Abstract

With the increasing proliferation of multitasking and Internet-connected devices, security has reemerged as a fundamental design concern in information systems. The shift of IS curricula toward a largely organizational perspective of security leaves little room for focus on its foundation in systems architecture, the computational underpinnings of processes and protection. Yet these architectural features are the foundation of systems security for all the layers above that they enable. They are also the prototypical mechanisms of protection that must be modeled throughout systems design to realize system security: confidentiality, integrity and availability. This paper presents a learning unit that proposes a special ontology of computer system architecture to explain computer security on the host-level and by extension the emerging standard security architecture of the cloud, the virtual machine. The ontology appears as a prose tutorial, a set theoretic model, and a two-page study reference that facilitates a security discussion ranging from host architecture to web-services. This treatment is a concise, self-contained module for standalone use or embedded in a systems course (analysis, modeling, design, database or systems architecture) where complete operating system or computer organization coverage may not be feasible.

Keywords: computer security, computer protection, special ontology of systems architecture, virtual machine, IS pedagogy

1. INTRODUCTION

The proliferation of multitasking personal devices and Internet-connected users thrusts security into the forefront of information system design considerations. Even casual computer users are beset with security concerns and must rely on the device and network designer for protection from violations of confidentiality, integrity or availability. Coincidentally, the shift of IS curricula toward a broader, organizational perspective on security leaves little room in curricula for a focus on the computational underpinnings of processes and protection that are the foundation of computer system security. (Topi, Valacich, Wright, Kaiser, Nunamaker, Sipior & de Vreede, 2010) These architectural features not only form the basis of systems security for all the system layers above them that they enable but, they also represent prototypical mechanisms of protection in organizational systems security. This computer security primer that follows offers an option to fill a curricular gap.

The primer begins with an abbreviated literature survey of the theory, policy and application of computer security as a context and a reading list for students who may wish to delve much deeper. Then follows the special ontology of systems architecture, a framework for explaining the role of protection in host computer security. That framework includes the protection provided by virtual machine architecture, the primary design platform for security in cloud computing. Finally there are some brief thoughts on
applying the security primer as a learning unit in undergraduate curricula. The primer is a concise self-contained module suitable for use standalone or embedded in a systems course (analysis, modeling, design, database or systems architecture). Appendices provide a set-theoretic representation of the ontology and a two-page reference handout as a study guide.

2. WHAT IS COMPUTER SECURITY?

The model posed in (McCumber, 1991) has stood the test of time as the de facto definition for computer security (See Figure 1).

![IS Security Model: McCumber](image)

**Figure 1 – IS Security Model: McCumber**

*Confidentiality, integrity, and availability express the trinity of properties that underpin virtually all the literature on computer security (Landwehr, 2001). The term computer security ranges over a large expanse of stakeholders, disciplines and theory often mediated by a particular stakeholder perspective. Those perspectives have shaped the security literature and settled into a layered decomposition of topics as indicated in (Bishop, 2003, p. 22). (See Figure 2)*

![Hierarchic Model of Security](image)

**Figure 2 – Hierarchic Model of Security**

Much of the early attention to computer security focused on supporting governmental and military requirements for control of information. The seminal work casting security control in the formal, mathematical paradigm is (Bell & LaPadula, 1973). This multi-layered, military security policy addressing a four-tiered classification scheme (i.e. unclassified, confidential, secret, and top secret) received extensive research attention over decades focusing primarily on protecting confidentiality, the non-disclosure of sensitive information (Denning, 1976, McLean, 1985). Non-military or commercial asset concerns lean more toward integrity (the protection of information from loss or corruption). (Lipner, 1982) Denial-of-service (DoS) attacks exemplify attempts to compromise the availability property of security (Wikipedia, 2013). Information security is affected by social-economic factors that extend beyond the business stakeholders who directly interact with information systems. These indirect factors shape the motivations and often the response affecting security threats and influencing policy. In many instances socio-engineering efforts are preferable to expanded protection mechanisms. (Anderson, 2001)

3. A SPECIAL ONTOLOGY OF COMPUTER SYSTEMS ARCHITECTURE

The computer and information sciences adopt special ontologies to identify a domain of interest within which the elements of relevance may be defined and their relationships explored to demonstrate concepts or theories. The special ontology proposed herein is consistent with the practice in computer science and information science categorizing a domain of concepts (i.e. individuals, attributes, relationships and classes). (See Figure 3 below.) The ontology abstracts the elements of systems architecture pertinent to computer security at the design, implementation, and operations / maintenance layers of the security life cycle. This abstraction focuses on the security properties and relationships that are often obscured by idiosyncratic processor or process architecture implementations. (A somewhat more formal and concise exposition of the special ontology in its set theoretic form may be found in Appendix A.) (Waguespack, 1975, 1985)
**Figure 3 – A Special Ontology of Computer Systems Architecture**

The reader is encouraged to envision resources at the hardware instruction set level in the descriptions that follow. Subsequently the exposition will expand that view to encompass all the layers indicated in the hierarchic model of security.

