples Danit had written on the blackboard]: Did you write these exercises in your notebook?

Moshe/Sharon: Yes.

Interviewer: Why did you write them?

Sharon: So we won't be confused or something...for example, I try to solve...

Moshe: She also told us to write in our notebooks.

Interviewer: And if she didn't tell you?

Moshe: We write.

Interviewer: Write...

Moshe [without letting the interviewer finish her remark]: This is all material for the exam, so it can help.

Interviewer: Do you also write Danit's explanations?

Moshe: You mean her words of explanation? No...I don't anyway.

These students, and others in the class, say that Danit explains her lessons well, but these explanations are not written in the notebooks, only what the teacher might see on the students' examinations sheets. In this connection, it is worth noting that one of the only signs of individuality we could discern in Danits' students' algebra notebooks was the decoration that often adorned the headings, decoration that one often finds adorning their exam sheets as well; but are not such decorations also an expression of the notebooks' public nature, as something to be seen by others?

The public character of the students' notebooks is, interestingly enough, mirrored in the character of Danit's own lesson book. During our first interview with her, we asked if we could see her own notebook. She said that she does not have a detailed lesson book for her 8th grade class since, having taught that grade often, she no longer needs a lesson book, however, she let us see her lesson book for her 9th grade class. The lessons on geometry consisted of pages of solved problems and those on algebra,
pages of numbered exercises. We could see no stated goal, no exposition of the material, no distinctions between major and minor examples, and no lesson structure. She also told us that she brings her lesson book to class and allows, even encourages, the students to compare their notes with hers (as we later confirmed in the lessons following this interview); this way, she said, the students can check and see if they have missed anything. We asked her if she hopes their notebooks will look like hers. She said yes. Thus, there is a notable consistency here between teacher and student practice, namely, that 1) a notebook is the place to record exercises only and 2) a notebook may be inspected at any time, that a notebook is always public.

PUBLIC AND PRIVATE FUNCTIONS OF NOTEBOOKS AND WRITING

To gain some insight on the significance of the observation concerning the public nature of notebooks in Danit’s classroom, we need to remember that questions about the importance and function of notebooks in students’ mathematical life are closely, if not intimately, related to questions about writing. Considerations of writing, on the other hand, suggest that notebooks, in principle, have a place in both private and public domains, and not, as we observed in the use of notebooks in Danit’s classroom, in the latter domain alone. In fact, it can be said that writing mediates between the two domains. Take its most perspicuous public function, that of being a form of communication.

Though one is tempted to say that, as a means of communication, one writes only to be read, it is clear that the act of writing is not completely separate from the thinking that goes on before it. That this is true of creative mathematicians was long ago recorded by Hadamard in his classic work on mathematical invention (Hadamard, 1949, chap. V). But it is no less true for young students of mathematics. Thus, in the communication standard for grades 6 to 8 of the NCTM Principles and Standards, it is stated that “To help students reflect on their learning, teachers can ask them to write commentaries on what they learned in lesson or a series of lessons and on what remains unclear to them” (NCTM, 2000, p.271). Carpenter and Lehrer (1999) are even more explicit in connecting internal mental activity and mathematical understanding to external expression. They write:

Articulation involves the communication of one’s knowledge, either verbally, in writing or through some other means like pictures, diagrams, or models. Articulation requires reflection in that it involves lifting out the critical ideas of an activity so that the essence of the activity can be communicated. In the process, the activity becomes an object of thought. In other words, in order to articulate our ideas, we must reflect on them in order to identify and describe critical elements. Articulation requires reflection, and, in fact, articulation can be thought of as a public form of reflection” (Carpenter & Lehrer, 1999, p.22).
The argument has been extended by some relatively new research by Lillie R. Albert (Albert, 2000). Albert highlights the mediating function of writing by seeing it as a bridge between Vygotsky’s socially dependent zone of proximate development (ZPD) and a zone of learning in which the student is independent and self-regulating, a zone of learning she calls the zone of proximate practice (ZPP). The question Albert addresses is, of course, the one Vygotsky himself saw as “an important concern of psychological research,” namely, “to show how external knowledge and abilities in children become internalized” (Vygotsky, 1978, p.91). For Albert, the ZPP “is the result of the students’ transformation from the interpsychological to the intrapsychological plane of functioning,” and adds that “A basic assumption that underpins the ZPP construct is that the writing students do, as shaped by the collective practice in which they engage, determines how they independently think about mathematical ideas or concepts” (Albert, 2000, p.117).

Whether it is understood as an activity of clarification in the course of articulation or of reflection and internalization following social interaction and collaborative work, writing is seen to come between communication, which is fundamentally public, and reflection, which belongs to a private domain. To the extent that it is connected to communication, surely, writing must be clear and organized, and to the extent that it is connected to reflection, it must be free and exploratory. As an illustration of the latter, consider this description by Thomas Mann concerning his work habits:

> For a longer book I usual have a heap of preliminary papers close at hand during the writing; scribbled notes, memory props, in part purely objective—external details, colorful odds and ends—or else psychological formulations, fragmentary inspirations, which I use in their proper place (quoted in John-Steiner, 1985, p.76).

Since students’ notebooks are their own notebooks, their own possession, it would seem that they are the proper loci for writing serving reflection, that is, writing in which thoughts are worked out and developed, and not only writing in which expected and taught solutions to given problems are recorded. In any case, since the notebook is the chief place in which students do their writing, the research by Albert and others alluded to above suggests strongly that notebooks lose an important function if they do not contain such writing serving reflection.

CONCLUSION

In Danit’s classroom, student notebooks are exclusively public: they contain finished work only and may be inspected at any time. They contain no exploratory work, no false starts, alternative strategies, or random reflections on material being taught to them. Since their notebooks contain no writing of this kind, the ability for writing to mediate between the students’ learning on an interpersonal plane and on an intrapersonal plane becomes seriously limited.
We would like to conjecture that a lack of a private domain in learning—and, surely, the notebook is the most natural place for such a domain—influences students’ very ability to grasp that mathematical ideas are the sort of thing requiring reflection. Our reason for making this conjecture is that in the course of our interviews with students, we found that they had great difficulty understanding and appreciating the connection between “doing mathematics in your head” and writing mathematics down; on the one hand, “doing mathematics in your head” lacked legitimacy, and, on the other hand, writing mathematics down is done only to show the teacher that “you understand the material, that you didn’t just guess.” What we are conjecturing is if students’ notebooks were allowed to be a private domain for the students, a place for written reflection, they might have the opportunity to see how writing mathematics down and “doing it in your head” can be complementary and mutually enriching.

If this conjecture is true, it would support the practical suggestion, such as that in the NCTM Principles and Standards (NCTM 2000), that students keep a mathematical journal together with an exercise notebook. We would stress, however, that in order for the benefits of a mathematical journal to be fully realized it ought to remain strictly within the student’s private domain; their journal must be the place for truly uninhibited reflection. For this reason, we differ with the NCTM’s recommendation that the journal play a part in assessment. But, be that as it may, we believe that, in general, our observations about notebooks point to a need for educators to recognize where the lines are drawn in mathematics classrooms between private and public domains, and to recognize that finding a balance between these domains may have serious implications for the students ability to reflect on mathematical ideas.

THE BRIDGE BETWEEN PRACTICAL AND DEDUCTIVE GEOMETRY:
DEVELOPING THE ‘GEOMETRICAL EYE’
Taro Fujita and Keith Jones
Centre for Research in Mathematics Education, University of Southampton, UK

The dual nature of geometry, as a theoretical domain and an area of practical experience, presents mathematics teachers with the opportunity to link theory with the everyday knowledge of their pupils. Very often, however, learners find the dual nature of geometry a chasm that is very difficult to bridge. With research continuing to focus on understanding the nature of this problem, with a view to developing better pedagogical techniques, this paper reports an analysis of innovative geometry teaching methods that were developed in the early part of the 20th Century, a time when significant efforts were being made to improve the teaching and learning of geometry. The analysis suggests that the notion of the geometrical eye, the ability to see geometrical properties detach themselves from a figure, might be a potent tool for building effectively on geometrical intuition.

INTRODUCTION
The teaching and learning of geometry remains a major problem for mathematics education. As Villani (1998, p321-2) observes, in the conclusion to the ICMI study, “to build a [geometry] curriculum is a very difficult and demanding task” yet “teaching methods [in geometry] are even more important than content. And it is also more difficult to improve them”. In a similar vein, the recent UK study of geometry teaching (Royal Society, 2001) concludes that “the most significant contribution to improvements in geometry teaching will be made by the development of good models of pedagogy, supported by carefully designed activities and resources” (p19).

One of the major characteristics of geometry, as each the aforementioned reports acknowledges, is its dual nature. Geometry is both a theoretical domain and perhaps the most concrete, reality-linked part of mathematics. This dual nature has dual consequences for the teaching and learning of geometry. While, hypothetically, the dual nature of geometry should help teachers to link mathematical theory to pupils’ lived experience, in practice for many pupils the dual nature is experienced as a gap that they find very difficult to bridge. Thus, research continues to focus on the difficulties that pupils have in developing an understanding of geometrical theory and making the transition to formal proofs in geometry (see, for example, Arzarello et al, 1998; Malara and Iadorosa, 1997; Miyazaki, 2000).

While the use of software tools, such as dynamic geometry, is proving to be helpful (for recent research evidence, see the special issue of Educational Studies in Mathematics edited by Jones et al, 2000), there is an urgent need to develop a more effective pedagogical theory for geometry so that such tools can be integrated more successfully.
in mathematics classrooms. With a view to informing the development of better pedagogical models, this paper reports some of the findings from a study of forms of innovative geometry teaching that were developed in the early part of the 20th Century, a time when significant efforts were being made to improve the teaching and learning of geometry. The analysis of curriculum materials and associated teaching methods undertaken as part of this study focuses, in part, on ways of bridging the gap between practical and deductive geometry. The analysis suggests that much promise lies in the notion of the geometrical eye, a term coined by one of the major movers behind the reform of the geometry teaching in the early 20th Century, Charles Godfrey (1910). Godfrey defined the geometrical eye as “the power of seeing geometrical properties detach themselves from a figure” (ibid, p197). This paper argues that this notion might be a potent tool for building effectively on geometrical intuition.

THEORETICAL CONSIDERATIONS

Of the range of theoretical work concerned with the learning of geometrical ideas, that of Piaget (and colleagues) and of the van Hiele’s is probably the most well-known. In the Piagetian work (see, Piaget, Inhelder and Szeminska, 1960), one of the major themes is that a learner’s mental representation of space is not a perceptual ‘reading off’ of what is around them. Rather, learners build up mental representation of the world through progressively reorganising their prior active manipulation of that environment. The van Hiele model also suggests that learners advance through levels of thought in geometry, characterised as visual, descriptive, abstract/relational, and formal deduction (see, van Hiele 1986). Both the Piagetian approach and the van Hiele model have been subject to critical review that is beyond the scope of this paper. Suffice to say that much additional research is needed on the relations between intuitive, inductive and deductive approaches to geometrical objects, the role and impact of practical experiments, and the age at which geometrical concepts should be introduced.

