Abstract

Bounds are established for log cross-product ratios (log odds ratios) involving pairs of items for item response models. First, expressions for bounds on log cross-product ratios are provided for unidimensional item response models in general. Then, explicit bounds are obtained for the Rasch model and the two-parameter logistic (2PL) model. Results are also illustrated through an example from a study of model-checking procedures. The bounds obtained can provide a basis for assessment of goodness of fit of these models.

Key words: Rasch model, 2PL model, cumulant generating function
1 Introduction

Latent-variable models for item responses have strong implications for customary
descriptive measures from contingency table analysis such as log cross-product ratios
(Section 2). In the case of the Rasch model, this issue has been suggested by simulation
studies intended to explore model diagnostics for the Rasch model (Sinharay & Johnson,
2003). These studies indicated that the log cross-product ratios predicted by the Rasch
model showed remarkably little variability among different pairs of items. This note seeks
to explain the observed results from simulation and to provide general bounds for log-cross
product ratios for some familiar item response models. These bounds have importance
in derivation of starting values for algorithms for item response analysis and for checking
of models. Section 2 provides the required theoretical results. Section 3 illustrates their
application to an example concerned with model checking. Section 4 considers application
of results to point-biserial correlations and tables of log cross-product ratios.

2 Theoretical Results

The desired bounds for log cross-product ratios can be obtained without loss of
generality by study of just two items because all items are conditionally independent given
the ability parameters of an item response model. General expressions for log cross-product
ratios will be provided for general one-dimensional item response models. Results will be
illustrated by use of the Rasch and 2PL models.

Consider the relationship between two item responses $X_1$ and $X_2$. Let each $X_j$ be a
random variable with values 0 or 1, and let $\mathbf{X} = (X_1, X_2)$, and let $p(\mathbf{x}) = p(x_1, x_2)$ be the
probability that $\mathbf{X} = \mathbf{x} = (x_1, x_2)$ for a two-dimensional vector $\mathbf{x}$ with coordinates 0 or 1.
In the analysis of contingency tables, the log cross-product ratio (also known as log odds
ratio) of $X_1$ and $X_2$ is

$$\gamma = \log \frac{p(0,0)p(1,1)}{p(1,0)p(0,1)}.$$  (1)

The coefficient $\gamma$ is positive if, and only if, $X_1$ and $X_2$ are positively correlated, for the
correlation of $X_1$ and $X_2$ is

$$\rho = \frac{p(1,1)p(0,0) - p(1,0)p(0,1)}{[p_1(0)p_1(1)p_2(0)p_2(1)]^{1/2}},$$

1
where \( p_j(x) \) is the probability that \( X_j = x \) (Bishop, Fienberg, & Holland, 1975, p. 381).

In general, the formula for the correlation implies that \( \rho \) is between \( 1 - \exp(-\gamma) \) and \( \exp(\gamma) - 1 \).

In this note, the implications of item response models on the parameter \( \gamma \) are considered for models with a one-dimensional ability variable. One basic result, Theorem 1, is that \( \gamma \) must be positive for an item response model with an ability distribution not concentrated at a single point and with monotone increasing item characteristic curves for the items. Theorems 2 and 3 provide bounds on \( \gamma \) for the Rasch model. Similar bounds are also considered for the 2PL model. The bounds are especially easy to apply if the ability distribution is normal.

To define the implications of an item response model on the log cross-product ratio \( \gamma \), let the ability variable \( \theta \) be a real random variable with distribution function \( F \), let the \( X_j \) be conditionally independent given \( \theta \), let \( P_j(\theta) > 0 \) be the probability that \( X_j = 1 \) given \( \theta \), let \( Q_j(\theta) = 1 - P_j(\theta) > 0 \) be the corresponding probability that \( X_j = 0 \) given \( \theta \), and let

\[
\lambda_j(\theta) = \log \frac{P_j(\theta)}{Q_j(\theta)}
\]

be the item logit function (ILF) of \( X_j \). Then the probability \( p(x) \) satisfies

\[
p(x) = \int \prod_{j=1}^{2} P_j^{x_j} Q_j^{1-x_j} dF.
\] (2)