**Individuals** in this ontology are defined as environment, resource, resource map, and access mechanism. The environment is the union set of all other elements in a system and in fact defines the universe of interest and discourse as conceived by the stakeholders of the system. Resources encompass all the “namable” elements in the environment and thus are uniquely distinguishable, the property of identity. Two subsets of resources define the range and function of resource manipulation: 1) a resource map that delineates a resource subset called an access scope, and 2) an access mechanism that activates access to resources in an access scope.

**Attributes** characterize the individuals in the ontology. Storage resources exhibit the attribute of remembrance, the capacity to retain state information in the environment. Transformational resources exhibit the attribute of behavior operating on instances of storage resource to set, access, and/or modify state information. (The most common form of transformational resource is the machine instruction that interacts with state information sometimes accessing – sometimes modifying the state. In this special ontology state changes result exclusively through the behavior of transformational resources.)

**Relationships** define the interaction / interdependence of individuals in the special ontology. The environment is the composition of all resources. Both access mechanism(s) and resource map(s) are instances of resource. The relationship between a resource map and the set of all resources is the delineation of a subset of those resource instances, an access scope. The relationship between two resource maps defines an intersection of their access scopes. An intersection that is the null set defines the separation property of that intersection. The application of an access mechanism to a pertinent resource map activates an access scope. (It may be preferable to say an access mechanism acts an access scope since resource behavior may be more naturally understood as animation or activity.)

An access scope may include instructions (transformational resources) and/or storage. The quintessential example of transformational resource activation is the application of the mechanism of instruction execution cycle to an access scope delineating an otherwise inanimate collection of instruction specification fusing their association into an executing process. Storage resources in the access scope remember the instructions, which one is current and the residual state at each instruction’s completion.

A common example of storage activation is a virtual memory mechanism. The physical memory pages enumerated in a process’s page table delineate its access scope of storage. Swapping activation from one process to another occurs by replacing the page table entries for one process by those of another process. (Saltzer & Schroeder 1975: p. 1286)

**Classes** distinguish resources whose function in the environment engenders control. Since all “activity” in an environment results from the application of an access mechanism to a resource map, those two specific resources jointly realize the instrument of “animation,” the progression of state changes or “execution.” Any resource that effects the initiation, sequencing, alteration or suspension of “animation” exhibits the property of control. Access to a process's resource map denotes the opportunity of controlling that process. Detecting attempts to access control resources is a key to managing computer systems security. This is the purpose of the privilege property in designating resources susceptible to potentially harmful application.
4. HOST PROCESS ARCHITECTURE

This section describes some common design choices found in contemporary computer systems. They illustrate how the special ontology describes a specific process execution environment. In most computing literature the unit of animation, execution, in a computer system is called a process and the environment in which the process executes is called the host computer, host machine or host (reminiscent of calculating machines). (A generous survey of computer architectures and their properties is found in (Blaauw & Brooks, 1997)).

Mono-processing is the execution of only a single process on a host. Process animation results from the association of access mechanism with resource map – the instruction execution cycle, a collaboration of resources combining state information with transformation. The state information specific to execution is delineated in the process status vector (psv) that indicates residual state information: (e.g. conditional comparison flags, error conditions, and what the next instruction to execute should be, etc.). Each instruction execution occurs in the state of the machine resulting from the previous instruction’s execution, hence a “cycle.” The psv also delineates the subset of storage resources accessible by the process. The psv realizes the special ontology’s resource map delineating both the transformational and storage resources accessible by the process. (As indicated in the set theoretic ontology description in Appendix A, it is also common for the resource map to be realized as two discrete elements: one focusing on instruction execution and a second mapping the accessible storage space.) In the common case where external resources exist (i.e. input/output devices, networking), their design may be treated as additional namable resources. (An example of such a connection is the mapping of I/O interfaces as storage locations in the DEC PDP11 UNIBUS configuration.) (Blaauw & Brooks, 1997: p. 967)

Multiprogramming occurs in the presence of more than a single process residing on one host. Although there are multiple processes, there may exist only a single instruction execution cycle that is shared (by multiplexing) among them. This processing protocol requires a managing process usually called an operating system (OS) that includes supervisory and service components arranged as a collection of agent processes. These agents manage the association of the instruction execution cycle with the various processes one at a time. (The protocol for delegating execution among the various processes is called process scheduling and may be based upon various priority schemes to manage the progress of the individual processes respectively.) The agents may themselves be processes – each with its own resource map.