Geometry is an area of mathematics in which intuition is frequently mentioned. Views vary, however, about the role and nature of geometrical intuition, and how it might help or hinder the learning of geometry (and other areas of mathematics). Piaget, for instance, appears to suggest a hierarchy when he equates intuition to what he calls non-formalised operational thought:

Although effective at all stages and remaining fundamental from the point of view of invention, the cognitive role of intuition diminishes (in a relative sense) during development. .... there then results an internal tendency towards formalisation which, without ever being able to cut itself off entirely from its intuitive roots, progressively limits the field of intuition (in the sense of non-formalised operational thought).

Piaget 1966, p225

Van Hiele similarly gives intuition a relatively minor role in the latter stages of learning. In contrast, Fischbein suggests either a plurality or a dialectic when he writes that:
The interactions and conflicts between the formal, the algorithmic, and the intuitive components of a mathematical activity are very complex and usually not easily identified or understood.

Fischbein 1994, p244

Geometers, nevertheless, tend to recognise the importance of geometrical intuition. In his classic text on geometry and the imagination, Hilbert wrote:

In mathematics ... we find two tendencies present. On the one hand, the tendency towards abstraction seeks to crystallise the logical relations inherent in the maze of materials ... being studied, and to correlate the material in a systematic and orderly manner. On the other hand, the tendency towards intuitive understanding fosters a more immediate grasp of the objects one studies, a live rapport with them, so to speak, which stresses the concrete meaning of their relations.

Hilbert 1932, piii

More recently, Atiyah writes:

spatial intuition or spatial perception is an enormously powerful tool and that is why geometry is actually such a powerful part of mathematics - not only for things that are obviously geometrical, but even for things that are not. We try to put them into geometrical form because that enables us to use our intuition. Our intuition is our most powerful tool...

Atiyah, 2001

Yet not all mathematicians share this view. For many, intuition, even geometrical intuition, is not to be relied upon. As Tall (2000, p20) reminds us, the influential Bourbaki approach rejected any notion of geometrical intuition as being untrustworthy. Such a view remains fairly prevalent amongst many mathematicians.

The question that these considerations highlight is how to resolve these apparently opposing positions, if this is possible. To address this question, and attempt to illuminate the relationship between practical and deductive geometry, we examine a time in mathematics education when these issues were being seriously tackled.

METHOD

In the UK at the beginning of the 20th Century, the teaching of geometry was in the spotlight. The suitability of the formal teaching of deductive geometry in the form of Euclid’s Elements was being seriously questioned. The form of theorems and the order in which they should be introduced was the subject of great debate (see, Howson, 1982).

As part of a wider study of the process of change in geometry teaching in the early 20th Century, the historic sources examined in this paper are the geometry textbooks and educational writings of two influential scholars of the time, Charles Godfrey and Arthur Siddons. The pivotal role played by Godfrey and Siddons and the lasting importance of their textbooks in the history of the teaching of geometry is confirmed by Howson (1982) and Quadling (1996). The methodological approach is documentary analysis (Jupp and Norris, 1993) enhanced by the methodology for textbook analysis proposed by Schubring (1987).
The documents analysed include the two main textbooks by Godfrey and Siddons, *Elementary Geometry* (Godfrey and Siddons, 1903) and *A Shorter Geometry* (Godfrey and Siddons, 1912), together with many of their articles published in the journal *Mathematical Gazette*, a collection of educational writing published in the 1930s (Godfrey and Siddons, 1931) and a memoir published in the 1950s (Siddons, 1952). The analysis conducted for the study focused on the design and various roles of practical tasks in the textbooks and on their pedagogical purpose gleaned from documents written by Godfrey and Siddons. Through this analysis we consider Godfrey and Siddons’ approach to the relationship between practical and deductive geometry, and propose some insights for future research.

**PRACTICAL TASKS IN THE TEXTBOOKS BY GODFREY AND SIDDONS**

In both *Elementary Geometry* (op cit) and *A Shorter Geometry* (op cit), and unlike that recorded in Euclid’s *Elements*, the design was such that the early stages of each book comprised practical activities while the latter stages were devoted mainly deductive proof of various geometrical theorems. Throughout both of the Godfrey and Siddons texts, experimental tasks can be seen.

For example, through the exercise below, students would learn how to measure angles (Godfrey and Siddons, 1903, p. 12);

**Exercise 37.** Measure the angles of your set square (i) directly, (ii) by making a copy on paper and measuring the copy.

An example of an exercise (Godfrey and Siddons; 1903, p. 28) that would lead students to discover a geometrical truth that is proved deductively in a later section of the book is as follows;

**Exercise 123.** Cut out a paper triangle; mark its angles; tear off the corners and fit them together with their vertices at one point. What relation between the angles of a triangle is suggested by this experiment?

In some of the practical exercises, students apply chosen theorems in a practical way. For example, the following exercise would be undertaken after the students have learn that ‘there is one circle, and one only, which passes through three given points not in a straight line’.

**Exercise 1162.** (using graph paper.) Draw a circle to pass through the points (0, 3), (2, 0), (-1, 0), and measure its radius. Does this circle pass through (i) (0, -3), (ii) (1, 3), (iii) (0, -2/3)?

In summary (for more details of the analysis see, Fujita, 2001a and 2001b), the roles of these tasks can be categorised as follows:

a) Making students familiar with geometrical instruments and figures;

b) Leading students to discover geometrical facts; and
c) Applying the theorems to practical problems.

In addition, some of the exercises are included to justify geometrical facts through work on experimental tasks. Godfrey discusses the importance of this from a general educational point of view in one of his articles (see, Godfrey and Siddons; 1931).

THE RELATIONSHIP BETWEEN PRACTICAL AND DEDUCTIVE GEOMETRY

It is clear from the writings of Godfrey and Siddons that they considered that a disconnection between experiment and deductive geometry would be inappropriate in the teaching of geometry (Godfrey and Siddons; 1931, p21, Siddons; 1952, p9). Godfrey, for example, was explicit that mathematics cannot be undertaken by logic alone (Godfrey; 1910, p. 197). He wrote that another important ‘power’ is necessary for solving mathematical problems. This he called geometrical power, defined as “the power we exercise when we solve a rider [a difficult geometrical problem requiring the use of several pieces of theoretical knowledge]” (Godfrey; 1910, p. 197). To develop this geometrical power, Godfrey suggested that it was essential to train what he called the geometrical eye. This, Godfrey defines as ‘the power of seeing geometrical properties detach themselves from a figure’ (Godfrey; 1910, p. 197).

To illustrate what Godfrey means by the geometrical eye, consider an example:

If A, B are the mid-points of the equal sides XY, XZ of an isosceles triangle, prove that AZ=BY’ (Godfrey and Siddons; 1903, p. 94).

When we consider this problem, we would not be able to prove this statement unless we could ‘see’, first of all, that, for example, triangle AYZ and triangle BZY are likely to be congruent. A study, carried out in Japan, showed that some students could not ‘see’ which triangles, in the problem above, were likely to be congruent. Nakanishi (1987), who tried to identify the difficulties that students experience when they solve geometrical problems, gave 87 Japanese students aged 14-15 the isosceles triangle question quoted above. Even though 65 students could prove this problem correctly, nine of them were not sure what to do because they could not see any congruent triangles, and four of them could not focus on an adequate pair of congruent triangles (op cit p71).

Godfrey stated that this kind of ‘power’ would be essential to solve geometrical problems, and it was experimental tasks that would make possible to train the geometrical eye’ at any stages in geometry:

There must be a good foundation of practical work, and recourse to practical and experimental illustration whenever this can be introduced naturally into the later theoretical course. Only in this way can the average boy [sic] develop what I will call the ‘geometrical eye’.

Godfrey; 1910, p197

When we analyse Godfrey and Siddons’ textbooks from this point of view, we can find that practical exercises were placed in various places in the deductive stages in Elementary Geometry or A Shorter Geometry. For example, before the theorem ‘a
straight line, drawn from the centre of a circle to bisect a chord which is not a diameter, is at right angles to the chord", the following exercises were included in A Shorter Geometry (Godfrey and Siddons, 1912, pp. 151-2),

Exercise 877. Draw a circle of about 3 in. radius, draw freehand a set of parallel chords (about 6), bisect each chord by eye. What is the locus of the mid-points of the chord?

Exercise 878. Draw a circle and a diameter. This is an axis of symmetry. Mark four pairs of corresponding points. Is there any case in which a pair of corresponding points coincide? (Freehand.)

Exercise 879. What axes of symmetry has (i) a sector, (ii) a segment, (iii) an arc, of a circle?

These exercises would make students aware of the symmetry of the circle as well as leading them to discover the theorem (notice that a symbol in the textbook against each exercise denoted that each required classroom discussion between the teacher and students). Also, to prove the theorem, the fact that the triangles OAD and OBD (see the figure 1 below) are congruent needs to be shown. Our analysis suggests that the precursor exercises are designed to help the students to ‘see’ the congruency of the triangles. That is, that the exercises are purposefully included to develop the students’ geometrical eye.

![Fig. 1](image-url)

CONCLUDING COMMENTS
In a number of countries, the early stages of geometry in schools comprise practical activities such as the drawing and measurement of geometrical figures. Later stages of schooling are then devoted to deductive geometry. The specification for geometry in the Japanese ‘National Course of Study’ (Japan Society of Mathematics Education, 2000), for example, takes such an approach. While this is somewhat in line with the van Hiele (1986) model of learning in geometry, the relationship between practical and deductive geometry remains unclear, and, in particular, the transition between them is one of the major concerns in the study of the teaching of geometry.

A major improvement in geometry pedagogy would be to improve on calls to develop geometrical intuition by linking more directly with geometrical theory. This would entail
developing pedagogical methods that mean that a deductive and an intuitive approach are mutually reinforcing when solving geometrical problems (see, Jones 1998).

This paper argues that Godfrey’s notion of the geometrical eye might be a potent tool for building effectively on geometrical intuition. As we have shown through our analysis, Godfrey and Siddons considered that practical and deductive geometry should be combined in the latter in the teaching of geometry. Godfrey considered that the geometrical eye would be essential for successfully solving geometrical problems, and that it should be trained by practical tasks at all stages of geometry. It is illuminating that innovative teachers 100 years ago mentioned the importance and roles of visual images in geometry, and it is worth considering the following issues in the future research for improvement of the teaching of geometry in primary and secondary schools. Future research could examine whether it would be possible to define more clearly the notion of the geometrical eye, what the relationships are between difficulties of proof in geometry and the geometrical eye, and how (or whether) it would be possible to train students’ geometrical eye though practical tasks.

DEFINING WITHIN A DYNAMIC GEOMETRY ENVIRONMENT: NOTES FROM THE CLASSROOM

Fulvia Furinghetti* & Domingo Paola**

*Dipartimento di Matematica dell'Università di Genova. Italy
**Liceo Scientifico ‘A. Issel’, Finale Ligure (Sv). Italy

ABSTRACT. This paper concerns the activity of defining. We report about an experiment in which we studied students' behavior in constructing and classifying quadrilaterals within a dynamic geometry environment (Cabri-Geomètre). In particular, we considered the problem of the consistence of certain definitions with the constructions made with Cabri, i.e. we used the microworld to make students reflect on the adequacy (within the microworld) of the definition they use. The findings show that there are kinds of thinking that are developed as a result of the interaction with the tool and suggest considerations on the problem of providing students with a meaningful and active approach to theoretical thinking.