The log cross-product ratio can be expressed in terms of the cumulant generating function of the item logit functions \( \lambda_j \) conditional on \( X_1 \) and \( X_2 \) both being 0. To verify this claim, let \( \lambda \) be the vector of \( \lambda_j \), \( 1 \leq j \leq 2 \), and let \( x'\lambda \) be \( \sum_{j=1}^{2} x_j \lambda_j \). Let \( V \) be \( Q_1 Q_2 \). Let \( t_1 \) and \( t_2 \) be real numbers, and let \( t \) be the two-dimensional vector with coordinates \( t_1 \) and \( t_2 \). Let \( \mathbf{0} = (0, 0) \). Let

\[
M(t) = M(t_1, t_2) = [p(\mathbf{0})]^{-1} \int \exp(t'\lambda) V dF
\] (3)

be the moment generating function at \( t \) of \( \lambda(\theta) \) given \( X = \mathbf{0} \), and let \( C(t) = C(t_1, t_2) = \log M(t) \) be the conditional cumulant generating function of \( \lambda(\theta) \) at \( t \) given that \( X = \mathbf{0} \). The Dutch identity (Holland, 1990) states that

\[
p(x) = p(\mathbf{0}) M(x).
\] (4)
By (4),
\[ \gamma = C(1, 1) - C(1, 0) - C(0, 1) + C(0, 0). \] (5)

Thus the log cross-product ratio can be expressed in terms of the cumulant generating function \( C \).

The cumulant generating function \( C \) is closely related to the conditional cumulants of \( \lambda(\theta) \) given \( X = 0 \). Let \( I \) be the set of integer pairs \( i = (i_1, i_2) \) such that \( i_1 \) and \( i_2 \) are nonnegative and at least one of \( i_1 \) and \( i_2 \) is positive, and let \( J \) be the set of \( i \) in \( I \) with both \( i_1 \) and \( i_2 \) positive. Provided that, for some real \( r_M > 0 \), \( M(t) \) is finite whenever \( |t|^2 = t_1^2 + t_2^2 < r_M^2 \), there exists an \( r_C > 0 \) such that, for \( |t| < r_C \),
\[ C(t) = \sum_{i \in J} \frac{\kappa_{i_1 i_2} t_1^{i_1} t_2^{i_2}}{i_1! i_2!}. \]

The coefficient \( \kappa_i = \kappa_{i_1 i_2} \) is the conditional product cumulant of \( \lambda(\theta) \) given \( X = 0 \) corresponding to the conditional expectation of \( \lambda_{i_1}(\theta) \lambda_{i_2}(\theta) \) given \( X = 0 \). For example, \( \kappa_{01} \) is the conditional mean of \( \lambda_1(\theta) \), \( \kappa_{20} \) is the conditional variance of \( \lambda_1(\theta) \), and \( \kappa_{11} \) is the conditional covariance of \( \lambda_1(\theta) \) and \( \lambda_2(\theta) \). If \( r_C > 2^{1/2} \), then \( \gamma \) has the power series expansion
\[ \gamma = \sum_{i,j} \frac{\kappa_{i,j}}{i_1! i_2!}. \]

The expansion suggests a crude approximation of \( \gamma \) by the conditional covariance \( \kappa_{11} \) of \( \lambda_1(\theta) \) and \( \lambda_2(\theta) \), with a more refined approximation by \( \kappa_{11} + (\kappa_{21} + \kappa_{12})/2 \). If the conditional distribution of \( \lambda(\theta) \) given \( X_1 = X_2 = 0 \) is bivariate normal, then \( \gamma \) is exactly equal to \( \kappa_{11} \).

For any distribution of \( \theta \), if \( \lambda_1(\theta) \) or \( \lambda_2(\theta) \) is constant, so that \( X_1 \) or \( X_2 \) is independent of \( \theta \), then \( \gamma = \kappa_{11} = 0 \).