What distinguishes a process that is an OS is the privilege of an access scope including any and all host resources. Where the resource map of a non-OS process is denoted psv for process state vector, the resource map of an OS process is denoted csv, control state vector. The distinction highlights the OS as in control of the entire host.

A control resource is one that permits a process to assign the instruction execution cycle to a particular process or to access/modify the resource map of a process, including itself. The most common mechanism for enforcing the OS’s prerogatives (privileges) is the interrupt that extends the behavior of the instruction execution cycle and permits the OS to gain access to the instruction execution cycle at will.

The normal course of the instruction execution cycle proceeds with each succeeding instruction determined by the current process’s psv (i.e. the process’s execution continues without interruption.) An interrupt mechanism is the detection and response to a condition signaling the need for a departure from the current sequence of execution (suspending the current process) and designating execution of the next instruction in a different process (activating another process). In a nominal OS design the interrupt would cause the sequence of instruction execution to transfer to an agent of the OS called the interrupt handler. Once an interrupt handler is activated its instructions determine the system’s ensuing behavior. The result is a transfer of the sequence of instruction execution from the interrupted process to another, a process swap.

Interrupts are designed to support a variety of supervisory tasks. Interrupts may occur due to: external signals (i.e. input/output connections), execution exceptions (i.e. erroneous instruction specifications), attempts to access resources designated as privileged, access exceptions (i.e. attempts to access resources not delineated in the process’s resource map), or solely to relinquish the instruction execution cycle. The interrupt mechanism’s design incorporates state
information (i.e. psv) to designate the precise process swap behavior (e.g. what state information is to be set in the suspended process). Hence, the psv is (in itself) a control resource. Whether or not interrupts are enabled or suppressed in the current process and which process is to be activated in the process swap is indicated in the csv, hence these are controlled by the OS.

**Multiprocessing** differs from the multiprogramming protocol in that more than one instruction execution cycle resource is available to associate with the processes present on the host. Multiple processes may concurrently execute their instructions. Each instruction execution cycle must manage a separate interrupt protocol. Individual process management in the presence of multiprogramming is not significantly different from multiprogramming unless concurrently executing processes are allowed to communicate and/or share resources. In which case inter-process communication and sharing require addition supervisory services that monitor and mediate process interactions.

**5. OS AND PROCESS SECURITY**

Monoprocessing is the least complex form of process management. It depends exclusively on the process’s fidelity of programming to its specifications. The primary threat is programming error. (A monoprocessing system often includes OS services to offload I/O or job-scheduling tasks from individual processes. It earns trust from the quality assurance it receives. Regardless, any error in programming can compromise the system.)

Multiprogramming requires an OS that shares its attention with more than one process. Where the OS protects itself from the user process, it now must also protect user processes from the misbehavior of one another. **Encroachment** is the unauthorized access of one process’s resources by another. Encroachment occurs due to errors/malice among the cohabitant processes.

Although the added instruction execution capabilities in a multiprogramming environment make resource management and coordination among processes more complicated, the basic principles of process closely resemble multiprogramming.

**Separation** is the major protection mechanism in a multiprogramming environment – to prevent the undesirable behavior of one process from causing the failure of or undue interference with the other processes. **Separation** is achieved by: 1) devising resource maps that delineate resources according to process, and 2) enforcing **complete mediation** where each access mechanism enforces adherence to its delineated resources by prohibiting unsanctioned access and, usually, by raising an interrupt condition when an attempt occurs (Bishop, 2003, p. 345). Effective separation eliminates the risk of encroachment.

**Privilege** denotes the supervisory authority of an OS to control the resources of individual processes. The supervisory functions of the OS (the kernel or nucleus) exercise control over every process in the system. Complete mediation also controls the number of consecutive instructions that a process may execute (based on either a real or virtual “clock,” as prescribed in host csv). That prohibits any process from monopolizing the instruction execution (e.g. the infinite loop!). The OS kernel protects itself by managing the csv of the host to retain control over every process while at the same time it remains **separated** from all processes on the host except itself – a secure operating system.