INTRODUCTION AND THEORETICAL FRAMEWORK

In this paper we discuss the problem of defining that we have faced elsewhere, see (Furinghetti & Paola, 1999 and 2000). The reason why we pay such a great attention to the theme of definition is that it is the first gate to enter a theory. Thus a way of defining not suitable to students' mind may affect the entire path in the construction of a theory. This theme is set in our general concern of providing students with means to approach theoretical thinking with awareness. Other authors have faced the issue of awareness in doing mathematics, e.g. Mason (1987). In using the term “awareness” we mean that students must be active participants in the process of constructing a theory and have to grasp the meaning of what they are doing. This view is based both on recent literature in mathematics education and on evidence emerging from the past. At the beginning of the twentieth century, when the foundation movement stressed the importance of the axiomatic method and logic, mathematical programs (and, as a consequence, textbooks and teaching style) became oriented to follow a pattern based on axioms-theorems-deduction. This “axiomatic style” affected mathematics teaching in many countries. Even at the beginning, however, this approach was questioned by teachers, as evidenced by papers appearing in early journals oriented to mathematics teaching, and also by important mathematicians. Felix Klein claimed that in school, as well as in research, the phase of formalization must be preceded by a phase of exploration based on intuition. He wrote: “I maintain that mathematical intuition [...] is always far in advance of logical reasoning and covers a wider field”. (Klein, 1896, p.246). We find a similar statement in the introduction of a school geometry book by a famous Italian mathematician, Francesco Severi. He wrote (1930, Vallecchi, Florence, p.IX; our translation): “Who is aware of the value of foundation theories, does not make the dangerous mistake of giving to the elementary teaching a critical and excessively abstract style.” Giovanni Vailati (1907), an Italian secondary teacher and
researcher in logic, supported a method of teaching in which exploration, experimental mathematics, drawing with rule and compass have to precede deduction.

In the 1920s the idea of a “genetic” principle took shape and interesting treatises were published\(^1\). For example, Gusev and Safuanov (2000) refer about a school geometry book by N. A. Izvolsky, in which it was advocated that teachers explain to students the origin of geometrical theorems. According to the author, when this is done, students see geometry in a different way. The idea of a genetic approach later took a definite form in the book by Otto Toeplitz (1963) on infinitesimal calculus. This author was aware that in this domain the notion that learning mathematics takes place in a sequence predetermined by mathematical logic has shown its pedagogical limitations. Indeed, when organized around their logical kernel, the definitions of the main concepts of calculus (integrals, limits, derivatives) come out of the blue and the burden of formal rules and of theorems makes it difficult for students to grasp the meaning of what they are doing.

Our historical outline stresses the widespread (over the years and across the countries) concern about providing students with an active and meaningful approach to theoretical thinking and about the search for mediators/environments to realize this approach. Some of the authors we have mentioned look at history as a mediator effective for this purpose. Others of them consider different mediators: in some passage of Izvolsky’s writings we find an embryo of classroom discussion, Vailati’s program is centered on the use of exploration and of mathematical instruments.

In the present paper we have chosen the dynamic geometry software *Cabri-Géomètre* as a mediator to make students aware in defining. Our aim is to study which strategies students apply and how this environment affects their behavior. To realize it we have studied the work on the definition of quadrilaterals of 21 students of junior high school (15 years old). Quadrilaterals (which, in theory, were a topic known by our students) have been chosen because the focus of the described activity is not on the mathematical object to be defined, but just on definitions considered as mathematical objects which need of careful reflection. We think one masters and reifies a concept when this concept is used as an object. For example, one understands the concept of function when the function becomes an element of the domain in which he/she works. Thus one starts to understand what a definition is when definition itself becomes an object of study\(^2\).

The family of quadrilaterals has been often considered for the purpose of studying the problem of defining (both as for students and for teachers). For example, among the articles and departments (about 700 and 1000 respectively) published in the years 1990-2000 in the journal *Mathematics teacher* we have singled out only 26

---

\(^1\) A pioneer example of the application of this method is offered by the book *Éléments de géométrie* by the mathematician Alexis-Claude Clairaut first published in 1741 (Paris: David fils).

\(^2\) For a wider description of our theoretical framework on definition see (Furinghetti & Paola, 1999 and 2000; Shir & Zaslavsky, 2001).
contributions that may be considered belonging to the domain of definitions. Of them, 6 treat quadrilaterals. The reason of the popularity of quadrilaterals as object of definition is that there is a great experience (from Euclid onwards) about this subject both from the theoretical and from the teaching side. As shown in the papers (De Villiers, 1994 and 1998; Shir & Zaslavsky, 2001) this subject allows to work on hierarchical classification and application of notions about sets, it may be treated through verbalization or visualization, and it is a good field in which one may test the notion of equivalent definitions, see (Leikin & Winicki-Landman, 2000). Moreover this subject is suitable to exploit the intrinsic cognitive character of the dynamic geometry environment, see (Jones, 1998 and 2000; Mariotti, 2000). In particular, we deal with the problem of the consistence of certain definitions with the constructions that can be done with Cabri. We use the microworld to make students reflect on the adequacy (within the microworld) of the definitions they use. Our study has not the pretense to give final answers to the issues in question, but we hope that it can be a further tessera in the mosaic that researchers are constructing about these issues.

METHODOLOGY

The experiment involved 21 Italian 10-grade students with previous experience of using Cabri for solving geometrical problems. They worked in pairs (one PC per pair), except one group of three students. The teacher and a researcher acting as observer (he was one of the authors) were present. The observer was not passive, but talked with students and addressed their activity to Cabri in order to obtain more information about the interaction student-Cabri. We know from other experiments that if the teacher use Cabri as a blackboard students do not enter completely in the "logic" of software, see (Arzarello et al., 1998).

The first day of the experiment the students received the following instructions:
- Give a classification of quadrilaterals.
- You can use what you know from the previous school years, and, if you think it is useful, Cabri.
- Please keep a diary of the sessions (the final classification, discussions with the mates working with you, ideas that have not been completely developed).
- Remember that a construction with Cabri is validated only if it is kept by the dragging test.

All students used Cabri; after two sessions of work they wrote a report, as it was requested. In the next session the teacher orchestrated a classroom discussion on the students' work, and wrote a report. Since she had the impression that the less extroverted students were not able to express their thoughts in front of all mates, she asked students to answer some written questions prepared by her. Our reflections are based on the notes by the observer, students' reports, the report of the teacher, and the written interviews.

DIRECT OBSERVATION OF THE WORK WITHIN THE DYNAMIC GEOMETRY ENVIRONMENT

Few days before the experiment students had classified triangles (only through paper and pencil), nevertheless they were quite worried about the task of classifying quadrilaterals. The reason of that was the anxiety for the technical problems linked
to Cabri. The presence of an external person, however, has motivated students and they worked with good will. The groups acted collaboratively. Who used the mouse was the leader in the activity, but the low number of students in each group allowed to use the mouse alternatively (at least this happened in the most collaborative groups), so that the risk of passivity in the group was avoided.

All groups began with the construction of a square. The most common sequence was “to draw a circle and a square inscribed or circumscribed”. The pair Dalila-Chiara drew a circle and two points on it, then the square circumscribed to the circle. At the beginning they wrote the macro construction before checking if their construction passed the dragging test. They had four times the message “Macro is not consistent”. They never checked the geometrical construction, but wrote again the macro until the computer said that it was correct (the construction, indeed, was correct, while the macro was wrong).

This behavior was widespread among students working with the dynamic software. Also the pairs Elisa-Michela and Paolo-Carlotta did not think to validate their construction when found that their rectangles did not pass the dragging test. This means that, even if they were able to construct macro and had sufficient abilities to use the software, they did not enter the logic of the tool. They worked only at the level Laborde (1998) terms “spatio-graphical level”: thus they were not able to use Cabri as a mediator to pass from drawing to the geometrical theory.

The other groups (except one) made drawings which were figural (i.e. not obeying geometrical rules). After having drawn a parallelogram as a mere drawing, Luca asked himself “How can I decide that this is really a parallelogram?” This is a question that would not have arisen without Cabri. It was spontaneous to discuss on which conditions the figure was really a parallelogram. It was important to have an expert at disposal (the teacher or the observer) who listened to the questions and answered in real time, not after some time when the questions are no more important.

Paolo and Carlotta drew a circle and after drew the symmetric C of a point B respect to the center O, then constructed the perpendicular line to the line BC. The intersection of this perpendicular line with the circle gave two points A and D. ABCD was the resulting square. After that they used (correctly) symmetries to obtain a rhombus. They used symmetries and definitions which are construction-oriented (i.e. rich of hints for constructing). They succeeded in doing figure, even if they were not able to state the characteristic properties of the figures they have correctly drawn. When the researcher asked a definition of the rhombus they repeated the construction learnt in junior secondary school based on drawing two perpendicular lines and taking congruent segments on them.

---

3 We have emphasized with the boldface type the features we consider interesting in our experiment.
Elisa and Michela constructed a rectangle by combining two right-angled triangles. They tried with translations, with 180° degrees rotation. This pair was very collaborative, students tried to explain how it is possible to obtain rectangles from right-angled triangles, but the figures they produced did not pass the dragging test. Thon and Federica were much worse: they drew objects and erased them without the project necessary to perform the task in Cabri.

The attitude of combining blocks of elementary figures to obtain sophisticated figures, as it is done with the Lego blocks, was even more evident in the second session dedicated to trapezia. Students looked at the figure as a mere drawing and act as a scanner in reproducing the stereotyped figures of their textbook. The conceptual aspect was absent. In this behavior we may see a certain analogy with the behavior in algebra were signs are manipulated without meaning. Cabri may be useful to change this behavior, since emphasizes the construction-oriented aspects to the detriment of the pure reproductive ones and thus it calls for meaning.

From this first session we may draw some general conclusions that have been corroborated in the second session on trapezia:

- Students have in their mind figures (not the properties of figures).
- They desperately explore Cabri looking for a way to reproduce figures and use strange means and tricks on the Cabri screen. Figures they have in mind are static. They, indeed, recognize only the figures, which are in particular configurations. We’ll find these observations also in the teacher’s report. For students the construction is not validated by the fact that a certain property is kept by dragging, but by the drawing obtained in a particular position. Cabri has made visible the students’ remoteness from the theory they should study.
- Students do not use the potentialities of the tool in a rational way.
- Only one pair uses symmetry. This is done to construct the figure, but not to define the figure.
- Some behavior observed is fostered by the current teaching style: since many years drawing with rule and compass has been abandoned in school.

**THE TEACHER’S REPORT ON THE DISCUSSION**

The teacher’s report reflects her concern about the practical teaching problems she has to face. The report is based on the discussion in classroom. As an example of what happened during this session we give the following description of the discussion about “dragging”.

Chiara began by stating that if the construction is correct, the shape of the figure is kept.

Elisa: “No! Because sides shorten or lengthen!”

Patrizia: “But what do you mean by shape of a figure? Even if measures change a square is always a square!”