A more general expression for \( \gamma \) can be derived by consideration of a new random vector based on \( \lambda \). This result is always available. Standard convexity properties of moment generating functions imply that \( M(t) \) is finite for \( 0 \leq t_j \leq 1, 1 \leq j \leq 2 \). As a consequence, if \( 0 < t_j < 1 \) for \( 1 \leq j \leq 2 \) and \( A(t) \) is a random variable with distribution function
\[ [M(t)p(0)]^{-1} \int_{-\infty}^{x} \exp(t'\lambda)VdF \]
at \( x \) real, then the two-dimensional random vector \( A(t) \) with coordinates \( A_j(t) = \lambda_j(A(t)) \) for \( 1 \leq j \leq 2 \) has finite moments of all orders. In particular, the expectation \( \mu_j(t) \) of \( A_j(t) \),
1 ≤ j ≤ 2, and the covariance τ(t) of Λ₁(t) and Λ₂(t) are defined and finite. The moment generating function of Λ(t) is \( M(t + u)/M(t) \) at \( u \) if \( 0 < u_j + t_j < 1 \) for \( 1 ≤ j ≤ 2 \). To explore required integrals derived from \( C \), let \( T \) be uniformly distributed on the unit square \( S \) of \( t \) with \( 0 < t_j < 1 \) for \( 1 ≤ j ≤ 2 \).

Use of the mean value theorem of calculus shows that

\[
\gamma = E(\tau(T))
\]

is the expected conditional covariance of \( \Lambda_1(T) \) and \( \Lambda_2(T) \) given \( T \).

The following theorem provides a simple condition that ensures that log cross-product ratio \( \gamma \) is positive. It is already known that \( \gamma ≥ 0 \) (Holland & Rosenbaum, 1986).

**Theorem 1** Let \( \lambda_1 \) and \( \lambda_2 \) be monotone increasing functions. Assume that no constant \( c \) exists such that \( \theta \) is \( c \) with a probability of 1. Then \( \gamma \) is positive.

**Proof.** It suffices to show that \( \tau(t) \) is positive. To verify that \( \tau(t) \) is positive, let \( A'(t) \) be a random variable independent of \( A(t) \) with the same distribution as \( A(t) \). Then \( 2\tau(t) \) is the expected value of the product

\[
U = [\lambda_1(A(t)) - \lambda_1(A'(t))][\lambda_2(A(t)) - \lambda_2(A'(t))].
\]

If \( \lambda_1 \) and \( \lambda_2 \) are monotone increasing, then \( U \) is nonnegative, and the probability is positive that \( U \) is positive. \( || \)

In the special case of a Rasch model with item difficulties \( \beta_j \) for \( j \) from 1 to 2,

\[
\lambda_j(\theta) = \theta - \beta_j,
\]

so that \( \tau(t) \) reduces to the variance of \( A(t) \), and \( \gamma \) is the expected conditional variance of \( A(T) \) given \( T \). If the conditional moment generating function of \( \theta \) given \( X = 0 \) is finite in an open interval that includes 0, if \( \kappa_i \) denotes the \( i \)th conditional cumulant of \( \theta \) given \( X = 0 \), and if the conditional cumulant generating function \( K \) of \( \theta \) given \( X = 0 \) satisfies \( K(t) \) is finite and

\[
K(t) = \sum_{i=1}^{\infty} \kappa_i t^i / i!
\]

for \( |t| < r_K \) for some \( r_K > 2^{1/2} \), then

\[
\gamma = \sum_{i=2}^{\infty} (2^i - 2) \kappa_i / i!.
\]
If the conditional distribution of $\theta$ given $X = 0$ is a normal distribution with variance $\sigma^2_c$, then $\gamma = \sigma^2_c$.

If $\theta$ has a continuous distribution with a positive density $f$ that is twice differentiable, then a lower bound on $\gamma$ may be obtained as in the following theorem.

**Theorem 2** Let the Rasch model hold, and let $\theta$ have continuous positive and twice differentiable density $f$. Assume that real $\delta > 0$ and real $c > 0$ exist such that the derivative $f_1$ of $f$ satisfies the condition that

$$|f_1(z + a)| < cf(z), -\infty < z < \infty, |a| < \delta.$$ 

Let $g = \log f$, let $g_1$ be the derivative of $g$, and let $g_2$ be the second derivative of $g$. Let $-g_2(A(t))$ have a finite positive variance $\eta(t)$ for each $t$ in $S$. Let $\eta_j(t)$ be the expectation of $P_j(A(t)Q_j(A(t))$ for $j$ equal 1 or 2. Then