**6. VIRTUAL MACHINES IN THE CLOUD**

The multiprocessor environment is the least complex and therefore, the most easily quality assured – trustworthy. That explains the growing preference for multiprogramming virtual machines as the security framework for cloud computing. (Rosenblum & Garfinkel, 2005)

A virtual machine is an execution environment in which the process that executes cannot determine if it resides on a (physical) host machine or is a “guest” on a simulation of that host. Each guest process can be treated as the sole process on that virtual machine. A layer of supervisory software, the virtual machine monitor (VMM), manages the execution environment of each guest by configuring the resource maps and the interrupt behavior of the access mechanisms to intercept any guest attempts to directly access control resources. When a guest needs access to resources that might compromise “safety,” that access must be mediated by the VMM through a reference monitor that simulates the process’s resource access by virtualizing that resource while protecting the VMM’s control of the host. These
protocols rely on control and access mechanism design. (Smith, J.E. & Nair, R., 2005)

**Self-virtualizable:** When a virtual machine appears identical to its underlying host, it can provide direct access to the exact same instruction set and access mechanisms of that host. We call this host architecture self-virtualizable because it can provide a complete replica of itself for guest process(s). (Waguespack, 1985) A guest process may execute at the same level of efficiency as it would if it were the sole process on the underlying host except for those resources that must be virtualized to maintain the VMM’s control.

Host hardware design decisions make virtualization straightforward or complex. (Garfinkel & Rosenblum, 2005) Process control protocols prior to the advent of virtual machines focused primarily on facilitating a host-based OS’s capacity to maintain control. Design decisions for processor hardware architecture did not always support complete mediation. When host instruction set designs include instructions that access control resources but are not designated as privileged they do not raise interrupt conditions even when executed in a process without privilege. There are two options that support virtual machines on these hosts. In one approach the VMM pre-scans all the process’s instructions before execution and replaces “unsafe” instruction sequences with “safe” instructions – usually including instructions that do cause interrupts to allow the VMM to intercede and simulate the indicated service. Alternatively, the VMM simulates all instructions running on the virtual machine; an approach that results in a dramatic reduction in effective execution speed since simulation is orders of magnitude slower than direct host hardware execution. (Complete simulation is the common approach used to execute Java code. (Lindholm, Yellin, Bracha, & Buckley, 2013).)

The most efficient virtual machine realization requires that all control resources include the privilege property with appropriate interrupt conditions to allow a VMM to enforce complete mediation. Secondly all resource access attempts that would otherwise be directed to “hardware resources” (i.e. I/O and communication devices) need to be intercepted allowing the VMM to virtualize those resources through reference monitors. This combination of intercession provides the maximum guest performance with the minimum of VMM overhead.

**Multiple OS’s:** The earliest implementations of VMM technology supported guest processes that themselves were OS’s, guest OS’s. The ability to run multiple versions of OS concurrently on the same physical host provided flexibility and cost savings. In the description of process swapping and control above the key resource designating process activation is the process state vector. (Waguespack, 1985) The privilege of designating which psv(s) is active determines control over the entire environment. Each virtual machine environment is a simulation of the physical host and thus as these guest OS’s manage the processes that reside on them the OS’s believe they are controlling the host. But their “control” is virtualized by the VMM with virtualized csv access. The VMM manages the VM’s as its processes retaining control over all the physical host resources. This permits a multi-layered arrangement of virtual machines some supporting mono-processing, others supporting multiprogramming OS’s and finally some supporting replicas of the VMM itself telescoping the illusion of host environment layer after layer limited only by physical of performance and resource virtualization capabilities.

**Security through virtualization:** Virtual machines provide a convenient architectural foundation for security. Each guest process (or virtual machine) resides in a naturally separated execution environment. Complete mediation through VM instruction execution and virtualized resource access facilitates connectivity beyond the boundaries of the virtual machine, but only through contractually defined protocols, VMM mediated services. (Garfinkel & Rosenblum, 2005)

Although initially virtual machines were intended to support concurrently executing OS’s on a single host, guest VM’s may also be VMM’s in their own right. Such an arrangement permits a hierarchically encapsulated progression of secure execution environments. Virtualization enables sharing and protection protocols administered through complete mediation that both enables and structures security. VM architecture is the basis of cloud computing. VM’s make possible the protections and scalability of system security in the cloud. (DeKeyrel, Waldbusser & Jones, 2012)
7. CONCLUSION

Security is an essential topic in IS education today. But, finding room for it in an already crowded curriculum is a challenge. The "shrinking real estate" for technical content in IS curricula will continue to require compactly designed primers (similar to this one on computer security structures) if our IS graduates will have any practical grounding to discern credible information systems capabilities and performance potential.