This clam addressed the discussion on what the “shape” of figure is. For someone it was “the set of sides”, for others “the construction one has made”, “the aspect with
which the figure appears”, “enlargement or reduction (scaling off)”. Ambra stated that perimeter and area of figures are kept by dragging. The teacher asked whether the dragging is an isometry; Ambra was puzzled and changed her mind. The teacher writes in her report that, even if isometries have been treated in the previous school year, students’ reactions show that isometries remained very abstract. The movement originates confusion and students have difficulties in singling out invariants. This difficulty emerged also in the written interviews. Students were more able in recognizing the symmetric of a figure in respect to a point or a straight line and in recognizing symmetries of figures. Some student have noticed that the “little hand”, which allows to drag, appears only in some positions.

ANSWERS TO THE WRITTEN INTERVIEW

The questions of the written interview have been prepared by the teacher on the ground of the crucial points emerged in the discussion. They concerned:
- which quadrilateral has been the starting figure
- what is kept and what is left by dragging
- how the passage from the construction to the definition happens: 1. Listing the actions in the menu? 2. Enunciating the properties used in the construction? 3. Enunciating only the properties sufficient to construct the figure?
- why it is required to drag the figure one has constructed.

Students answered individually on the ground of the work at the computer and the discussion in classroom. Protocols give interesting insights on kinds of thinking brought to light by the activity with Cabri. All students confirmed that they started from the square. A paradigmatic explanation of this fact given by a student is:

I started from the square because it is the quadrilateral with more properties and because I can imagine it more easily than the other quadrilaterals.

Other students say that “The square is the easiest quadrilateral”. The generic is more difficult to be conceived than the particular and figures with regularities (i.e. specified figures) are more easily perceived.

To have started from a square has reflections on the classification of quadrilaterals. Even if this subject had been developed before in classroom, 11 students did not answer. Six students drew a figure with Venn diagrams showing the hierarchical classification presented in their textbook (may be reproduced in a ritual way). Four students chose a classification going from squares to trapezia, which is inspired by the sequence they used in constructing quadrilaterals with Cabri. Two of them simply listed quadrilaterals, one explicitly wrote that she did not agree with her textbook classification. One student drew the figure below (“quadrato” means “square”). The dynamic geometry environment, indeed, has oriented to a different criterion of classification, which we may term “by default”. It is a kind of reverse hierarchy: one starts from the more specified figure (the square) having the greatest number of properties and goes on by leaving some properties.
CONCLUDING REMARKS

Coming back to the issue discussed in the introduction (what may be the suitable sequence for introducing students with awareness to theoretical thinking) we have now further elements of reflections. From many examples provided by ethnomathematics of the present and of the past we already know that each environment gives different stimuli and opportunities to mathematical thinking. As it is reported in (Gerdes, 1988) Mozambicans peasants conceive and use “spontaneously” properties of parallelograms, which in the teaching sequence of our schools are theorems that must be proved. In teaching spatial geometry we have observed that students have difficulties in dealing with some polyhedra (e.g. dodecahedron), but this does not mean that these polyhedra are difficult to be conceived in an absolute way. Artmann (2001) reports that not only dodecahedra appear naturally (this is one of the three shapes in which the mineral of pyrite crystallizes), but also bronze dodecahedra were popular craft objects in Roman Imperial times. In the same way the dynamic geometry environment, as a new kind of ethnomathematical feature, brings to light forms of approaching mathematical situations different from those emerging when working with paper and pencil (with or without rule and compass). In our experiment the dynamic geometry software enriched students’ experience in certain fields, by providing new situations. Also it revealed itself a powerful environment to detect students’ behaviors and difficulties. In addition, the discussion orchestrated by the teacher brought to light interesting teaching implications: the crossing of metric and non-metric properties, the fuzziness of the concept of transformation, the relation between perimeter, area and shape, the difficulty of invariants.

In our experiment we have observed a kind of “computer anxiety”, i.e. students’ main concern was to exploit the facilities of Cabri rather than to design a project for performing the task (constructing and classifying quadrilaterals). The choice of the circle as a figure on which to work for constructing, and of the square instead of a generic quadrilateral as a starting figure for classifying quadrilaterals is conditioned by the dynamic geometry software.

The environment of Cabri addresses students towards definitions construction-oriented. A student constructed rhombuses starting from the properties of diagonals. And, when
he attempted to inscribe a given rhombus in the circle that he had drawn at the beginning, he discovered that this is possible on particular conditions. Thus a statement to be proved may be spontaneously generated by the activity with Cabri. Also the environment fosters the use (even limited) of symmetries, which are object of teaching, but are rarely used by students when working with paper and pencil.

We point out that the persistence of the figural conceptions and the reluctance to use the dragging test show the lack of links with theory. Sometimes students seem to consider the construction of figures as a mere practical activity separated from a mathematical theory. Educational research provides teachers with means to perceive the existence of this gap and to fill it with appropriate strategies.

SITUATIONS BY THEORY OF PERCEPTION
Hagar Gal  - Liora Linchevski
The Hebrew University of Jerusalem, Yellin Teachers College, Israel

Abstract
In this paper we suggest an analysis of ‘elementary’ difficulties and PLS (problematic learning situations) encountered in geometry classes in junior high school using theories of perception and perception-based knowledge representation. Our purpose is to illustrate a neglected aspect of the difficulties encountered in geometry studies. The demonstrations in this paper are based on and taken from a longitudinal research study using methodology described in previous works (e.g. Gal & Linchevski, 2000).

FOREWORD
Over an extended period of time we observed student teachers that taught geometry to slow and average junior high school students. The focus was on locating, identifying, and analyzing Problematic Learning Situations - PLS. (We use the terminology of PLS for situations arising in the course of teaching where teachers find it difficult to help students with problems in learning. See also Gal & Linchevski, 2000). We were interested in both the student’s and teacher’s point of view in an attempt to explain difficulties encountered (e.g. Gal & Vinner, 1997, Gal, 1998, Gal & Linchevski, 2000).

While analyzing the PLS we found that perception and perception-based knowledge representations, among other cognitive theories, provide explanations for many of the difficulties. Therefore, introducing these theories to teachers and showing their relevancy help teachers uncover and understand student difficulties that they were not previously aware of, and propose coping strategies.

As part of our research, we have planned a yearly academic course that aims to enhance teacher understanding of the ways that students think. Teachers participating in this course are presented with theory (general topics - e.g. concept and concept image - and specific topics included mainly topics relevant to understanding geometrical concepts - e.g. visual perception, Van- Hiele theory etc.) and actual student difficulties in geometry (using video clips of PLS, reports of class discussions, etc.) We found that teachers’ ability to analyze the reasons for student and teacher difficulties increased significantly during the course. Later in this paper we will present some examples of difficulties that were recognized and explained by these teachers. Describing the method used and results of the involvement are beyond the scope of this paper.
In this paper we wish to focus on theories of perception and demonstrate their use to explain and analyze difficulties in geometry class.

THEORIES ABOUT PERCEPTION AND PERCEPTION-BASED KNOWLEDGE REPRESENTATION

Visual perception

Visual perception involves processing information that comes through our eyes (e.g. Anderson, 1995). There are two phases:
1. Registering the sensory information - visual information processing.
2. Interpreting the identified shapes and objects - visual pattern recognition.

Visual information processing

In the first stage of visual perception, shapes and objects are extracted from the visual scene. In order to do this, we need to know "what goes with what" to form the object. The set of principles according to which objects are organized into groups is called the Gestalt principles of organization (e.g. Anderson, 1995).

a. Principle of proximity: elements close together tend to organize into units.
b. Principle of similarity: objects that look alike tend to be grouped together.
c. Principle of continuation: we perceive lines with continuous turns better than lines with a sharp turn.
d. Principle of closure and good form: we tend to see shapes as closed rather than open, and with a regular shape rather than an irregular one.

Visual pattern recognition

In the second stage of visual perception, shapes and objects are recognized. Recognition is the result of feature analysis, in which the object is segmented into a set of sub-objects, the output of early visual processing (first stage). Each sub-object is classified, and when the pieces out of which the object is composed and their configuration are determined, the object is recognized as a pattern composed of these pieces (Anderson, 1995; Barsalou, 1992).

Recognition can be the result of either 'bottom-up' or 'top-down' processing (Barsalou, 1992). Bottom-up processing uses information from the sensory physical stimulus for pattern recognition. When context or general world knowledge guides perception, we refer to the processing as top-down processing, because high-level general knowledge contributes to the interpretation of the low-level perceptual units (Anderson, 1995). The context has an important role in pattern recognition, tuning a specific interpretation in top-down processing.

Attention is another parameter that affects information processing. There are automatic processes that require no attention or conscious control, and there are controlled processes.
Perception-based knowledge representation

There are two ways for visual information to be represented in the cognitive system (Anderson, 1995): perception-based knowledge representation and meaning-based knowledge representation (which is beyond the scope of this paper). In perception-based knowledge representation, there are separate representations for verbal and visual information. Some visual information, such as the shape of geometric objects, is stored according to spatial position, while words are stored in linear order. Moreover, memory for pictorial material is superior to memory for verbal material.

Mental objects are dealt with like physical objects. Mental comparison of visual properties involves difficulties similar to those involved in visual perception. Complex figures composed of hierarchical decompositions (Anderson, 1995).

IMPLICATIONS FOR THE ANALYSIS OF STUDENTS' DIFFICULTIES IN GEOMETRY

Analysis by the Gestalt principles

Identifying an angle formed between two straight lines. Many students, when talking about perpendicular lines, cannot point out where the right angle lies. They point at the area near the point of intersection. Or if the perpendiculars are part of a complex shape, such as the diagonals of a square, the student sometimes points at other right angles (see Gal & Vinner, 1997). This difficulty can easily be explained by the principle of continuation (third Gestalt principle mentioned before): the tendency to perceive lines which continue in the same direction rather than lines with a sharp turn causes the student to see two straight lines (figure a) instead of two rays emanating from one point, forming an angle (figure b).

Mistaking an angle for a triangle. There are students who draw a triangle whenever they are asked to draw an angle. Why is that so? Generally, students encounter angles as parts of triangles and not as 'basic angles' i.e. two rays (or ray segments) emanating from one point. In such a case, separating the angle rays from the triangle's third side, in order to identify the basic angle, contradicts the principle of closure and good form. It also explains why the angle is frequently interpreted as a closed shape (triangle).

Identifying common parts (segments or angles) in complex shapes. A frequent task is pointing out shared parts of two (or more) triangles with a common side. Very often, students point out the wrong parts as shared parts: the side intersecting with the shared side may be identified as a shared side, or a combination of the two angles may be pointed out as a shared angle (see the darkened side/angle in the drawn figure). In order to find the right answer, one needs to separate the configuration into two triangles and check their parts. But the need for separation contradicts the principle of proximity as well as the principle of closure (of the "big" triangle).
A junior high school teacher reported problems with the drawing shown here, where students indicated AB as a common side for the two triangles. The teacher also explained that this was due to the principle of continuation. 