$$\gamma \geq E(\eta(T) + \eta_1(T) + \eta_2(T))^{-1}).$$

**Proof.** For $t$ in $S$, the density of $A(t)$ is

$$h = H^{-1} \prod_{j=1}^2 P_j^{t_j} Q_j^{1-t_j},$$

where

$$H = \int f \prod_{j=1}^2 P_j^{t_j} Q_j^{1-t_j},$$

so that $e = \log h$ has first derivative

$$e_1 = g_1 - \sum_{j=1}^2 [(1 - t_j) - Q_j]$$

and second derivative

$$e_2 = g_2 - \sum_{j=1}^2 P_j Q_j.$$ 

The first derivative of $h$ is

$$h_1 = e_1 h.$$
Consider estimation of the expectation of a random variable $Z$ under the model that $Z - \alpha$ has the distribution of $A(t)$ for some real $\alpha$ with $|\alpha| < \delta$. Apply the Cramér-Rao inequality (Cramér, 1946, p. 475). Then elementary calculations show that

$$\tau(t) \geq [\eta(t) + \eta_1(t) + \eta_2(t)]^{-1}.$$ 

The conclusion follows. ||

In many cases, an upper bound on $\gamma$ may be established as in the following theorem.

**Theorem 3** Let the Rasch model hold, and let $\theta$ have continuous positive and twice differentiable density $f$. Let $g = \log f$, let $g_1$ be the derivative of $g$, and let $g_2$ be the second derivative of $g$. For some constant $b > 0$, let $g_2 \leq -b$. Then $\gamma < 1/b$.

**Proof.** From the proof of Theorem 2, it follows that $e_2 < -b$. As a consequence, $\log h$ must achieve a maximum at some real $z$.

For any random variable $Y$ with mean $\mu$ and variance $\sigma^2$,

$$E([Y - z]^2) = \sigma^2 + (z - \mu)^2.$$ 

Thus the variance $\tau(t)$ of $A(t)$ does not exceed the expected value of $[A(t) - z]^2$, so that

$$\tau(t) \leq \int uwv,$$

where, for a real,

$$u(a) = (a - z)^2,$$

$$v(a) = h(a)/w(a),$$

and

$$w(a) = (2\pi/b)^{-1/2} \exp[-bu(a)/2].$$

Because $h$ and $w$ are density functions,

$$\int w = 1$$

and

$$\int (vw) = 1.$$
Because $w$ is the density function of the normal distribution with mean $z$ and variance $b^{-1}$,

$$\int (uw) = b^{-1}.$$ 

Use of standard formulas for changes of variables yields

$$\int (uvw) = \int_0^\infty (u^*v^*w^*)$$

$$\int_0^\infty (v^*w^*) = 1, \quad \int_0^\infty w^* = 1,$$

and

$$\int_0^\infty (u^*w^*) = b^{-1},$$

where, for $a > 0$,

$$u^*(a) = a,$$

$$v^*(a) = \frac{1}{2} \left[ v(z + a^{1/2}) + v(z - a^{1/2}) \right],$$

and

$$w^*(a) = \left( \frac{2a\pi}{b} \right)^{-1/2} \exp\left(-\frac{ba}{2}\right)$$

(Cramér, 1946, p. 168).

It follows that, for any real $d$,

$$\int_0^\infty (u - b^{-1})(v^* - d)w^* = \int_0^\infty (u^*v^*w^*) - b^{-1}.$$ 

The definition of $z$ and the assumptions of the theorem imply that $v^*$ is a decreasing function, so that the choice of $d = v^*(b^{-1})$ implies $y = (u^* - b^{-1})(v^* - d)$ is negative except at $b^{-1}$, and $y(b^{-1}) = 0$. Thus $\tau(t)$ is less than $b^{-1}$. It follows that $\gamma$ is less than $b^{-1}$. ||

In the important special case of $\theta$ with a normal distribution with mean $\mu$ and variance $\sigma^2$, $g_2$ in Theorem 2 is the constant $-1/\sigma^2$, so that $\eta(t_2) = 1/\sigma^2$ and $\tau(t)$ and $\gamma$ are both at least $2\sigma^2/(2 + \sigma^2)$. On the other hand, it also follows from Theorem 3 that $\gamma$ is less than $\sigma^2$. So, for example, for $\sigma^2 = 1$, the lower and upper bounds on $\gamma$ are $2/3$ and $1$, respectively. For fixed $\mu$ and $\sigma^2$, if $|\beta_j|$ approaches $\infty$ for $j$ equals $1$ and $2$, then $\gamma$ approaches $\sigma^2$. The
proof of this claim is an application of Scheffé’s theorem (Scheffé, 1947). For example, if $\beta_1$ and $\beta_2$ both approach $-\infty$, then multiplication of the numerator and denominator by