This primer addresses the key architectural security issues concisely. The primer is a useful pedagogical foundation for computer, network and Internet security discussions. It is suitable for embedding in a generic systems, networking or business process course for upper level undergraduates or graduate IS or MBA students. Teachers may use it as a survey, tutorial or as an outline for a student research project. It is appropriate for either an individual or a comparative system security study. The special ontology is applicable to the full range of computing architectures from Turing and von Neumann through the DEC, Cray, IBM, Motorola and Intel generations – as well as architectures of loosely coupled processors (e.g. the World Wide Web). (Turing, 1936, Bell & Newell, 1971, Blaauw & Brooks, 1997)

8. ACKNOWLEDGEMENTS

Thanks for helpful comments from the referees. Special thanks are due my colleagues David Yates and Bill Schiano at Bentley University for their insightful discussions and comments on these ideas. And thanks to the students who have labored through the development of this learning unit.

9. REFERENCES

Editor’s Note:
This paper was selected for inclusion in the journal as a ISECON 2013 Meritorious Paper. The acceptance rate is typically 15% for this category of paper based on blind reviews from six or more peers including three or more former best papers authors who did not submit a paper in 2013.
Appendix A – Set Theoretic Representation of the Special Ontology (Waguespack, 1975, 1985)

E → environment “→” reads “…is defined as…”
S → storage resources (all state information)
T → transformational resources (all computation capable of modifying the state)
E → {T, S} (all transformational and storage resources)
M → a machine, {Tm, Sm}, (i.e. M ⊆ E)
tb → the “map” delineating an access scope of transformation resources
[] → a mechanism (function) to access a resource access scope
T[tb] → a resource subset of T defined by tb (i.e. T[tb] ⊆ T)
sb → the “map” delineating an access scope of memory/storage resources
S[sb] → a partition of the resource S defined by sb (i.e. S[sb] ⊆ S)
{tb, sb} → {eb}; environment base: a composite access scope
E[eb] = {T[tb], S[sb]} a program is a specification of transformational and storage resources
psw → the process status word of a program (process not yet initiated)
psv → the process status vector (word) as “idle” or suspended process
Ξ → the transformational resource that executes instructions in a process
Ξ (psv) → the process state word of an “active” program under execution
{T[tb], S[sb], psw} → an “idle” program (not yet initiated)
{T[tb], S[sb], psv} → an “idle” process (having been initiated but not currently active)
{T[tb], S[sb], Ξ (psv)} → an “active” process currently executing
CSV → the control state vector enabling the control of a machine
Sm → all the memory/storage of M
Sm[j] → the storage of M accessible by user j
Sm = {Sm[csv], Sm[u1], Sm[u2], Sm[u3], ... }
Sm[csv] → the storage that contains/accesses the CSV of M
Sm[psv] → the memory/storage that covers/accesses the PSV of a process
Sm[u] → {Sm[csv], Sm[u] = ∅ } the memory/storage not including the CSV of M
Tm → instruction set of M
Tm[c] → instruction set of M that can control M (also named C)
Tm[u] → { Tm - Tm[c] } (non-control) “user” instruction set of M (also named U)
E[csv] → {Sm[csv], Tm[c]} the control state vector of E that designates “control” of E
{ E[csv], Ξ (csv)} → the “active” process that controls the entire environment, (e.g. VMM)
Appendix B – The Computer Security Green Card

Computer Systems Architecture and Security

Without a Language or Syntax!
What is computer systems security world all about?

Special Ontology of Computer Systems Architecture

This ontology is consistent with the practice in computer science and information science categorizing a domain of concepts (i.e. individuals, attributes, relationships and classes). This ontology is based upon a set-theoretic model of computer system resources defining the architectural elements of information systems characterized by executable program code and accessible storage resources. The ontology identifies the elements of a computerized information system and their relationships relevant to the definition and protection of resource security – the state of being free from danger or threat.