**Using the principle of similarity.** The principle of similarity can be used to overcome difficulties based on the principle of proximity or the principle of continuation. Coloring parts we want to focus on can make use of the tendency to group together objects that look alike. (We can use a transparency placed on the figure, and color the relevant parts). To further demonstrate, in the first three examples presented above, we actually used this principle: the relevant parts of the figures were widened, darkened or drawn as a dotted line to group them together through similarity.

**Analysis by top-down and bottom-up processing**

1. Using the Gestalt principles to explain difficulties in identifying common parts in complex shapes we actually presumed a bottom-up processing which uses sensory information. Another explanation considers top-down processing, i.e. when a wrong context impairs recognition. The segment BC can be considered as a "common" segment to all three "small" triangles by means of 'in between', 'amongst', as in the case of a common yard or premises of several buildings. The same for the angle AOD, which can be considered as "common" in context of 'every one contribute a part' to create 'altogether'.

2. It is possible to recognize a right angle by bottom-up processing using sensory stimulus, which thus recognizes horizontal and vertical segments as a pattern of a (prototype – e.g. Rosch, 1978) right angle or a (prototype) right triangle: 

   Alternatively, recognizing a right angle by top-down processing occurs when using the conventional sign of a small right angle (instead of an arc). In this case, the special sign context is used to supplement feature information in recognition of the figure.

3. The following task requires the solver to identify two triangles in the configuration (in order to prove that they are congruent). This can be done by decomposing the figure into two triangles.

   ![Diagram](https://example.com/diagram.png)

   Given that: 
   \[ AO = OD, BO = OC, \]
   Prove that \[ AB = CD \]

   Such decomposition fits the principle of closure and good form. Therefore, information based on the stimulus is sufficient to enable the perceiver to recognize the triangles. This is an example of how bottom-up processing occurs.

A different task is presented by Duval (Duval, 1998, p. 41). In this case, bottom-up processing is generally not enough to get to the solution. That is because many sub-configurations can be seen. The Gestalt principles encourage decomposing into two "big" triangles (ABD, DBC), or six "small" polygons (APD,
ANJP, JBQ, etc.) In order to find the relevant decomposition (ABP, DQC) one needs to be aware of the context of *middles* explicitly recalling its theorem. This helps in finding the correct decomposition of the configuration. This is top-down processing.

**Analysis by automatic and controlled processes**

Many controlled processes are problematic for geometry students. Typical examples of a concept (prototypes) are easier to recognize (Rosch, 1978). The occurrence of an automatic process can explain this. A controlled process is needed to recognize less prototypical members of the category, e.g. recognizing a right angle in various orientations, an angle in a composite configuration, the height of triangle (oriented towards a not horizontal base), a square as a rectangle etc. Turning recognition into an automatic process can be part of the solution. Repeatedly exposing the learner to a wide set of examples can contribute to automation.

Another difficulty results because the organization of the prevailing field determines perception of its components (i.e. “field dependent/independence”, Witkin et al., 1977). Again, turning recognition of geometrical figures in “conflicting” surrounding frameworks into an automatic process can help to overcome the difficulty.

**Analysis by perception-based knowledge representation**

Some difficulties may be explained by the fact that we have different representations for verbal and visual information:

Naming polygons by indicating their vertex names in a clockwise fashion (according to the spacial path) is an accepted practice. For example, this rectangle is named ADRK. Unfortunately, students sometimes label such a rectangle according to its verbal representation. Therefore, instead of naming it ADRK it will mistakenly be called ADKR because of the linear representation of verbal information (reading from left to right, from top to bottom).

The three-letter notation for angles causes difficulties for many students. Many of them mistakenly call the angle in the figure $\angle$BAM. However, it may also be explained by the fact that the students consider the letters as conveying verbal information, and so they read them from left to right, and from top to bottom, as they would read English.

The following example demonstrates the mental comparison of visual properties:

A student who needs to use the properties of diagonals in different types of quadrilateral will probably check a mental image of the prototype of the specific quadrilateral.

In such a case, it may be easier to mentally analyze the kite’s (rhombus) diagonals’ properties rather than analyzing that of the parallelogram’s. This is because of the greater difference in the size of the diagonals in the prototype of the kite than in the parallelogram.
The following is one of the examples brought by the teachers during the course (see box). It demonstrates the hierarchical decomposition of complex figures. The teacher reported that the students could not see that the angles were equal.

Another teacher, one of the course participants, explained this as resulting from the hierarchical structure of the drawing, which prevents the students from seeing angle A2 as part of both BAD and CAE, simultaneously.

One more teacher reported difficulties in proving that the bisectors of adjacent angles form a right angle. She proposed two possible hierarchies for the configuration explaining, the difference between the desirable decomposition (needed for the proof) and the actual decomposition of the configuration:

**Actual decomposition:**

**Desirable decomposition:**

Finally, one teacher was asked if she can apply the different representations of visual and verbal information, and the superiority of memorizing pictorial material in comparison to that of verbal material to geometry instruction:

Of course these things can be applied to geometry instruction. In tests, before proving problems, I ask for definitions and phrasing of theorems. Though I'm doing it for long time, it's the first time I understand why most of the pupils draw a picture before the verbal definition, if they add the verbal definition at all.

For example, if I ask what are vertex angles, the common answer is to draw: \[\begin{array}{c}
\alpha \\
\beta
\end{array}\]

**ANALYZING PLS**

Here is an example of a protocol of a PLS. We shall give a detailed analysis involving theories of perception.

During a lesson on quadrilaterals in a ninth-grade class, the students were solving in class a problem they had been given for homework.

The students show that the triangles are congruent.

Some claim that they can use the fact that there is a right angle because they see it. They find it difficult to explain why the sides are parallel.

The teacher asks if they remember what they have learned about parallel lines.
Their answers compel her return to parallel lines. She draws two lines and a third one that intersects them, reminding them about the different types of angles.

Student A: But angle A has nothing to do with that thing!

The teacher extends RM and TA in both directions and also extends TM.

Now the students are unsuccessfully trying to figure the alternate and corresponding angles in the original drawing.

Student A suggests erasing RT and MA so that it will be possible to see the connection with the teacher's drawing of the parallel and intersecting lines.

The teacher accepts the idea, praising the student. The discussion goes on until they conclude that the sides are parallel.

Analysis

This PLS involves two kinds of difficulties: Difficulties of visual pattern recognition (feature analysis and object recognition), and difficulties concerning Van Hiele's theory. In this paper we discuss only the first one.

The configuration appearing in the assignment has two possible "natural" decompositions in accordance with the principle of closure and good form:

\[
\begin{array}{c}
\square \\
\end{array} \rightarrow \begin{array}{c}
\square \\
\end{array} \quad \text{or} \quad \begin{array}{c}
\square \\
\end{array} \rightarrow \begin{array}{c}
\square \\
\end{array}
\]

In order to recognize the applicability of the parallel theorem to this problem, however, it is necessary to decompose the configuration as follows:

\[
\begin{array}{c}
\square \\
\end{array} \rightarrow \begin{array}{c}
\Box \\
\end{array} \rightarrow \begin{array}{c}
\square \\
\end{array}
\]

(1)

Such decomposition contradicts the principle of closure and good form.

Moreover, the drawing demonstrating the parallel theorem is decomposed in accordance with the principle of similarity, (putting together the two parallels with same orientation):

\[
\begin{array}{c}
\square \\
\end{array} \rightarrow \begin{array}{c}
\Box \\
\end{array}
\]

But the decomposition needed for locating the relevant angles in the above discussed class problem is the following one:

\[
\begin{array}{c}
\square \\
\end{array} \rightarrow \begin{array}{c}
\Box \\
\end{array} \rightarrow \begin{array}{c}
\square \\
\end{array}
\]

(2)

This decomposition contradicts the similarity principle. And even if the proper decomposition is found, the phase of pattern recognition remains: the two patterns, (1) and (2) need to be recognized as being the same.

SUMMARY

Theories of perception, though not new, are rarely introduced to teachers in general, or in the context of geometry teaching in particular. These theories can be a powerful tool
for explaining a wide range of difficulties. In this paper, we have presented a few of the examples we encountered in order to exemplify the potential of these theories for teaching geometry. Being familiar with these theories can help teachers cope with Problematic Learning Situations by helping them to plan their instruction and making decisions during instruction. However, presenting this knowledge to teachers is not enough. Making it relevant, presenting actual class situations and inviting teachers to look carefully at their own teaching experiences, would likely improve their ability to recognize, analyze and cope with PLS. These methods were implemented in the course we suggested. Our findings regarding these intervention methods are the subject of a future paper.

[1] We include examples reported by teachers attending the above-described course in order to enrich ours. These examples may give an idea about the awareness and capability of the teachers participating the course to analyze PLS. Describing the changes in teachers' ability to identify and analyze difficulties and cope with PLS during the course is beyond of the scope of this paper.

REFERENCES

This report deals with the interiorisation of that form of argumentation which consists in the dialogic elaboration on, and transformation of, arguments within a given theoretical framework, up to getting a contradiction. A teaching experiment (carried out in a Grade VIII classroom) concerning the mathematical modelling of the elongation of a spring, and conceived in the perspective of the 'Voices and echoes game', will be analysed in order to better understand the mechanisms of interiorisation and the potential inherent in Galileo's dialogic voice.

The development of argumentative skills is a relevant issue in Mathematics Education. Argumentative skills that are important in mathematical activities include the mastery of sophisticated forms of organisation of the discourse, as for instance hypothetical reasoning, reductio ad absurdum, etc. How can students approach and develop such skills? In an early Piagetian perspective, their roots are embedded in appropriate social peer interactions (see Piaget, 1924, chapter II). In a Vygotskian perspective, the more such skills are far from 'common' forms of reasoning, the more they need the mediation of an adult (or a more competent peer). Imitation in the Zone of Proximal Development is seen as a possible way to perform the necessary mediation. (see Vygotsky, 1978, chapter VI). A reflection about these general hypotheses brought us to consider the potential of the "Voices and echoes game" (see Boero et al, 1997) as a possible effective educational methodology (based on active imitation) to convey some forms of organisation of argumentation which are inherent in the scientific debate.

Galileo's dialogues offer examples of high level organisation of scientific discourse. Empirical evidence is not so frequently used (due to reasons inherent in the counter-intuitive character of the hypotheses proposed by Galileo in his dialogues). A typical form of Galileo's argumentation consists of the elaboration on, and transformation of, the adverse arguments within the frame of the adverse theoretical position, up to getting an "evident" contradiction. Mental experiments, reduction to the limit, etc. are frequently used for this purpose. We can recognise this form of organisation of the scientific discourse as an inner dialogue in a number of important personal mathematical activities related to checking mathematical conjectures and scientific hypotheses in order to validate them, for instance in applied mathematics, when a mathematical model is put into question: by transforming an algebraic formula, proposed as a model, it is sometimes possible to draw conclusions, which are in contradiction with some known properties of the modelled situation. In the search for counter-examples of a mathematical conjecture, examples that work for it may be transformed in such a way to hold the coherence with the constraints inherent in the hypotheses and, at the same time, to contradict some aspects of the thesis.
It is out of the scope of this report to discuss the (controversial) historical and personal sources of the form of Galileo’s argumentation that we are considering. It is more important for us to remark that, according to our observations, this form of argumentation is not produced spontaneously by VIII-grade students neither in situations of interaction, nor in individual performances concerning mathematical modelling situations. But students of that age do elaborate on arguments and transform them in everyday life argumentative situations. In mathematical and scientific activities, the main difficulties in approaching the form of Galileo’s argumentation seem to consist for students (while trying to elaborate on, and transform, the arguments) in holding the coherence with a given theoretical framework and also in the complexity of the elaboration and transformations needed.