$$\exp[-(1-t_1)\beta_1 - (1-t_2)\beta_2]$$

shows that, in the proof of Theorem 2, $h$ converges to the density of a normal random variable with mean $\mu - (1-t_1) - (1-t_2)$ and variance $\sigma^2$. It follows that $\eta_j(t_2)$ converges to 0, so that the lower bound for $\gamma$ converges to $\sigma^2$. Because $\sigma^2$ is also the upper bound for $\gamma$, $\gamma$ converges to $\sigma^2$. Minor variations on the same argument apply if some $\beta_j$ approaches $\infty$.

The arguments in Theorems 2 and 3 are readily applied to the 2PL model of item response theory. In this case, $\lambda_j(\theta) = a_j(\theta - \beta_j)$ for an item difficulty $\beta_j$ and an item discrimination $a_j > 0$. The definition of $A(t)$ is changed due to the new definition of the $\lambda_j$; however, the remaining changes are quite limited. In Theorem 2, the lower bound becomes

$$a_1a_2E(\eta(T) + a_1^2\eta_1(T) + a_2^2\eta_2(T))^{-1},$$

and the upper bound becomes $a_1a_2/b$ in Theorem 3. In the case of $\theta$ with a normal distribution with mean $\mu$ and variance $\sigma^2$, a lower bound is

$$\frac{4a_1a_2\sigma^2}{4 + (a_1^2 + a_2^2)\sigma^2}$$

and an upper bound is $a_1a_2\sigma^2$. The previous result for the Rasch model is obtained with $a_1 = a_2 = 1$.

3 Example

In a study of assessment of fit of common models in item response theory (Sinharay & Johnson, 2003), prediction of log cross-product ratios for item pairs was examined under the Rasch model for $\mu = 0$ and $\sigma^2 = 1$. The authors reported that the predicted log cross-product ratios (from the Rasch model) among the item pairs fall within a very narrow range, all around 0.73 in their limited simulation study. These results are consistent with the bounds of $2/3$ and 1 established in Section 2. To corroborate their findings, numerical integration was employed to compute $\gamma$ using (1) for this case (Rasch model with $\mu = 0$ and $\sigma^2 = 1$) with $\beta_1$ and $\beta_2$ on a grid of integer values between $-4$ and 4. The values of the
log cross-product ratios are summarized in Table 1. As evident in Table 1, the smallest $\gamma$ is observed for $\beta_1 = \beta_2 = 0$. The largest values are obtained for $\beta_1$ and $\beta_2$ large in magnitude and opposite in sign. The log cross-product ratios show little variation, all falling between 0.71 and 0.90.

4 Conclusion

Although results are presented for two items, they obviously apply to more general item response models. Given any one-dimensional model for $J > 2$ binary responses in which local independence holds, the model applies to any two responses. For example, consider $J \geq 2$ items $X_j$ with values 0 or 1. If the $X_j$ are conditionally independent given a normally distributed random variable $\theta$ with mean 0 and variance $\sigma^2 > 0$ and if the conditional probability $P_j(\theta)$ that $X_j = 1$ given $\theta$ is

$$P_j(\theta) = [1 + \exp(-\theta + \beta_j)]^{-1}$$

for some real $\beta_j$, then $X_j$ and $X_k$ are positively correlated for each $j$ and $k$. Thus $X_j$ is positively correlated with the sum $S = \sum_{k=1}^{J} X_k$, so that the point-biserial correlation is
positive for $X_j$ and $S$. The log cross-product ratio for each pair $X_j$ and $X_k$ is less than $\sigma^2$, so that the correlation of $X_j$ and $X_k$ is less than $\exp(\sigma^2) - 1$.

The bounds obtained can provide a basis for elementary model checking. Log cross-product ratios, pairwise item correlations, and point-biserial correlations are readily estimated without use of model assumptions. If one observes negative estimates of item-pair correlations, cross-product ratios or point-biserial correlations for a data set, one can conclude even before fitting an item response model that the data are clearly incompatible with any one-dimensional item response model. Further, observed values of marginal log cross-product ratios that are clearly outside the bounds (computation of which require fitting an item response model) suggested in this paper will indicate the misfit of the item response model employed.