1. Individuals

A resource is a distinguishable element within the domain of discourse concerned with security. An environment is a stakeholder prescribed domain of interest defining the context and relevant elements of security concern; it is the set of all resources under consideration. A resource map is a specification of some subset of the environment. An access mechanism is an executive agent that effectuates behavior and/or mediates access to resources specified by a resource map.

2. Attributes

Each resource in an environment is uniquely distinguishable, the identity property. Each resource is either storage (the object of some behavior) or transformational (the instrument of some behavior). Storage resources exhibit the property of remembrance as they are associated with a value which may be retrieved or modified only through access to the storage resource itself. A transformational resource exhibits the property of behavior that acts upon a storage resource to modify its value (effect a change of “state”).

3. Relationships

Relationships exist on two dimensions: behavioral and structural.

3.1. Behavioral Relationships

3.1.1. Activation

The application of an access mechanism to a resource map is an activation, resulting in animation within an environment; realizing behavior and any corresponding state changes. Any and all access to resources is realized through the application of an access mechanism to a resource map. The animation (or activity) realized by the composition of access mechanism to resource map is called a process or a thread.

3.2. Structural Relationships

3.2.1. Composition

An environment is the composition, the union, of all resources, both storage and transformational resources (including all access mechanism(s)).

3.2.2. Instance

A resource map is an instance of storage resource. Access mechanism is an instance of transformational resource effectuating behavior.

3.2.3. Delineation

A resource map delineates a subset of resources called an access scope; thus determining what storage resources are accessible and/or what behaviors are possible through transformational resources.

©2013, Les Waguespack, Ph.D.
COMPUTER SECURITY “GREEN CARD”

MAY 3, 2013

3.2.4. Intersection

Access scopes intersect if they share access to the same resource. The separation property denotes the absence of the intersection of accessibility. Process X is said to be separated from Process Y if the resource map of Process X is not delineated in the access scope of Process Y. If the intersection of two access scopes is null then they are said to be mutually separated.

4. Classes

Resources enabling activation compose the class of control resources. All resources fall into either the class of control or non-control resources.

5. Security Apparatus

In the context of computerized systems, security is the state of being free from danger or threat ascribed to a stakeholder(s) whose interests are invested in the system behavior. That vestiture takes the form of agency behavior within the system carried out on behalf of a stakeholder(s). Security breach includes disruption, incursion, or the hijacking of resources.

5.1. Process

A process results from activating the combination of the transformational and storage resources in its access scope. A process realizes behavior as the agent of a stakeholder(s). The ongoing application of host access mechanism(s) to a process’s resource map(s) denotes an active process; withdrawing the host access mechanism(s) yields a suspended process.

5.2. Process Control

Process Control refers to regulating process behavior (initiating, sequencing, suspending, and/or terminating behavior). Process control is effected through the manipulation of access mechanisms and/or a process’s resource map. Process X is said to control Process Y if the resource map of Process Y is in the access scope of Process X. Separation precludes process control.

5.3. Encroachment

Encroachment (also called access violation) is an access within a process’s access scope by unauthorized process. Process X encroaches on Process Y if it accesses Process Y’s access scope without Process Y’s intentional cooperation.

5.4. Secure Process

Process X is protected from Process Y if Process X is separated from Process Y. A secure process is a process that is separated from all other processes in an environment and thus is free from danger of encroachment.

6. Operating System Principles

A host (sometimes called a machine) is a computer architecture upon which a process(s) executes. An operating system is a collection of processes that controls and extends the native resources of a host architecture to facilitate one or more processes other its own. The host architecture may be physical or virtual.

6.1. Nucleus

The nucleus (sometimes called a kernel) manages the host resources specific to control of the host realized as two functions: interrupt handlers (managing the instruction execution cycle) and reference monitors (mediating access to resources).

6.2. Secure Operating System

A secure operating system is a secure process(s) on a host with control of all processes on that host including itself.

6.3. Virtual Machine

A virtual machine is an execution environment in which any process that executes cannot determine if it resides on a (physical) host or on a simulation of that host.

6.4. Virtual Machine Monitor

A virtual machine monitor is a nucleus supporting processes that are themselves “guest” virtual machines. Each VM may either a single process or operating system managing multiple processes.

6.5. Self-Virtualizable Host

A self-virtualizable host supports complete mediation in the application of access mechanisms to control resources thus enabling a VMM to maintain its control as a secure operating systems and intercede by mediating “guest” access to virtual resources while allowing direct, benign access to native resources. A self-virtualizable host offers virtual machine efficiency comparable to that of the host for all unmediated process behavior.