This report will elaborate on the hypothesis that the use of Galileo’s dialogues in an active imitation perspective (like the one of the "Voices and echoes game" – see the next Section) can help students to appropriate the form of argumentation that we are considering, and use it in mathematical and scientific activities. We will present some essential features of a classroom activity concerning the problem of the elongation of a double length spring in relation to the elongation of one single spring hanging the same weight. Students produced two hypotheses, then discussed them and discovered the right one. Then they were asked to produce, as an ‘echo’, a Galilean dialogue about the two hypotheses, following the model of the Galileo dialogue about the falling body phenomenon. The discussion of collected data will lead us to consider the potential inherent in the virtual character of Galileo’s Dialogues.

THE ‘VOICES AND ECHOES GAME’ (VEG)

What is the VEG? Some verbal and non-verbal expressions (especially those produced by scientists in the past) represent important steps in the evolution of mathematics and science in a rich and communicative way. We called these expressions 'voices' (cf. Wertsch, 1991). We called VEG an educational situation aimed to make students produce echoes to a voice through specific tasks, for instance: "How might Aristotle have interpreted the fact that a feather falls down at a slower speed than a stone?".

What are the aims of the VEG? Our general initial hypothesis was that the VEG might broaden students’ cultural horizon, by embracing some elements of the theoretical knowledge that are difficult to construct in a constructivist approach and difficult to mediate through a traditional approach (see Boero & al, 1997). The need to exploit the potentialities that emerged in the first series of teaching experiments led us to try to find a better characterisation for the elements of the theoretical knowledge to be mediated through the VEG, in order to better organise and analyse how students interiorise them (see Boero & al, 1998). The research reported in Garuti et al (1999) concerned another potential of the VEG, namely the possibility of developing skills related to detecting conceptual mistakes and overcoming them by general explanation.

THE TEACHING EXPERIMENT

The teaching experiment involved one VIII-grade class with 17 students. The mathematics and science teacher has been the same since grade VI. The didactical
contract included (in particular) the production of exhaustive individual verbal reports about personal problem solving strategies, the comparison of solutions, argumentation about hypotheses discussed in the classroom, etc. Students' individual texts as well as transcripts of classroom discussions were systematically collected. This class had already been involved in two preceding teaching experiments concerning the VEG. In grade VII, the students had been asked to produce an echo to Plato's 'Menon' dialogue concerning the length of the side of a square of double area of a given square. The echo concerned a common conceptual mistake recognised and discussed in the classroom (see Garuti et al, 1999, and the end of the preceding Section). In Grade VIII, they had had to produce echoes to Aristotle's and Galileo's theories about the 'falling bodies' phenomenon, with tasks concerning the content of those theories (such as "How could Aristotle have interpreted the fact that ...?").

The Choice of the 'Double length spring' Problem as a Target Problem for This Study

The 'Double length spring' problem consists in the following task (the weight of the spring is supposed to be very small in relation to the weight hung up on it):

"Imagine to know the elongation of a spring under a given weight and to take another spring of the same material, diameter, etc. having a double length. What can you say about its elongation? Why?"

In previous teaching experiments concerning mathematical modelling, the 'double length spring problem' emerged as a very interesting elementary mathematical modelling problem because of the following reasons (see Boero & Garuti, 1994): it is a challenging problem, even for cultured adults; the "wrong" hypotheses rely on some principles which work very well in other situations; the "valid" hypothesis cannot be easily detected on the basis of immediate everyday life experience; the "wrong" hypotheses can be demolished through an argumentation which exploits accessible arguments in a suitable way. Our a priori analysis established some links with the falling body phenomenon. In the same way, in this case the 'wrong' hypothesis agrees with some principles, which work rather well in many other situations, and the immediate experimental evidence is not in favour of the 'good' hypothesis, but the "wrong" hypothesis can be put into question by an appropriate elaboration of accessible arguments.

Before this teaching experiment concerning the 'double length spring' problem, the students had already performed activities concerning the elementary mathematical model of the elongation of a spring. They had arrived, under the teacher's guidance, to discover that the formula $L = L_0 + KP$ is a good model for the length of a spring of initial length $L_0$ under the weight $P$, provided that the coefficient $K$ is well chosen for that specific spring and that $P$ takes values in a suitable interval (not too extended on the right). The activity had an experimental counterpart, allowing students to discover (in particular) that $K$ is smaller if the spring offers a stronger resistance to the elongation. Also the proportionality $L-L_0=KP$ had been discussed.
Afterwards the 'double length spring' problem was posed. The discussion of the "equal elongation" and "double elongation" hypotheses (produced during the individual solution phase) led students (even before the experimental testing) to share the correct hypothesis of the "double elongation". In this process the students brought forward different arguments, in particular: cutting the double length, and imagining what happens under the weight, then adding these effects; or thinking about each coil, and imagining the effect of the weight on it, then the global (additive) effect on the single length spring and on the double length spring. Then some parts of Galileo's Dialogue were read and discussed. Attention was paid to the role of the three interlocutors and to some Salviati's dialogic strategies (in particular, the use and transformation of Simplicio's arguments within the frame of Aristotle's theory in order to get an evident contradiction with his own premises). Finally, the following individual task was given:

"Imagine to be Galileo writing a dialogue about the problem of the double length spring. The characters are: Salviati, who represents you, trying to convince Simplicio (and the reader) that the double length spring elongates the double, and to explain why; Simplicio, who supports the hypothesis that the double length spring elongates the same length, because the material is the same and the coils have the same diameter; Sagredo, the moderator".

The students worked individually for approximately two hours. Their individual texts were analysed by us according to the criteria listed at the end of the next Section.

From Galileo's Dialogues to Some Criteria to Analyse Students' Dialogues

Here I will try to make a summary of a crucial part of Galileo's dialogue concerning the 'falling bodies' phenomenon. This part was read and discussed in the classroom with the help and under the guidance of the teacher:

Simplicio illustrates Aristotle's theory in general and with an example. Salviati elaborates on Aristotle's theory and puts it into question by using Simplicio's example. Simplicio tries to contrast Salviati's doubt by providing an interpretation of Aristotle's words, while Sagredo takes a position that relies on experimental evidence. But the core of the debate is not the experimental evidence! Salviati wants to provide Simplicio (and the reader) with a theoretical proof within Aristotle's framework. Galileo involves Simplicio in a mental experiment which in three steps leads to a contradiction with Aristotle's theory, by argumenting within Aristotle's framework. Then Simplicio reacts by making reference to intuition, and presenting an example. Galileo answers providing another example (which takes to the extreme the kind of example proposed by Simplicio).

The analysis of this part of Galileo's 'Dialogues' suggested some criteria to analyse students' dialogues and evaluate their quality:

- existence of a real dialogic structure, in the sense that the direct questions Salviati pose to Simplicio play the role of involving him in the argumentation and getting his consensus on crucial arguments and steps of reasoning
- elaboration on, and transformation of, the adverse hypotheses through examples or analogies;
evidence is explicitly shown for the contradiction;
- Salviati wins through the logical strength of his argumentation;
- concrete experiments deserve only the function of putting into question Aristotle's theory and justifying doubts about it;
- the final "passage to the limit" is used to win Simplicio's last resistance based on physical intuition.

During the discussion about Galileo's dialogue these criteria surfaced (under the teacher's guidance) as main characteristics of its organisation.

**Some Excerpts from Students' Dialogues'**

**Sara:**

Simplicio: *Two springs made of the same material and with the same coil diameter, but different initial length (one is the double of the other) elongate the same because the initial length is not influent. For instance (HERE AND AFTER: A SUMMARY OF OMITTED PARTS: the example of a 10 cm spring and a 20 cm spring follows; the L=H+KP formula is evoked to say that K is the same)*

Salviati: *I am against your supposition; I say that the initial length is influent and K varies; if your double length spring elongates 2 cm, the other one elongates 1 cm.*

Sagredo: *I am afraid, Simplicio, I made the experiment and saw that the double length spring elongates the double.*

Salviati: *We can prove it.*

Simplicio: *They must elongate the same because the weight is divided according to the number of coils. For instance let us suppose that the weight is 20 grams, if the number of coils of the shortest spring is 10, each of them elongates 20:10=2, while each of the 20 coils of the longest spring elongates 20:20=1. Summing up, we obtain the same elongation.*

Salviati: *You made a mistake, because if you take a double length spring and you divide it into two equal parts, each of them elongates the same under a given weight, so if I join them again, the elongation is double.*

Sagredo: *Salviati is right, because {Sagredo provides an example, showing that each part of the double length spring supports the same weight}*

Salviati: *Dear Simplicio, do you think that the weight hung up to the longer spring is different from the weight hung up to the first and the second spring?*

Simplicio: *I got it!*

Salviati: *As a conclusion {he says the valid hypothesis}*
Francesco:  
Simplicio: (he presents the erroneous hypothesis: general statement first, then an example, like Sara)  
Salviati: According to what you have said, it is as if you performed the experiment, but I have doubts about it  
Sagredo: I performed the experiment and I can tell you that the double length spring elongates the double  
Salviati: In accordance with Sagredo who performed the experiment, I can prove that a double length spring elongates the double. Do you share, Simplicio, the idea that all springs with the same length and made of the same material do elongate the same?  
Simplicio: Certainly (he provides an explanation for it)  
Salviati: And do you think, Simplicio, that two springs with the same length, same material, same coils when connected together elongate the same as one of them?  
Simplicio: It seems logical to me  
Salviati: Let us suppose that what you think is true. Let us consider two springs with the same initial length; let us hung up the same weight on each of them, then let us join the two springs keeping them elongated with the same weight: we get a double elongation, and this conclusion is against your hypothesis.  
Simplicio: I am confused; it seems to me that if I join the two springs together, I get one spring, then I get the same elongation  
Salviati: Here is your mistake: it is not true that if you join the two springs the elongation of one of them disappears (still Simplicio resists; and then Salviati suggests the comparison with two springs in parallel; finally, reacting to Simplicio’s scepticism, Salviati brings to the extreme Simplicio’s example with a 20 cm spring and a 100 m spring).  

An Overall View of Students’ Productions  
8 students out of 17 produced a “dialogue” like the one presented by Sara. They show they understood some crucial theoretical arguments in favour of the double elongation hypothesis. They also keep into account the result of the experiment. But their ‘dialogues’ do not fit the first, third and fourth criterion (and indeed in some cases, like in Sara’s dialogue, Sagredo must intervene to explain the right hypothesis). The second criterion is only partially satisfied: the dialogues refer to Simplicio’s hypothesis, but Salviati’s reasoning follows his own path, and there is no real interaction with Simplicio’s arguments. It is as if Salviati (or Salviati and Sagredo together) illustrated his (their) own theory against Simplicio’s theory. The students were able to perform a satisfactory ‘content’ echo to the voices, of the classroom.
discussion, supporting the valid hypothesis, but not to Galileo's dialogue; in particular, their dialogues do not contain its typical form of argumentation (see Section 1). 9 students out of 17 produced "dialogues" with the same quality as Francesco's (or even superior). They share all the crucial characteristics of Galileo's dialogue. It is interesting to observe that there was no intermediate performance: the dialogues that did not contain Galileo's typical form of argumentation were the same ones that do not meet the other main requirements of Galileo's dialogue. In particular, they were either parallel developments of two monologues, or dialogues with no real interactions between the arguments brought in by Salviati and Simplicio.

DISCUSSION

Our research hypothesis was that the use of Galileo's dialogues in an active imitation perspective (like the one of the VEG) could help students appropriate the form of Galileo's argumentation, which consists of the elaboration on, and transformation of, the adverse arguments within the frame of the adverse theoretical position, up to getting an "evident" contradiction. On the basis of the available data it is not possible to prove that students learned to do it in situations that are very far from the 'falling bodies' example. And it would be even more difficult to prove that they interiorised this method in the perspective of a real individual inquiry situation that requires questioning a personal hypothesis and demolishing it by elaborating and transforming some arguments supporting it. The available data only show that about one half of the students were able to use the form of Galileo's argumentation in another similar situation. The analysis of students' individual productions and recordings of classroom discussions in previous problem solving situations shows that this form of argumentation was far from the organisation of students' argumentative performances.

In our opinion, more interesting outcomes of the reported study concern the mechanism and the conditions of the interiorisation process in relation to the virtual character of Galileo's dialogue. Indeed Galileo's dialogues are not real interpersonal dialogues; they were produced by a scientist who wanted to present his theory and convince the reader through a virtual debate. As such, Galileo's dialogues are close to the inner dialogue that we, as adults, produce when we get ready for contrasting an interlocutor in a public debate (when we imagine his arguments and think about arguments which would convince him and the other listeners). They represent the inner, individual (or intra-personal) counterpart of interpersonal practices. This feature of the dialogic voices (with the inherent differences between a real debate and a virtual debate) might represent an important opportunity for the interiorisation of high level forms of argumentation. This specific issue is related to some ongoing research about the process of interiorisation (from interpersonal construction to intrapersonal development) (Engestrom, 1991; David'ov, 1991). In particular, considering the "interiorisation process", i.e. "the process of individual activity formation on the basis of collective activity" Davydov wrote: "Numerous versions of the theory... notice the fact that the structures of these two forms of activity are to a certain degree similar, but pay very little attention to their difference. But exactly the characteristics of this very difference and dissimilarity form a particular problem of
activity theory”. And then, referring to the need for revealing “structure and functions of the specific character of each activity form”, he wrote: “It is vital to give a more exact, certain and comprehensive description of various stages of this process [interiorisation] and emphasise the specific importance of the conditions of its realisation”. A reasonable outcome of the case study reported in this paper is the hypothesis that the active imitation of a virtual dialogic voice through the VEG creates the conditions for the interiorisation of those forms of organisation of the scientific discourse, which are inherent in the voice; this is due to the fact that the voice itself represents an interiorised activity. Another related indication that emerges from the analysis of the teaching experiment is that in future experiments attention should be paid not so much to the scientific debate in the classroom about a given subject as a preliminary, interpersonal construction in the perspective of the subsequent interiorisation, as to the interpersonal reflective practices on the functioning of Galileo’s dialogue before the ‘echo’ task. Those practices might represent a crucial condition for the development of the process of interiorisation. Indeed, the students who failed to construct a dialogue bearing that form of argumentation, which was the goal of the teaching experiment, were the same who were unable to produce a real dialogue. It was as if the lack of control on the dialogic structure of their text prevented them from producing the required argumentative form (cf. Engestroem: “The new activity structure... requires reflective appropriation of existing culturally advanced models and tools”).

DIFFERENTIAL EFFECTS OF DYNAMIC GEOMETRY SOFTWARE
ON THE ACQUISITION OF BASIC GEOMETRIC NOTIONS

Thomas Gawlick, Oberstufen-Kolleg, D-33501 Bielefeld, Germany

Introduction
The various capabilities of Dynamic Geometry (DG) have caused an ever-growing interest during the last decade. But many publications in this area might as well bear the generic title „The Impact of Computer Technology (on the Mathematics Classroom)“, as they focus mainly on technology and its really promising potential, but neglect somewhat the impact caused by it (and all too often only allude to the classroom).

Nevertheless, the ever-growing availability of computers in the classroom and the public expectations concerning their use entail administrative measures towards regular use of DGS, as nowadays can be readily noticed in Germany. Therefore it seems appropriate to investigate in regular classrooms the impact of DGS on students’ achievements, conceptions and attitudes. In this paper, we consider mainly differential effects on students’ achievement.

Related research
Only few concepts of computer application in the mathematics classroom have been evaluated on a scientific basis. Moreover, a detailed meta-analysis by Ruthven (1997) concluded that only a small number of studies (regarding CAS) had an acceptable design (i.e. experimental and control groups, pre- and post-tests). Concerning DGS, Hölzl (1996, 2000) meticulously performed a diversity of qualitative case studies revealing epistemological shiftings and increased cognitive challenges as unwanted, but perhaps unavoidable side effects of applying DGS.

His results show that the interactive aspects of the medium motivate the students to develop individual interests and stamina – But there are also subtle interactions between the implementation of geometry by the software and the students’ understanding of geometry. This shows clearly the double-edged character of computer application: on the one hand the heuristic potential yields a – mathematically extremely attractive – extension of scope, but on the other hand interactivity entails also the danger of "degoaling“ (Hoyles und Sutherland 1989).

Thus a "computational transposition“ (Balacheff 1993) seems inevitable also in the realm of DGS. In order to minimize its effect, a thoroughly and didactically reflected teaching concept is required.

Also, from an instructional psychologist’s point of view, the prospective value of DGS has to be appraised retentively, since it is usually taken for granted that the choice of medium is far less important than the nature of the treatment. But

---

1 Hölzl (2000)
2 Salomon (1978) and Clark (1983)
since the genuine possibilities of DGS cannot be reduced to just changing the medium, a comparative study seems nonetheless appropriate.

There are only few studies on the impact of highly interactive computer usage. Lewalter (1997) investigated cognitive information processing when learners utilized animated vs. static computer illustrations. Though the possibilities to interact with the software are far more restricted than with DGS, Lewalter's results shed some light on the core problem: even the restricted possibilities of the dynamic presentation are not really used by learners for the purpose of elaboration. Rather, her analysis reveals that dynamic visualizations of kinematical processes seemed so easily understandable to the learners that they all to early got the false impression to have grasped the whole issue. This result seems to be in accordance with the "degoaling" phenomena described by Hölzl (1996).

**Method**

**Procedure** The study was performed in nine grade 7 classes (N=214) of three senior high schools. At each school, three classes were assigned to the C(omputer), P(aper) and V(control) group yielding the following hierarchical design:

- Pre-and post-tests were performed in all classes (the pre-test surveyed the prior geometric knowledge of the students as well as their attainment levels).
- Meanwhile, the treatment was implemented in the experimental groups using the respective learning environment (i.e. paper and pencil in P resp. DGS in C). For the 12 lessons given, teacher students that had in advance been trained intensively on our courseware replaced the usual teachers. At every school, the C and P classes were taught by the same teacher student. In the V classes, ordinary geometry lessons took place. After six months, a follow-up post-test was performed in all classes.

**Treatment** The treatment covered perpendicular and angular bisector, the circumcentre and the circumcircle, the incentre and the incircle. In C, we used interactive electronic work sheets\(^3\) that focus on investigating given figures rather than constructing new ones. As an extra dimension, we added embeddings of geometric problems into problem contexts: for instance the distribution of soil was posed as a problem (compare fig.1) to introduce a small modelling process.

\(^3\) compare Elschenbroich (2001)
ending up with the necessity to find a construction for bisecting angles – thus demonstrating the utilizability of mathematical tools in "real life".

Measurement The tests can be divided into procedural and explanatory parts, so the pre-post-difference D splits into a procedural component \( D_p \) and an explanatory component \( D_e \): \( D = D_p + D_e \).

**Hypotheses**

1) The problem-based approach influences significantly the achievement\(^4\).
2) The use of DGS does not influence significantly the achievement\(^5\).

**Results**

The box plot of the pre-post-difference D and its explanatory component \( D_e \) in fig. 2 reveals:

- Overall outcomes were about equal in P and C and considerably higher than in V, with smaller variance in P.
- In the explanatory parts, students in P did somewhat better than in C and V, with considerably greater variance in V.
- All in all, C lay consequently a little behind (regarding both measures).

Inference statistics yields somewhat heterogeneous results: In the whole population we find for D that \( \mu (P) >> \mu (C) \approx \mu (V) \), \( \mu (P \cup C) >> \mu (V) \), so 1) can be confirmed, 2) has to be rejected – but this result is slightly obscured by the fact that the means of P and C differ only by .75. This difference is significant \((\alpha=.05)\), but is less than the insignificant difference 1.00 of C and V. So one might suspect a statistical artefact due to the diverging group sizes (the drop-out rate was –not uncommonly– significantly higher in V).

An explorative data analysis is thus in order. For practical purposes, we restricted ourselves to factors that are easily accessible to teachers: Besides gender, we distinguished higher and lower achievers by splitting at the median

---

\( ^4 \) measured as pre-post-difference, which were checked against mean posttest achievements adjusted by pretest.

\( ^5 \) but the chosen strategies!
(that has also statistical advantages). Here, we have to restrict to display some
tendencies in the data (fig. 3-5)⁶:

- except for girls at public schools, in C classes higher achiever profit more
  than lower achievers, vice versa in P,
- while in public schools P and C scores are about equal, for girls in the private
  schools P was (significantly) superior to C,
- for girls at public schools, C is slightly more effective than P, irrespective of
  achievement level.

![Graphs showing data for girls at private and public schools, and boys at public schools.](image)

Also, differences in achievements and strategies between P and C occurred with
"dynamic" problems⁷: Namely, the post-test contained one especially
"dynamical" task – the students were
given fig. 6 and had to answer the following questions:

1. This is a campground from above. The
   friends Anton, Bert and Charley want
   to have breakfast together. Can you
   place a table on the campground in
   equal distance to their tents?
2. What happens if Charley moves his
   tent along the sea to find the best fish
   ground? Why?
3. If he chooses a certain place for the
   tents, a problem will occur to the three
   friends. Can you figure it out?

1. involves of course the utilization of the circumcentre in a problem context.
   And to see, whether DGS was helpful in developing dynamic mental images
   they were asked 2. This made it also possible to check by 3. whether students

⁶ See Gawlick (2001a, 2002) for more details.
⁷ but surprisingly also with some "static" ones, compare Gawlick (2002).
realized the limitations of such a mathematical modelization. All in all, the “dynamic task” 2. is certainly apt to show differences in outcome if DGS is really more than “just another medium”. But again the results are rather ambiguous: The total score for the “dynamic task” does not show any significant differences. But if you consider only, their hypothesis what happens to the table when Charley moves his tent, C is clearly ahead of P – but vice versa if you consider their reasons, why this will happen. These adverse effects nearly cancel each other. A possible interpretation would be: DGS is helpful to generate hypotheses, but not to find arguments supporting them. This would fit neatly to the „‘degoaling’”–effects observed by Hörlzl (1996).

On the other hand, one of the rather procedural tasks was to explain the construction of the middle perpendicular. But in this rather “static” task the C groups did astonishingly somewhat better than the P groups. This may be some evidence for a reinforcement of mental images by DGS that can even strengthen students’ ability to scrutinize the rationale of the said construction.

**Discussion**

Of course, the findings should not be overestimated – they are based on a relatively small sample and difficult to generalize due to their heterogeneity. The inconclusive statistical results are in accordance with media and ATI research. But the interaction of environmental and gender factors seems to be new in the context of DGS and – though statistically insignificant – deserves further attention. It seems that in coeducative classes, girls profit from DGS treatment, but possibly at the cost of lower achieving boys. Therefore, special care should be taken of these in order to prevent them from using DGS as a plaything.

Hopefully the evaluation of the follow-up test (work in progress) will shed some light on these and eventually additional other differential factors. Also, the analysis of students’ strategies in the “dynamic” task may yield some further evidence how to ameliorate the disappointing outcome in this task.

Finally, it should also be noted that the preliminary evaluation of the follow-up data gives some evidence toward the conjecture that in the long run DGS as an additional tool for the acquisition of geometric notions may be superior to the paper-and-pencil-only approach.

**Concluding Remarks**

It seems at present that when dealing with fairly standard examples, the benefits of dynamic exploration can even in a carefully designed course far too easily be outweighed by the extra costs of DGS. So we strongly confirm that *dynamics is not a didactical advantage per se* (Hörlzl 2000) – the use of DGS should

---

8 The deviating results in the private school seems difficult to interpret, but should be kept in mind when discussing the issue of coeducation concerning DGS.

9 Eventually, evidence on this will be presented orally at the conference.

10 Again we have to refer the reader to the oral presentation and/or electronically obtainable information.
therefore be preceded by thorough consideration. It will be most favorable when an objective requirement for the tool meets an advanced mathematical experience. Therefore, the design of teaching units and learning environments that make the most out of the computer’s heuristic and computational capabilities continues to be one of the most challenging objectives of nowadays mathematics education.

References

This paper reports findings from a longitudinal study of a newly qualified elementary school teacher from the last year of her university studies up to the third year of teaching in a primary school. The development of this teacher’s teaching has been investigated in three strands, which have been distinguished in terms of the kind of support provided to this teacher. In particular, the teacher’s characteristic view of mathematics teaching as a process of children’s involvement in activities acquires a different meaning in her teaching actions as she experiences the various contexts.

Introduction

A number of research programmes on initial mathematics teacher education have been developed focusing on the integration of mathematics, pedagogy and children's ways of thinking (Cooney, 1994; Even et al, 1996). Most of these programmes are characterized by a constructivist view of learning, emphasising the role of research in the mathematics teacher’s development (Simon, 1995a, 1995b, Steffe and D'Ambrosio, 1995) and viewing the teacher as researcher and reflective practitioner (Rice, 1991; Joffili & Watts, 1995; Potari, 1997). Although research studies indicate positive results from these programmes, questions remain on whether and how the experience that these prospective teachers gained through their initial education could influence their professional life. There is also a body of research that investigates mathematics teachers’ development while teaching in their own classrooms. In particular, a number of in-service education programmes are conceptualised as contexts for integrating theory and practice by involving teachers in undertaking action research in their own classrooms (Cooney & Krainer, 1996; Irwin & Britt, 1999; Jaworski, 1998; Krainer, 1999). However, there is little research on how the teacher deals with the transition between pre-service education and actual teaching. This research is not very encouraging for the mathematics teacher educators as it reveals the difficulties beginning teachers find in making connections with their university experiences (Cooney, 1985; Raymond, 1997). However, these difficulties are mainly attributed to the “reality shock” that the teacher feels during his/her first year of teaching (Weinstein, 1988). Therefore, to study a teacher’s development only during the first year of his/her professional life limits our understanding of his/her potential development.

This study aims to investigate the development of the teaching of a primary school teacher while finishing her pre-service education and during her first three years of
teaching. More specifically, we focus on the influence of the particular contexts that this teacher experienced in her teaching practices throughout this time period. We attribute a personal character to the meaning of “context”, considering it as interactively constructed by the teacher through discussion and reflection on action (Jones, 1997).

Methodology

This is a longitudinal case study of a newly qualified teacher, Christina, who has been working in a primary school for three years. The research started when Christina was a student teacher in the last year of her university studies, and continued over her next three years of teaching in the school. We distinguish three strands: the period at the university; the first year of teaching in the school, and the second and third year of teaching. These strands were formed in relation to the kind of support provided to her for the duration of the study. During her university studies, Christina took two courses concerning mathematics and mathematics teaching and learning. In the last year of her studies she did her teaching practice in schools, and participated in an optional course characterised by two general perspectives: the teacher as researcher of children’s thinking and the integration of mathematics and pedagogy (Potari, 1997). In that period the two authors, one being the teacher educator in the course and the other the mentor, supported Christina through discussions during the various activities of the course and while she was planning and reflecting on her teaching. During the first year of her teaching in the school, Christina’s support came mostly from the school; for example, her colleagues and the principal. However, she continued informal discussions about her new experiences with one of the authors and her peer student teacher. In the second and third year, Christina participated in a research project organised by one of the authors (Georgiadou-Kabouridis, 2000). The other author acted as a participant observer in some of the group meetings, a model which has been suggested by Simon (2000). In this case, support was provided mostly through a number of meetings with her colleagues-participants, where the researcher aimed to link theoretical issues about teaching and learning of mathematics to the teachers’ experiences in their classrooms. Support was also given to Christina through discussions with the researcher about her teaching.

Research data consisted of transcripts of videotaped sessions from Christina’s teaching in the first and third strand, transcripts of audio recorded informal discussions and semi-structured interviews between Christina and the researchers in the period of the three strands, Christina’s lesson plans, worksheets and her written comments on the group meetings. Analysis of the data is realised in two dimensions. One concerns what Christina discusses about her teaching and the other what she is actually doing in her classroom. More specifically, in each strand we analyse certain classroom incidents, which are typical of Christina’s interactions with the children. The latter dimension identifies Christina’s teaching approach and reveals possible
teaching development. By linking the two dimensions we explore Christina’s awareness of her actions and we investigate how the context affects her teaching.

**Christina’s typical teaching approaches throughout the three strands**

Christina’s beliefs about mathematics and mathematics teaching have been investigated in a previous study (Georgiadou & Potari, 1999). In that study Christina seemed to have developed a rather broader view about mathematics than it being “just numbers, rules, exercises”, viewing it as “logic, thinking, and a particular way of seeing things”, during the last year of her university studies. Moreover, she seemed to have developed an inquiry approach to teaching while interacting with children in the lower grades where she was feeling mathematically confident. Christina viewed mathematics teaching as a process of actual involvement of the children in a variety of activities, and she acknowledged the role of multiple representations in understanding mathematical concepts. This view seems to be consistent throughout the period of the research but it acquired a different meaning in Christina’s teaching actions as she experiences the various contexts. In the following analysis we attempt to illustrate the above assumption.

**Exploratory teaching**

Since being a student teacher Christina has believed in the power and efficacy of activities in mathematics teaching. This view had been expressed in various discussions between her and the researchers but was also evident in her actual teaching practice during her university studies. The following example shows the practical character that she attributed to such activities. In an interview at the end of the course, Christina discussed the following problem that a peer who had taken a third year class, experienced: “A window is 4m long and a door is 2m long. Which one is longer and how much longer is it?” Most children added the two numbers to get the result, although the student teacher read the problem to them many times. Christina judged his approach as inappropriate: “He (the student-teacher) did not realise that the children could not understand the words of the problem. I suggested that he asks the children to represent it. Well, he did so...four children were placed along the window and two children along the door. Then the children gave a correct answer. The problem is that they (her peers) do not interpret children’s thinking.”

Here, Christina recognises the importance of interpreting children’s thinking and their needs in planning appropriate activities. Thus she considered that making the problem concrete for the children could possibly help them to tackle it. Moreover, in her teaching practice in that period, she attempted to get the children involved in activities where her main aim was to encourage them to explore mathematical ideas. The activity acted as the starting point for exploration, which was encouraged by her rather “open” questions. Christina’s teaching actions seemed to be influenced mainly by the course where she was expected to act as a researcher. The mathematics classroom was more a place for experimentation rather than a place where the
children had to acquire certain mathematical knowledge. Constraints like the mathematics curriculum; the classroom teachers' goals and time pressures did not seem to be an obstacle to her teaching decisions.

It is somewhat unrealistic to attempt to find "cause-effect" relations between Christina's university experiences and her teaching actions. However, we can infer that this particular context had challenged existing traditional approaches that she had experienced as a student at school, and helped her at the time of her studies to develop tools for her future professional development. As she admitted: "If I hadn't attended the course I would have continued to teach in a mechanistic way as I was accustomed to in the previous year, where my teaching was based on the textbook and the children could not understand".

**Exploratory versus instructive teaching**

Christina's first year experience has been studied in terms of the way that she conceptualised her teaching role in the school environment (Georgiadou & Potari, 2000). In that study we identified specific elements of the general school environment such as the educational policy of the school, and the important role her colleagues and her former peer student teachers played in Christina's process of adaptation. In this paper, we will focus on the way that she adapted her view concerning the importance of children's involvement in activities in this new context. Christina claimed that during that year she was doing a lot of activities in the playground where the children played games with numbers. However, she did not organise classroom instruction around these kinds of activities. From her teaching planning it appeared that she used activities that aimed to inquire into her pupils' ways of understanding, by getting them involved mostly in written work.

It seems that Christina worked on two planes: the exploratory and the instructive. In the first plane she "transferred" experiences from the university while, in the second, her actions were affected by the reality of the school environment and, in particular, by the restraints of the national curriculum. So, she was striving to see immediate results in the children's learning, although she was still interested in developing their thinking. In the interview, Christina claimed that she only had 5 to 10 minutes per day for oral activities. She also had a difficult experience at the beginning of the school year: she devoted the whole of the first week to activities and games on preliminary mathematical notions, such as orientation. At the end of the week the principal admonished Christina because parents had complained that she had not done any work because nothing had appeared in their children's homework notebooks. In this difficult year Christina managed to survive and, at the same time, to keep alive her view on how children learn mathematics. This was unconsciously achieved by separating these two planes of work; in some cases, she balanced these two different perspectives of the role of the activities in teaching. For example, while working in the second plane, she realised that the children faced difficulties in
understanding the pairs of numbers adding to ten, from their responses to the written work she had planned based on the textbook. She overcame this difficulty by developing the 'Box' task described in Hughes (1986), which she had used in the context of her university studies.

**Discovery teaching**

In the following year Christina felt well established in school, as she had gained the approval of the head, other colleagues, the children and the parents, and recognition of her effectiveness as a teacher of Year 1. Thus she was appointed to teach Year 1 for the next two years of the study. At the same time she participated in the research programme aiming at teacher's professional development as described in the methodology section.
